Praise for *Javascript® Bible*

"*JavaScript® Bible* is the definitive resource in JavaScript programming. I am never more than three feet from my copy."

— Steve Reich, CEO, PageCoders

"This book is a must-have for any web developer or programmer."

— Thoma Lile, President, Kanis Technologies, Inc.

"Outstanding book. I would recommend this book to anyone interested in learning to develop advanced Web sites. Mr. Goodman did an excellent job of organizing this book and writing it so that even a beginning programmer can understand it."

— Jason Hensley, Director of Internet Services, NetVoice, Inc.

"Goodman is always great at delivering clear and concise technical books!"

— Dwayne King, Chief Technology Officer, White Horse

"*JavaScript® Bible* is well worth the money spent!"

— Yen C.Y. Leong, IT Director, Moo Mooltimedia, a member of SmartTransact Group

"A must-have book for any internet developer."

— Uri Fremder, Senior Consultant, TopTier Software

"I love this book! I use it all the time, and it always delivers. It's the only JavaScript book I use!"

— Jason Badger, Web Developer

"Whether you are a professional or a beginner, this is a great book to get."

— Brant Mutch, Web Application Developer, Wells Fargo Card Services, Inc.

"I never thought I'd ever teach programming before reading your book [*JavaScript® Bible*]. It's so simple to use — the Programming Fundamentals section brought it all back! Thank you for such a wonderful book, and for breaking through my programming block!"

— Susan Sann Mahon, Certified Lotus Instructor, TechNet Training

"Danny Goodman is very good at leading the reader into the subject. *JavaScript® Bible* has everything we could possibly need."

— Philip Gurdon

"An excellent book that builds solidly from whatever level the reader is at. A book that is both witty and educational."

— Dave Vane

"I continue to use the book on a daily basis and would be lost without it."

— Mike Warner, Founder, Oak Place Productions

"*JavaScript® Bible* is by *far* the best JavaScript resource I've ever seen (and I've seen quite a few)."

— Robert J. Mirro, Independent Consultant, RJM Consulting

To Tanya, with whom I share this loving orbit with Briar and Callum in our own cozy Klemperer rosette.
— Paul Novitski

To my husband, Edward, whose love, support, and encouragement kept me going through this and all my adventures, and to the memory of my parents who inspired me to step out in faith.
— Tia Gustaff Rayl

About the Authors

Danny Goodman is the author of numerous critically acclaimed and best-selling books, including *The Complete HyperCard Handbook*, *Danny Goodman's AppleScript Handbook*, *Dynamic HTML: The Definitive Reference*, and *JavaScript & DHTML Cookbook*. He is a renowned authority on and expert teacher of computer scripting languages. His writing style and pedagogy continue to earn praise from readers and teachers around the world.

Michael Morrison is a writer, developer, toy inventor, and author of a variety of books covering topics such as Java, C++, Web scripting, XML, game development, and mobile devices. Some of Michael's notable writing projects include *Faster Smarter HTML and XML*, *Teach Yourself HTML & CSS in 24 Hours*, and *Beginning Game Programming*. Michael is also the founder of Stalefish Labs (www.stalefishlabs.com), an entertainment company specializing in unusual games, toys, and interactive products.

Paul Novitski has been writing software as a freelance programmer since 1981. He once taught himself BASIC in order to write a machine language disassembler so that he could lovingly hack Wang's OIS microcode. He has focused on internet programming since the late '90s. His company, Juniper Webcraft, produces HTML-strict websites featuring accessible, semantic markup, separation of development layers, and intuitive user interfaces. He knows the righteousness of elegant code, the poignancy of living on the bleeding edge of wilderness, the sweet melancholy of mbira music, and the scorching joy of raising twin boys.

Tia Gustaff Rayl is a consultant who does development and training in database and Web technologies. Most recently she has published courseware for XHTML, CSS, JavaScript, and SQL. It comes as no surprise to those who know her that she began her software career with degrees in English and Education from the University of Florida. As is usual for most newcomers to the field, her introduction to computing was maintaining software. She went on to a long-standing career in the software industry in full life cycle system, application, and database development; project management; and training for PC and mainframe environments. In the mid-nineties she worked on early Web-enabled database applications, adding JavaScript to her repertoire. She continues to take on development projects to maintain her code-slinging skills. If she had any spare time (and money) she would go on an around-the-world cruise with her husband and two dogs.

About the Technical Editor

Benjamin Schupak holds a master's degree in computer science and has more than 11 years of professional programming experience for large corporations and U.S. federal departments. He lives in the New York metro area and enjoys traveling.

Acknowledgments

My gratitude for being given the opportunity and the latitude to work on this immense tome extends to Carol Long of Wiley, editor John Sleeva, Carole Jelen at Waterside Productions, Julian Hall, my partner in crime at Juniper Webcraft, and, above all, my sweet, loving, supportive, and nearly homicidal spouse Tanya Wright, all of them long-suffering and all to be commended for not actually throttling me in the course of this overlong birthing. The solid foundation of research and explication established by Danny Goodman and his past collaborators in previous editions is awesome and I am humbled to have been able to help move this great body of knowledge forward to the next step. Tia Gustaff Rayl, who with wings spread and sparks flying rode in to the rescue, has been a kick in the pants to work with; she's smart and funny, but more than that she is gifted with the precise serendipity and good taste to share a birthday with me.

—Paul Novitski

I have been blessed with the support of many people who have reviewed my work and encouraged me along the way. I could never have done any of this without the devoted support of my husband, Edward. I love him without cease and thank God for bringing him into my life. I have been blessed by the remarkable patience of an incredibly tolerant immediate and extended family, as well as amused friends, who put up with my "Hi, I love you. Don't talk to me right now." way of answering the phone and greeting visitors at the door. My husband, family and friends are the ones who sacrificed the most for this book. Thank you all. I want to thank Paul for being great to work with and for his wry sense of humor which left me on the floor laughing just when I most needed a lift. I want to thank my editor, John Sleeva, who with great patience and humor guided me through the maze of the publishing world. I also want to thank Rebecca Anderson and Maraya Cornell for forcing me to be a better writer. Finally, I want to thank Miss Bigelow, my 11th and 12th grade English teacher, who instilled within me a great respect and love for the written word.

—Tia Gustaff Rayl

Introduction

This seventh edition of the *JavaScript Bible* represents knowledge and experience accumulated over fifteen years of daily work in JavaScript and a constant monitoring of newsgroups for questions, problems, and challenges facing scripters at all levels. Our goal is to help you avoid the same frustration and head-scratching we and others have experienced through multiple generations of scriptable browsers.

While the earliest editions of this book focused on the then-predominant Netscape Navigator browser, the browser market share landscape has changed through the years. For many years, Microsoft took a strong lead with its Internet Explorer, but more recently, other browsers that support industry standards are finding homes on users' computers. The situation still leaves an age-old dilemma for content developers: designing scripted content that functions equally well in both standards-compliant and proprietary environments. The job of a book claiming to be the "bible" is not only to present both the standard and proprietary details when they diverge, but also to show you how to write scripts that blend the two so that they work on the wide array of browsers visiting your sites or web applications. Empowering you to design and write good scripts is our passion, regardless of browser. It's true that our bias is toward industry standards, but not to the exclusion of proprietary features that may be necessary to get your content and scripting ideas flowing equally well on today's and tomorrow's browsers.

Organization and Features of This Edition

Like the previous three editions of the *JavaScript Bible*, this seventh edition contains far more information than can be printed and bound into a single volume. The complete contents can be found in the electronic version of this book (in PDF form) on the CD-ROM that accompanies the book. This edition is structured in such a way as to supply the most commonly needed information in its entirety in the printed portion of the book. Content that you use to learn the fundamentals of JavaScript and reference frequently are at your fingertips in the printed version, while chapters with more advanced content are in the searchable electronic version on the CD-ROM. Here are some details about the book's structure.

Part I: Getting Started with JavaScript

Part I of the book begins with a chapter that shows how JavaScript compares with Java and discusses its role within the rest of the World Wide Web. The web browser and scripting world have undergone significant changes since JavaScript first arrived on the scene. That's why Chapter 2 is devoted to addressing challenges facing scripters who must develop applications for both single- and cross-platform browser audiences amid rapidly changing standards efforts. Chapter 3 introduces some tools you can use to compose your pages and scripts, while Chapter 4 delves into the nitty-gritty of how to use JavaScript to run in a wide variety of browsers.

Part II: JavaScript Tutorial

All of Part II is handed over to a tutorial for newcomers to JavaScript. Ten lessons provide you with a gradual path through browser internals, basic programming skills, and genuine browser scripting, with an emphasis on industry standards as supported by most of the scriptable browsers in use today. Exercises follow at the end of each lesson to help reinforce what you just learned and challenge you to use your new knowledge (you'll find answers to the exercises in Appendix D, on the CD-ROM). The goal of the tutorial is to equip you with sufficient experience to start scripting simple pages right away while making it easier for you to understand the in-depth discussions and examples in the rest of the book.

Part III: JavaScript Core Language Reference

Reference information for the core JavaScript language fills Part III. In all reference chapters, a compatibility chart indicates the browser version that supports each object and object feature. Guide words near the tops of pages help you find a particular term quickly.

Part IV: Document Objects Reference

Part IV, the largest section of the book, provides in-depth coverage of the document object models as implemented in today's browsers, including the object used for modern Ajax applications. As with the core JavaScript reference chapters of Part III, these DOM chapters display browser compatibility charts for every object and object feature. One chapter in particular, Chapter 26, contains reference material that is shared by most of the remaining chapters of Part IV. To help you refer back to Chapter 26 from other chapters, a shaded tab along the outside edge of the page shows you at a glance where the chapter is located. Additional navigation aids include guide words near the tops of most pages to indicate which object and object feature is covered on the page. Note that the Objects Reference begun in Part IV of the book continues in Part VI on the CD, with an additional 13 chapters of reference material.

Part V: Appendixes

Appendix A offers a JavaScript and Browser Objects Quick Reference. Appendix B provides information about using the CD-ROM that comes with this book, which includes numerous bonus chapters and examples.

Part VI: Document Objects Reference (continued)

Beginning the portion of the book that resides only the accompanying CD, Part VI continues the document objects reference discussions that begin in Part IV by providing an additional 13 chapters of reference material.

Part VII: More JavaScript Programming

Chapters 46–51 discuss advanced JavaScript programming techniques, including data-entry validation, debugging, and security issues.

Part VIII: Applications

The final ten chapters of the book, available only on the CD-ROM, feature sample applications that cover the gamut from calendars to puzzles.

Part IX: Appendixes (continued)

The final three appendixes provide helpful reference information. These resources include a list of JavaScript reserved words in Appendix C, answers to Part II's tutorial exercises in Appendix D, and Internet resources in Appendix E.

CD-ROM

The CD-ROM is a gold mine of information. It begins with a PDF version of the entire contents of this seventh edition of the *JavaScript Bible*. This version includes bonus chapters covering:

- Dynamic HTML, data validation, plug-ins, and security
- Techniques for developing and debugging professional web-based applications
- Ten full-fledged JavaScript real-world applications

Another treasure trove on the CD-ROM is the `Listings` folder where you'll find over 300 ready-to-run HTML documents that serve as examples of most of the document object model and JavaScript vocabulary words in Parts III and IV. All of the bonus chapter example listings are also included. You can run these examples with your JavaScript-enabled browser, but be sure to use the `index.html` page in the Listings folder as a gateway to running the listings. We could have provided you with humorous little sample code fragments out of context, but we think that seeing full-fledged HTML documents (simple though they may be) for employing these concepts is important. We encourage you to manually type the script listings from the tutorial (Part II) of this book. We believe you learn a lot, even by aping listings from the book, as you get used to the rhythms of typing scripts in documents.

Be sure to check out the Chapter 4 listing file called `evaluator.html`. Many segments of Parts III and IV invite you to try out an object model or language feature with the help of an interactive workbench, called The Evaluator — a *JavaScript Bible* exclusive! You see instant results and will quickly learn how the feature works.

The Quick Reference from Appendix A is in PDF format on the CD-ROM for you to print out and assemble as a handy reference, if desired. Adobe Reader is also included on the CD-ROM, in case you don't already have it.

Prerequisites to Learning JavaScript

Although this book doesn't demand that you have a great deal of programming experience behind you, the more web pages you've created with HTML, the easier you will find it to understand how JavaScript interacts with the familiar elements you normally place in your pages. Occasionally, you will need to modify HTML tags to take advantage of scripting. If you are familiar with those tags already, the JavaScript enhancements will be simple to digest.

To learn JavaScript, you won't need to know server scripting or how to pass information from a form to a server. The focus here is on client-side scripting, which operates independently of the server after the JavaScript-enhanced HTML page is fully loaded into the browser. However, we strongly believe that a public web page should be operational in the absence of JavaScript, so any dynamic functionality that looks up results or modifies the content of a page should interact with a server-side script fundamentally. After that foundation is laid, we add JavaScript to make a page faster, easier, or more

fun. So although you don't need to know server-side scripting in order to learn JavaScript, for serious web work you should either learn a server-side scripting language such as PHP in addition to JavaScript or look for server-side programmers to complement your client-side scripting abilities.

The basic vocabulary of the current HTML standard should be part of your working knowledge. You should also be familiar with some of the latest document markup standards, such as XHTML and Cascading Style Sheets (CSS). Web searches for these terms will uncover numerous tutorials on the subjects.

If you've never programmed before

Don't be put off by the size of this book. JavaScript may not be the easiest language in the world to learn, but believe us, it's a far cry from having to learn a full programming language such as Java or C. Unlike developing a full-fledged monolithic application (such as the productivity programs you buy in stores), JavaScript lets you experiment by writing small snippets of program code to accomplish big things. The JavaScript interpreter built into every scriptable browser does a great deal of the technical work for you.

Programming, at its most basic level, consists of nothing more than writing a series of instructions for the computer to follow. We humans follow instructions all the time, even if we don't realize it. Traveling to a friend's house is a sequence of small instructions: Go three blocks that way; turn left here; turn right there. Amid these instructions are some decisions that we have to make: If the stoplight is red, then stop; if the light is green, then go; if the light is yellow, then floor it! (Just kidding.) Occasionally, we must repeat some operations several times (kind of like having to go around the block until a parking space opens up). A computer program not only contains the main sequence of steps, but it also anticipates what decisions or repetitions may be needed to accomplish the program's goal (such as how to handle the various states of a stoplight or what to do if someone just stole the parking spot you were aiming for).

The initial hurdle of learning to program is becoming comfortable with the way a programming language wants its words and numbers organized in these instructions. Such rules are called syntax, the same as in a living language. Computers aren't very forgiving if you don't communicate with them in the specific language they understand. When speaking to another human, you can flub a sentence's syntax and still have a good chance that the other person will understand you. Not so with computer programming languages. If the syntax isn't perfect (or at least within the language's range of knowledge), the computer has the brazenness to tell you that you have made a syntax error.

The best thing you can do is just accept the syntax errors you receive as learning experiences. Even experienced programmers make mistakes. Every syntax error you get — and every resolution of that error made by rewriting the wayward statement — adds to your knowledge of the language.

If you've done a little programming before

Programming experience in a procedural language, such as BASIC, may actually be a hindrance rather than a help to learning JavaScript. Although you may have an appreciation for precision in syntax, the overall concept of how a program fits into the world is probably radically different from JavaScript's role. Part of this has to do with the typical tasks a script performs (carrying out a very specific task in response to user action within a web page), but a large part also has to do with the nature of object-oriented programming.

If you've programmed in C before

In a typical procedural program, the programmer is responsible for everything that appears on the screen and everything that happens under the hood. When the program first runs, a great deal of code is dedicated to setting up the visual environment. Perhaps the screen contains several text entry fields or clickable buttons. To determine which button a user clicks, the program examines the coordinates of the click and compares those coordinates against a list of all button coordinates on the screen. Program execution then branches out to perform the instructions reserved for clicking in that space.

Object-oriented programming is almost the inverse of that process. A button is considered an object — something tangible. An object has properties, such as its label, size, alignment, and so on. An object may also contain a script. At the same time, the system software and browser, working together, can send a message to an object — depending on what the user does — to trigger the script. For example, if a user clicks in a text entry field, the system/browser tells the field that somebody has clicked there (that is, has set the focus to that field), giving the field the task of deciding what to do about it. That's where the script comes in. The script is connected to the field, and it contains the instructions that the field carries out after the user activates it. Another set of instructions may control what happens when the user types an entry and tabs or clicks out of the field, thereby changing the content of the field.

Some of the scripts you write may seem to be procedural in construction: They contain a simple list of instructions that are carried out in order. But when dealing with data from form elements, these instructions work with the object-based nature of JavaScript. The form is an object; each radio button or text field is an object as well. The script then acts on the properties of those objects to get some work done.

Making the transition from procedural to object-oriented programming may be the most difficult challenge for you. But when the concept clicks — a long, pensive walk might help — so many light bulbs will go on inside your head that you'll think you might glow in the dark. From then on, object orientation will seem to be the only sensible way to program.

By borrowing syntax from Java (which, in turn, is derived from C and C++), JavaScript shares many syntactical characteristics with C. Programmers familiar with C will feel right at home. Operator symbols, conditional structures, and repeat loops follow very much in the C tradition. You will be less concerned about data types in JavaScript than you are in C. In JavaScript, a variable is not restricted to any particular data type.

With so much of JavaScript's syntax familiar to you, you will be able to concentrate on document object model concepts, which may be entirely new to you. You will still need a good grounding in HTML to put your expertise to work in JavaScript.

If you've programmed in Java before

Despite the similarity in their names, the two languages share only surface aspects: loop and conditional constructions, C-like "dot" object references, curly braces for grouping statements, several keywords, and a few other attributes. Variable declarations, however, are quite different, because JavaScript is a loosely typed language. A variable can contain an integer value in one statement and a string in the next (though we're not saying that this is good style). What Java refers to as methods, JavaScript calls methods (when associated with a predefined object) or functions (for scripter-defined actions). JavaScript methods and functions may return values of any type without having to state the data type ahead of time.

Perhaps the most important Java concepts to suppress when writing JavaScript are the object-oriented notions of classes, inheritance, instantiation, and message passing. These aspects are simply non-issues when scripting. At the same time, however, JavaScript's designers knew that you'd have some hard-to-break habits. For example, although JavaScript does not require a semicolon at the end of each statement line, if you type one in your JavaScript source code, the JavaScript interpreter won't balk.

If you've written scripts (or macros) before

Experience with writing scripts in other authoring tools or macros in productivity programs is helpful for grasping a number of JavaScript's concepts. Perhaps the most important concept is the idea of combining a handful of statements to perform a specific task on some data. For example, you can write a macro in Microsoft Excel that performs a data transformation on daily figures that come in from a corporate financial report on another computer. The macro is built into the Macro menu, and you run it by choosing that menu item whenever a new set of figures arrives.

Some modern programming environments, such as Visual Basic, resemble scripting environments in some ways. They present the programmer with an interface builder, which does most of the work of displaying screen objects with which the user will interact. A big part of the programmer's job is to write little bits of code that are executed when a user interacts with those objects. A great deal of the scripting you will do with JavaScript matches that pattern exactly. In fact, those environments resemble the scriptable browser environment in another way: They provide a finite set of predefined objects that have fixed sets of properties and behaviors. This predictability makes learning the entire environment and planning an application easier to accomplish.

Formatting and Naming Conventions

The script listings and words in this book are presented in a `monospace font` to set them apart from the rest of the text. Because of restrictions in page width, lines of script listings may, from time to time, break unnaturally. In such cases, the remainder of the script appears in the following line, flush with the left margin of the listing, just as it would appear in a text editor with word wrapping turned on. If these line breaks cause you problems when you type a script listing into a document yourself, we encourage you to access the corresponding listing on the CD-ROM to see how it should look when you type it.

As soon as you reach Part III of this book, you won't likely go for more than a page before reading about an object model or language feature that requires a specific minimum version of one browser or another. To make it easier to spot in the text when a particular browser and browser version is required, most browser references consist of an abbreviation and a version number. For example, WinIE5 means Internet Explorer 5 for Windows; NN4 means Netscape Navigator 4 for any operating system; Moz stands for the modern Mozilla browser (from which Firefox, Netscape 6 or later, and Camino are derived); and Safari is Apple's own browser for Mac OS X. If a feature is introduced with a particular version of browser and is supported in subsequent versions, a plus symbol (+) follows the number. For example, a feature marked WinIE5.5+ indicates that Internet Explorer 5.5 for Windows is required at a minimum, but the feature is also available in WinIE8 and probably future WinIE versions. If a feature was implemented in the first release of a modern browser, a plus symbol immediately follows the browser family name, such as Moz+ for all Mozilla-based browsers. Occasionally, a feature or some highlighted behavior applies to only one browser. For example, a feature marked

NN4 means that it works only in Netscape Navigator 4.x. A minus sign (e.g., WinIE-) means that the browser does not support the item being discussed.

The format of HTML markup in this edition follows HTML5 coding conventions, but also adheres to many XHTML standards such as all-lowercase tag and attribute names.

Note **Tip**

Caution **Cross Reference**

Note, Tip, Caution, and Cross-Reference icons occasionally appear in the book to flag important points or suggest where to find more information.

CHAPTER 1

JavaScript's Role in the World Wide Web and Beyond

IN THIS CHAPTER

How JavaScript blends with other web-authoring technologies

The history of JavaScript

What kinds of jobs you should and should not entrust to JavaScript

Many of the technologies that make the World Wide Web possible have far exceeded their original goals. Envisioned at the outset as a medium for publishing static text and image content across a network, the Web is forever being probed, pushed, and pulled by content authors. By taking for granted so much of the "dirty work" of conveying the bits between server and client computers, content developers and programmers dream of exploiting that connection to generate new user experiences and practical applications. It's not uncommon for a developer community to take ownership of a technology and mold it to do new and exciting things. But with so many web technologies — especially browser programming with JavaScript — within reach of everyday folks, we have witnessed an unprecedented explosion in turning the World Wide Web from a bland publishing medium into a highly interactive, operating system–agnostic authoring platform.

The JavaScript language, working in tandem with related browser features, is a web-enhancing technology. When employed on the client computer, the language can help turn a static page of content into an engaging, interactive, and intelligent experience. Applications can be as subtle as welcoming a site's visitor with the greeting "Good morning!" when it is morning in the client computer's time zone — even though it is dinnertime where the server is located. Or, applications can be much more obvious, such as delivering the content of a slide show in a one-page download while JavaScript controls the sequence of hiding, showing, and "flying slide" transitions as we navigate through the presentation.

Of course, JavaScript is not the only technology that can give life to drab web content. Therefore, it is important to understand where JavaScript fits within the array of standards, tools, and other technologies at your disposal. The alternative technologies described in this chapter are HTML, Cascading Style Sheets (CSS), server programs, and plug-ins. In most cases, JavaScript can work side by side with these other technologies, even though the hype can make them sound like one-stop shopping places for all your interactive needs. (That's rarely the case.) Finally, you learn about the origins of JavaScript and what role it plays in today's advanced web browsers.

Competing for Web Traffic

Web page publishers revel in logging as many visits to their sites as possible. Regardless of the questionable accuracy of web page hit counts, a site consistently logging 10,000 dubious hits per week is clearly far more popular than one with 1,000 dubious hits per week. Even if the precise number is unknown, relative popularity is a valuable measure. Another useful number is how many links from outside pages lead to a site. A popular site will have many other sites pointing to it — a key to earning high visibility in web searches.

Encouraging people to visit a site frequently is the Holy Grail of web publishing. Competition for viewers is enormous. Not only is the Web like a 50 million–channel television, but also, the Web competes for viewers' attention with all kinds of computer-generated information. That includes anything that appears onscreen as interactive multimedia.

Users of entertainment programs, multimedia encyclopedias, and other colorful, engaging, and mouse-finger-numbing actions are accustomed to high-quality presentations. Frequently, these programs sport first-rate graphics, animation, live-action video, and synchronized sound. By contrast, the lowest-common-denominator web page has little in the way of razzle-dazzle. Even with the help of Dynamic HTML and style sheets, the layout of pictures and text is highly constrained compared with the kinds of desktop publishing documents you see all the time. Regardless of the quality of its content, an unscripted, vanilla HTML document is flat. At best, interaction is limited to whatever navigation the author offers in the way of hypertext links or forms whose filled-in content magically disappears into the web site's server.

Other Web Technologies

With so many ways to spice up web sites and pages, you can count on competitors for your site's visitors to do their darnedest to make their sites more engaging than yours. Unless you are the sole purveyor of information that is in high demand, you continually must devise ways to keep your visitors coming back and entice new ones. If you design for an intranet, your competition is the drive for improved productivity by colleagues who use the internal web sites for getting their jobs done.

These are all excellent reasons why you should care about using one or more web technologies to raise your pages above the noise. Let's look at the major technologies you should know about.

Figure 1-1 illustrates the components that make up a typical dynamic web site. The core is a dialog between the server (the web host) and the client (the browser); the client requests data and the server responds. The simplest model would consist of just the server, a document, and a browser, but in practice web sites use the other components shown here, and more.

The process begins when the browser requests a page from the server. The server delivers static HTML pages directly from its hard drive; dynamic pages are generated on-the-fly by scripts executed in a language interpreter, such as PHP, but likewise delivered by the server to the client, usually in the form of HTML markup. For example, a server-side database can store the items of a catalog, and a PHP script can look up those data records and mark them up as HTML when requested by the browser.

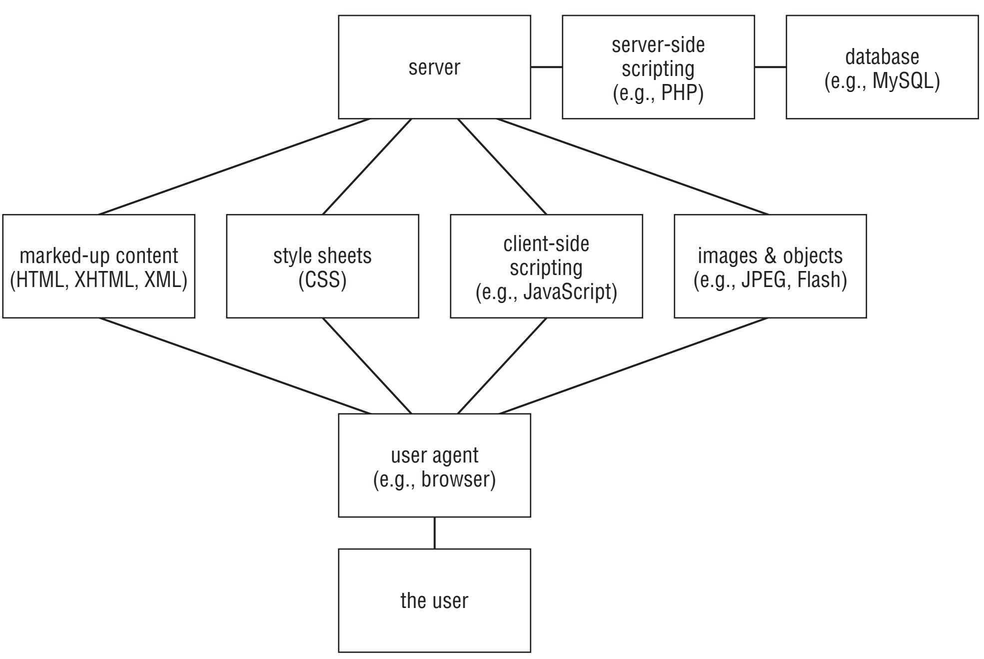
The downloaded page may contain the addresses of other components: style sheets, JavaScript files, images, and other assets. The browser requests each of these, in turn, from the server, combining them into the final rendering of the page.

A JavaScript program is inert — just another hunk of downloaded bits — until it's received by the browser, which validates its syntax and compiles it, ready for execution when called upon by the

HTML page or the human user. It's then part of the web page and confined to the client side of the sever-client dialog. JavaScript can make requests of servers, as we'll see later, but it cannot directly access anything outside of the page it's part of and the browser that's running it.

FIGURE 1-1

The components of a typical dynamic web site.



Hypertext Markup Language (HTML and XHTML)

As an outgrowth of SGML (Standard Generalized Markup Language), HTML brings structure to the content of a page. This structure gives us handles on the content in several important ways:

- Markup transforms a sea of undifferentiated text into discrete parts, such as headlines, paragraphs, lists, data tables, images, and input controls. Structure augments the meaning of the content by establishing relationships between different parts: between headline and subhead; between items in a list; between divisions of the page such as header, footer, and content columns. The semantics of a page are important to every reader: visual browsers for the sighted, vocal and Braille browsers for the visually impaired, search engines, and other software that parses the page, looking for a comprehensible structure.
- The browser transforms some marked-up structures into objects with particular behaviors. An image spills out rows of pixels in visually meaningful patterns. A form control accepts input from the user, while a button submits those form control values to the server. A hyperlink can load a new page into the browser window. These different types of objects would not be possible without some form of markup.

- The way a page is presented on screen, in Braille, or in speech, is determined by a style sheet that points to elements on the page and assigns appearance, emphasis, and other attributes. Every browser comes with a default style sheet that makes headlines, body text, hyperlinks, and form controls look a particular way. As web developers, we create our own style sheets to override the browser defaults and make our pages look the way we want. A style sheet tells the browser how to render the HTML page by referring to the document's markup elements and their attributes.
- Most importantly for the topic at hand, HTML markup gives JavaScript ways to locate and operate on portions of a page. A script can collect all the images in a gallery, or jump to a particular paragraph, because of the way the document is marked up.

Clearly, HTML markup and the way we handle it are critical to a document's structure and meaning, its presentation, and its successful interaction with JavaScript. While all the details of how best to use HTML are outside the scope of this book, it's clear that you'll want to hone your markup skills while you're learning JavaScript. Even the best script in the world can fail if launched on faulty, sloppy, or unplanned markup.

In the early years of web development, back before the turn of the century, in that medieval era now known as "the 90s," web designers didn't have much consciousness about markup semantics and accessibility. Pages were marked up in any way that would produce a desired visual presentation, relying on the default styling of the browser and without regard for the sensibility of the markup. A developer might choose an `h4` tag simply in order to produce a certain size and style of font, regardless of the document's outline structure, or use data table markup for non-tabular content, simply to force the page layout to align. Required spaces and faux spacer images were mashed into the real content merely to tweak the appearance of the page: how things *looked* took complete precedence over what things *meant*. Fortunately, today that perspective seems quaintly old-fashioned, but unfortunately, there are still thousands of people producing pages that way and millions of pages left over from that dark era, their finger bones clutching at our sleeves and urging us to join them in their morbid pastime. It is one goal of this book to encourage you to code like a modern, living mammal, and not like a fossil.

Relegating HTML to the category of a tagging language does disservice not only to the effort that goes into fashioning a first-rate web page, but also to the way users interact with the pages. To our way of thinking, any collection of commands and other syntax that directs the way users interact with digital information is *programming*. With HTML, a web-page author controls the user experience with the content just as the engineers who program Microsoft Excel craft the way users interact with spreadsheet content and functions.

Version 4.0 and later of the published HTML standards endeavor to define the purpose of HTML as assigning context to content, leaving the appearance to a separate standard for style sheets. In other words, it's not HTML's role to signify that some text is italic but rather to signify *why* we might choose to italicize it. For example, you would tag a chunk of text that conveys emphasis (via the `<em>` tag) or to mark its purpose (`<span class="title">`) separately from the decision of how to format it with the style sheet. This separation between HTML markup and CSS presentation is an extremely powerful concept that makes the tweaking and redesign of web sites much faster than in the old days of inline styling and `<font>` tags.

XHTML is a more recent adaptation of HTML that adheres to stylistic conventions established by the XML (eXtensible Markup Language) standard. No new tags come with XHTML, but it reinforces the notion of tagging to denote a document's structure and content. While for several years XHTML was seen as the next stage of evolution of HTML toward the holy grail of a universal XML markup for documents, that promise has failed to deliver, in part because Microsoft, with its enormous share of the browser market, has consistently declined to accommodate XHTML served correctly as `application/xhtml+xml`. Nearly all XHTML documents

today are served as `text/html`, which means that browsers treat them as just more HTML "tag soup." Perhaps the only advantage gained by using XHTML markup is the stricter set of rules used by the W3C HTML Validator (`http://validator.w3.org`), which checks to make sure that all tags are closed in XHTML documents, but isn't so fussy with HTML with its looser definitions.

For convincing arguments against the use of XHTML served as `text/html`, read "Sending XHTML as text/html Considered Harmful," by Ian Hickson (`http://hixie.ch/advocacy/xhtml`) and "Beware of XHTML," by David Hammond (`http://www.webdevout.net/articles/beware-of-xhtml`).

More recently, HTML5 has been growing in the Petri dishes of the World Wide Web Consortium (W3C). While modern browsers have only just begun to implement some of its features, HTML5 is considered by many to offer a more promising future than the seemingly abandoned XHTML. HTML5 offers an enriched vocabulary of markup tags compared to version 4, the better to align the markup language with the uses to which HTML is put in the real world.

Because HTML 4.01 is the prevailing markup language for the web today, the HTML samples in this book are compatible with HTML 4.01, except for those that illustrate newer HTML5 elements such as `canvas`. With the proper `DOCTYPE`, the samples should validate as HTML5. They are easily convertible to XHTML1.0 with a few simple transforms: change the `DOCTYPE`, add `lang` attributes to the `HTML` element, and close empty elements such as `input` and `link` with `/>`. It's our hope that this will make the samples useful to folks heading up either HTML or XHTML paths, and also make the book more future-friendly as HTML5 comes into its own.

Cascading Style Sheets (CSS)

Specifying the look and feel and speech of a web page is the job of Cascading Style Sheets (CSS). Given a document's structure as spelled out by its HTML markup, a style sheet defines the layout, colors, fonts, voices, and other visual and aural characteristics to present the content. Applying a different set of CSS definitions to the same document can make it look and sound entirely different, even though the words and images are the same.

(CSS 2.1 is the version of the W3C style sheet specification most widely supported by today's user agents. Aural style sheets that let us assign voices and other sounds to the markup of a web page are a module of the CSS 3 specification and, at this writing, are supported only by Opera and the FireVox extension to Firefox, although other browsers are sure to follow.)

Mastery of the fine points of CSS takes time and experimentation, but the results are worth the effort. The days of using HTML tables and transparent "spacer" images to generate elaborate multicolumn layouts are very much on the wane. Every web developer should have a solid grounding in CSS.

The learning curve for CSS can be steep because of the inconsistent support for its many features from one browser to the next. You can make your life much easier by triggering *standards mode* in the browser, whereby it adheres more closely to the W3C CSS specification. We recommend triggering standards mode by using a correct `DOCTYPE` at the top of your markup, such as one of these:

HTML 4.01 Strict:

```
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.01//EN"
   "http://www.w3.org/TR/REC-html40/strict.dtd">
```

HTML 5:

```
<!DOCTYPE html>
```

```
XHTML 1.0 Strict:

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Strict//EN"
   "http://www.w3.org/TR/xhtml1/xhtml1-strict.dtd">
```

For a clear explanation of `DOCTYPE` switching, read Eric Meyer's essay "Picking a Rendering Mode" (`http://www.ericmeyeroncss.com/bonus/render-mode.html`).

Server-side programming

Web sites that rely on database access, or change their content very frequently, incorporate programming on the server that generates the HTML output for browsers and/or processes forms that site visitors fill out on the page. Even submissions from a simple login or search form ultimately trigger some server process that sends the results to your browser. Server programming takes on many guises, the names of which you may recognize from your surfing through web development sites. PHP, ASP, .NET, JSP, and ColdFusion are among the most popular. Associated programming languages include Perl, Python, Java, C++, C#, Visual Basic, and even server-side JavaScript in some environments.

Whatever language you use, the job definitely requires the web-page author to be in control of the server, including whatever *back-end* programs (such as databases) are needed to supply results or massage the information coming from the user. Even with the new, server-based web site design tools available, server scripting is often a task that a content-oriented HTML author will need to hand off to a more experienced programmer.

Client-side JavaScript is not a replacement for server-side scripting. Any web site that reacts dynamically to user actions or that saves data must be driven by server-side scripting, even if JavaScript is used in the browser to enhance the user's experience. The reasons are simple: First, JavaScript itself cannot write to files on the server. It can help the user make choices and prepare data for upload, but after that it can only hand off data to a sever-side script for database updating. Second, not all user agents run JavaScript. Screen readers, mobile devices, search engines, and browsers installed in certain corporate contexts are among those that don't invoke JavaScript, or that receive web pages with the JavaScript stripped out. Therefore, your web site should be fully functional with JavaScript turned off. Use JavaScript to make the browsing experience faster, cooler, or more fun when it's present, but don't let your site be broken if JavaScript isn't running.

As powerful and useful as server-side scripting can be, its speed of interaction with the user is limited by the speed of the Internet connection between server and user agent. Obviously, any process that results in updating data on the server must include some client-server dialog, but there are many aspects of user interaction that, with the help of JavaScript, can take place entirely within the browser — form validation and drag-&-drop are two examples — then update the server when the response-sensitive process is complete.

One way that server programming and browser scripting work together is with what has become known as *Ajax* — Asynchronous JavaScript and XML. The "asynchronous" part runs in the browser, requesting XML data from, or posting data to, the server-side script entirely in the background. XML data returned by the server can then be examined by JavaScript in the browser to update portions of the web page. That's how many popular web-based email user interfaces work, as well as the draggable satellite-photo closeups of Google Maps (`http://maps.google.com`).

Working together, server programming and browser scripting can make beautiful applications together. You'll want to write in a server-side language such as PHP, or team up with someone who does, to lay the foundations for the JavaScript-enhanced pages you'll be creating.

Of helpers and plug-ins

In the early days of the World Wide Web, a browser needed to present only a few kinds of data before a user's eyes. The power to render text (tagged with HTML) and images (in popular formats such as GIF and JPEG) was built into browsers intended for desktop operating systems. Not wanting to be limited by those data types, developers worked hard to extend browsers so that data in other formats could be rendered on the client computer. It was unlikely, however, that a browser would ever be built that could download and render, say, any of several sound-file formats.

One way to solve the problem was to allow the browser, upon recognizing an incoming file of a particular type, to launch a separate application on the client machine to render the content. As long as this helper application was installed on the client computer (and the association with the helper program was set in the browser's preferences), the browser would launch the program and send the incoming file to that program. Thus, you might have one helper application for a MIDI sound file and another for an animation file.

Beginning with Netscape Navigator 2 in early 1996, software *plug-ins* for browsers enabled developers to extend the capabilities of the browser without having to modify the browser. Unlike a helper application, a plug-in can enable external content to blend into the document seamlessly.

The most common plug-ins are those that facilitate the playback of audio and video from the server. Audio may include music tracks that play in the background while visiting a page, or live (streaming) audio, similar to a radio station. Video and animation can operate in a space on the page when played through a plug-in that knows how to process such data.

Today's browsers tend to ship with plug-ins that decode the most common sound-file types. Developers of plug-ins for Internet Explorer for the Windows operating system commonly implement plug-ins as ActiveX controls — a distinction that is important to the underpinnings of the operating system, but not to the user.

Plug-ins and helpers are valuable for more than just audio and video playback. A popular helper application is *Adobe Acrobat Reader,* which displays Acrobat files that are formatted just as though they were being printed. But for interactivity, developers today frequently rely on the *Flash* plug-in by Macromedia (now owned by Adobe). Created using the Flash authoring environment, a Flash application can have active clickable areas and draggable elements, animation, and embedded video. Some authors simulate artistic video games and animated stories in Flash. A browser equipped with the Flash plug-in displays the content in a rectangular area embedded within the browser page. A variant of JavaScript called *ActionScript* enables Flash to interact with the user and components of the HTML page. Like JavaScript, ActionScript gets access to outside resources by making data-read and -write requests of the server. YouTube.com is a popular example of a web site with richly integrated Flash.

One potential downside for authoring interactive content in Flash or similar environments is that if the user does not have the correct plug-in version installed, it can take some time to download the plug-in (if the user even wants to bother). Moreover, once the plug-in is installed, highly graphic and interactive content can take longer to download to the client (especially on a dial-up connection) than some users are willing to wait. This is one of those situations in which you must balance your creative palette with the user's desire for your interactive content.

Another client-side technology — the Java applet — was popular for a while in the late 1990s, but has fallen out of favor for a variety of reasons (some technical, some corporate-political). But this has not diminished the use of Java as a language for server and even cellular telephone programming, extending well beyond the scope of the language's founding company, Sun Microsystems.

JavaScript: A Language for All

Sun's Java language is derived from C and C++, but it is a distinct language. Its main audience is the experienced programmer. That leaves out many web-page authors. Java's preliminary specifications in 1995 were dismaying. How much more preferable would have been a language that casual programmers and scripters who were comfortable with authoring tools such as Apple's once-formidable HyperCard and Microsoft's Visual Basic could adopt quickly. As these accessible development platforms have shown, nonprofessional authors can dream up many creative applications, often for very specific tasks that no professional programmer would have the inclination to work on. Personal needs often drive development in the classroom, office, den, or garage. But Java was not going to be that kind of inclusive language.

Spirits lifted several months later, in November 1995, when we heard of a scripting language project brewing at Netscape Communications, Inc. Born under the name *LiveScript,* this language was developed in parallel with a new version of Netscape's web server software. The language was to serve two purposes with the same syntax. One purpose was as a scripting language that web server administrators could use to manage the server and connect its pages to other services, such as back-end databases and search engines for users looking up information. Extending the "Live" brand name further, Netscape assigned the name *LiveWire* to the database connectivity usage of LiveScript on the server.

On the client side — in HTML documents — authors could employ scripts written in this new language to enhance web pages in a number of ways. For example, an author could use LiveScript to make sure that the user had filled in a required text field with an e-mail address or credit card number. Instead of forcing the server or database to do the data validation (requiring data exchanges between the client browser and the server), the user's computer handles all the calculation work — putting some of that otherwise-wasted computing horsepower to work. In essence, LiveScript could provide HTML-level interaction for the user.

LiveScript becomes JavaScript

In early December 1995, just prior to the formal release of Navigator 2, Netscape and Sun Microsystems jointly announced that the scripting language thereafter would be known as JavaScript. Though Netscape had several good marketing reasons for adopting this name, the changeover may have contributed more confusion to both the Java programming world and HTML scripting world than anyone expected.

Before the announcement, the language was already related to Java in some ways. Many of the basic syntax elements of the scripting language were reminiscent of the Java style. However, for client-side scripting, the language was intended for very different purposes than Java — essentially to function as a programming language integrated into HTML documents rather than as a language for writing applets that occupy a fixed rectangular area on the page (and that are oblivious to anything else on the page). Instead of Java's full-blown programming language vocabulary (and conceptually more difficult-to-learn object-oriented approach), JavaScript had a small vocabulary and a more easily digestible programming model.

The true difficulty, it turned out, was making the distinction between Java and JavaScript clear to the world. Many computer journalists made major blunders when they said or implied that JavaScript provided a simpler way of building Java applets. To this day, some new programmers believe JavaScript is synonymous with the Java language: They post Java queries to JavaScript-specific Internet newsgroups and mailing lists.

The fact remains that client-side Java and JavaScript are more different than they are similar. The two languages employ entirely different interpreter engines to execute their code.

Enter Microsoft and others

Although the JavaScript language originated at Netscape, Microsoft acknowledged the potential power and popularity of the language by implementing it (under the JScript name) in Internet Explorer 3. Even if Microsoft might prefer that the world use the VBScript (Visual Basic Script) language that it provides in the Windows versions of IE, the fact that JavaScript is available on more browsers and operating systems makes it the client-side scripter's choice for anyone who must design for a broad range of users.

With scripting firmly entrenched in the mainstream browsers from Microsoft and Netscape, newer browser makers automatically provided support for JavaScript. Therefore, you can count on fundamental scripting services in browsers such as Opera or the Apple Safari browser (the latter built upon an Open Source browser called KHTML). Not that all browsers work the same way in every detail — a significant challenge for client-side scripting that is addressed throughout this book.

JavaScript versions

The JavaScript language has its own numbering system, which is completely independent of the version numbers assigned to browsers. The Mozilla Foundation, successor to the Netscape browser development group that created the language, continues its role as the driving force behind the JavaScript version numbering system.

The first version, logically enough, was JavaScript 1.0. This was the version implemented in Navigator 2, and the first release of Internet Explorer 3. As the language evolved with succeeding browser versions, the JavaScript version number incremented in small steps. JavaScript 1.2 is the version that has been the most long lived and stable, currently supported by Internet Explorer 7. Mozilla-based browsers and others have inched forward with some new features in JavaScript 1.5 (Mozilla 1.0 and Safari), JavaScript 1.6 (Mozilla 1.8 browsers), and JavaScript 1.7 (Mozilla 1.8.1 and later).

Each successive generation of JavaScript employs additional language features. For example, in JavaScript 1.0, arrays were not developed fully, causing scripted arrays not to track the number of items in the array. JavaScript 1.1 filled that hole by providing a constructor function for generating arrays and an inherent `length` property for any generated array.

The JavaScript version implemented in a browser is not always a good predictor of core language features available for that browser. For example, although JavaScript 1.2 (as implemented by Netscape in Netscape Navigator 4) included broad support for regular expressions, not all of those features appeared in Microsoft's corresponding JScript implementation in Internet Explorer 4. By the same token, Microsoft implemented `try-catch` error handling in its JScript in Internet Explorer 5, but Netscape didn't include that feature until the Mozilla-based Netscape Navigator 6 implementation of JavaScript 1.5. Therefore, the language version number is an unreliable predictor in determining which language features are available for you to use.

Core language standard: ECMAScript

Although Netscape first developed the JavaScript language, Microsoft incorporated the language in Internet Explorer 3. Microsoft did not want to license the Java name from its trademark owner (Sun Microsystems), which is why the language became known in the Internet Explorer environment as

JScript. Except for some very esoteric exceptions and the pace of newly introduced features, the two languages are essentially identical. The levels of compatibility between browser brands for a comparable generation are remarkably high for the core language (unlike the vast disparities in object model implementations discussed in Chapter 25, "Document Object Model Essentials").

As mentioned, standards efforts have been under way to create industry-wide recommendations for browser makers to follow (to make developers' lives easier). The core language was among the first components to achieve standard status. Through the European standards body called ECMA, a formal standard for the language was agreed to and published. The first specification for the language, dubbed ECMAScript by the standards group, was roughly the same as JavaScript 1.1 in Netscape Navigator 3. The standard (ECMA-262) defines how various data types are treated, how operators work, what a particular data-specific syntax looks like, and other language characteristics. A newer version (called version 3) added many enhancements to the core language (version 2 was just version 1 with errata fixed).

The current version of the ECMAScript specification is known as ECMAScript, Fifth Edition, published online at `www.ecma-international.org`. To quote the ECMA, "The Fifth Edition codifies de facto interpretations of the language specification that have become common among browser implementations and adds support for new features that have emerged since the publication of the Third Edition. Such features include accessor properties, reflective creation and inspection of objects, program control of property attributes, additional array manipulation functions, support for the JSON object encoding format, and a strict mode that provides enhanced error checking and program security."

If you are a student of programming languages, you will find the document fascinating; if you simply want to script your pages, you might find the minutia mind-boggling.

All mainstream browser developers have pledged to make their browsers compliant with the ECMA standard. The vast majority of the ECMAScript standard has appeared in Navigator since version 3 and Internet Explorer since version 4, and as new features are added to the ECMA standard, they tend to find their way into newer browsers as well. The latest version of ECMAScript is version 5. The previous edition, the 3rd, has been supported in all mainstream browsers for the past few years.

Note

Even as ECMAScript, Fifth Edition was in the works, The Mozilla Foundation and Microsoft were implementing comparable versions of JavaScript 2.0 and JScript, respectively. An extension to ECMAScript called E4X (ECMAScript for XML) was finalized in late 2005 and is implemented in browsers based on Mozilla 1.8.1 or later (for example, Firefox 2.0). The Adobe ActionScript 3 language, which is used in the development of Flash animations, fully supports E4X. E4X is a significant addition to JavaScript because it makes XML (Extensible Markup Language) a native data type within the syntax of the language, making the processing of data in XML format much easier. XML is the data format used by many data exchange processes, including Ajax (see Chapter 39). ■

JavaScript: The Right Tool for the Right Job

Knowing how to match an authoring tool to a solution-building task is an important part of being a well-rounded web site author. A web designer who ignores JavaScript is akin to a plumber who bruises his knuckles by using pliers instead of the wrench from the bottom of the toolbox.

By the same token, JavaScript won't fulfill every dream. The more you understand about JavaScript's intentions and limitations, the more likely you will be to turn to it immediately when it is the proper tool. In particular, look to JavaScript for the following kinds of solutions:

- Getting your web page to respond or react directly to user interaction with form elements (input fields, text areas, buttons, radio buttons, checkboxes, selection lists) and hypertext links
- Distributing small collections of database-like information and providing a friendly interface to that data
- Controlling multiple-frame navigation, plug-ins, or Java applets based on user choices in the HTML document
- Preprocessing data on the client before submission to a server
- Changing content and styles in modern browsers dynamically and instantly, in response to user interaction
- Requesting files from the server, and making read and write requests of server-side scripts

At the same time, it is equally important to understand what JavaScript is *not* capable of doing. Scripters waste many hours looking for ways of carrying out tasks for which JavaScript was not designed. Most of the limitations are intentional, to protect visitors from invasions of privacy or unauthorized access to their desktop computers. Therefore, unless a visitor uses a modern browser and explicitly gives you permission to access protected parts of his or her computer, JavaScript cannot surreptitiously perform any of the following actions:

- Setting or retrieving the browser's preferences settings, main window appearance features, action buttons, and printing capability
- Launching an application on the client computer
- Reading or writing files or directories on the client computer (with one exception: cookies)
- Writing directly to files on the server
- Capturing live data streams from the server for retransmission
- Sending secret e-mails from web site visitors to you (although it can send data to a server-side script capable of sending email)

Web site authors are constantly seeking tools that will make their sites engaging (if not cool) with the least amount of effort. This is particularly true when the task of creating a web site is in the hands of people more comfortable with writing, graphic design, and page layout than with hard-core programming. Not every webmaster has legions of experienced programmers on hand to whip up some special, custom enhancement for the site. Neither does every web author have control over the web server that physically houses the collection of HTML and graphics files. JavaScript brings programming power within reach of anyone familiar with HTML, even when the server is a black box at the other end of a telephone line.

CHAPTER

2

Developing a Scripting Strategy

IN THIS CHAPTER

How leapfrogging browser developments help and hurt web developers

Separating the core JavaScript language from document objects

The importance of developing a cross-browser strategy

If you are starting to learn JavaScript at this point in the history of scriptable browsers, you have both a distinct advantage and a disadvantage. The advantage is that you have the wonderful capabilities of mature browser offerings from Microsoft, The Mozilla Foundation (under brand names such as Firefox, Netscape, and Camino), Apple, and others at your bidding. The disadvantage is that you have not experienced the painful history of authoring for older browser versions that were buggy and at times incompatible with one another due to a lack of standards. You have yet to learn the anguish of carefully devising a scripted application for the browser version you use, only to have site visitors send you voluminous email messages about how the page triggers all kinds of script errors when run on a different browser brand, generation, or operating system platform.

Welcome to the real world of scripting web pages with JavaScript. Several dynamics are at work to help make an author's life difficult if the audience for the application uses more than a single type of browser. This chapter introduces you to these challenges before you type your first word of JavaScript code. Our fear is that the subjects we raise may dissuade you from progressing further into JavaScript and its powers. But as developers ourselves — and some of us have been using JavaScript since the earliest days of its public prerelease availability — we dare not sugar-coat the issues facing scripters today. Instead, we want to make sure you have an appreciation for what lies ahead to assist you in learning the language. We believe that if you understand the big picture of the browser-scripting world as it stands today, you will find it easier to target JavaScript usage in your web application development and be successful at it.

Browser Leapfrog

Browser compatibility has been an issue for authors since the earliest days of the web gold rush — long before JavaScript. Despite the fact that browser developers and other interested parties voiced their opinions during formative stages of standards development, HTML authors could not produce a document that appeared

the same, pixel by pixel, on all client machines. It may have been one thing to establish a set of standard tags for defining heading levels and line breaks, but it was rare for the actual rendering of content inside those tags to look identical on different brands of browsers on different operating systems.

Then, as the competitive world heated up — and web browser development transformed itself from a volunteer undertaking into profit-seeking businesses — creative people defined new features and new tags that helped authors develop more flexible and interesting-looking pages. As happens a lot in any computer-related industry, the pace of commercial development easily surpassed the studied progress of standards. A browser maker would build a new HTML feature into a browser and only then propose that feature to the relevant standards body. Web authors were using these features (sometimes for prerelease browser versions) before the proposals were published for review.

When the deployment of content depends almost entirely on an interpretive engine on the client computer receiving the data — the HTML engine in a browser, for example — authors face an immediate problem. Unlike a stand-alone computer program that can extend and even invent functionality and have it run on everyone's computer (at least for a given operating system), web content providers must rely on the functionality built into the browser. This led to questions such as, "If not all browsers coming to my site support a particular HTML feature, then should I apply newfangled HTML features for visitors only at the bleeding edge?" and "If I do deploy the new features, what do I do for those with older browsers?"

Authors who developed pages in the earliest days of the Web wrestled with these questions for many HTML features that we today take for granted. Tables and frames come to mind. Eventually, the standards caught up with the proposed HTML extensions — but not without a lot of author woe along the way.

Despite the current dominance of the Microsoft Internet Explorer browser on the dominant Windows operating system, the number of browsers that people use is not shrinking. Several recent browsers, including the modern Netscape, Firefox, and Camino browsers, are based on an Open Source browser called Mozilla. The Macintosh operating system includes its own Apple-branded browser, Safari (released in 2003). And the independent Opera browser also has a home on some users' computers. All of these non-Microsoft browser makers obviously believe that they bring improvements to the world to justify their development — building better mousetraps, you might say.

Duck and Cover

Today's browser wars are fought on different battlegrounds than in the early days of the Web. The breadth and depth of established web standards have substantially fattened the browser applications — and the books developers read to exploit those standards for their content. On one hand, most developers clamor for deeper standards support in new browser versions. On the other hand, everyday users care little about standards. All they want is to have an enjoyable time finding the information they seek on the Web. Most users are slow to upgrade, holding out until their favorite sites start breaking in their ancient browsers.

Industry standards don't necessarily make the web developer's job any easier. For one thing, the standards are unevenly implemented across the latest browsers. Some browsers go further in their support than others. Then, there are occasional differences in interpretation of vague standards details. Sometimes the standards don't provide any guidance in areas that are vital to content developers. At times, we are left to the whims of browser makers who fill the gaps with proprietary features in the hope that those features will become de facto standards.

As happens in war, civilian casualties mount when the big guns start shooting. The browser battle lines shifted dramatically in only a few years. The huge market-share territory once under Netscape's command came under Microsoft's sway. More recently, however, concerns about privacy and security on the Windows platform have driven many users to seek less vulnerable browsers. Mozilla Firefox has so far been the biggest beneficiary in the search for alternatives. Although a fair amount of authoring common ground exists between the latest versions of today's browsers, uneven implementation of the newest features causes the biggest problems for authors wishing to deploy on all browsers. Trying to define the common denominator may be the toughest part of the authoring job.

Compatibility Issues Today

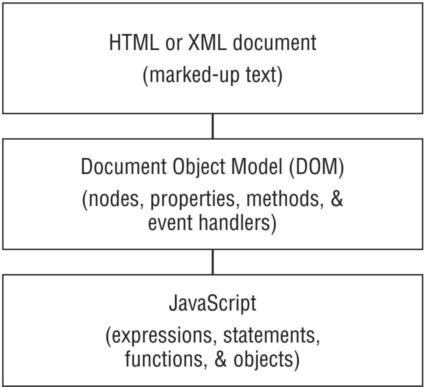
Allow us to describe the current status of the compatibility situation among the top three browser families: Microsoft Internet Explorer, browsers based on Mozilla, and Apple Safari. The discussion in the next few sections intentionally does not get into specific scripting technology very deeply; some of you may know very little about programming at this point. In many chapters throughout this book, we offer scripting suggestions to accommodate a variety of browsers.

Separating the core JavaScript language from document objects

Although early JavaScript authors initially treated client-side scripting as one environment that permitted the programming of page elements, the scene has changed as the browsers have matured. Today, a clear distinction exists between specifications for the core JavaScript language and for the elements you script in a document — for example, buttons and fields in a form (see Figure 2-1).

FIGURE 2-1

The document object model is the programming interface between the HTML or XML document and the JavaScript programming language.



On one level, this separation is a good thing. It means that one specification exists for basic programming concepts and syntax that could become the programming language in any number of other environments. You can think of the core language as basic wiring. When you know how electric

wires work, you can connect them to all kinds of electrical devices. Similarly, JavaScript today is used to wire together elements in an HTML document. Tomorrow, operating systems could use the core language to enable users to wire together desktop applications that need to exchange information automatically.

At the ends of today's JavaScript wires inside browsers are the elements on the page such as paragraphs (`p`), images (`img`), and input fields (`input`). In programming jargon, these items are known as *document objects*. By keeping the specifications for document objects separate from the wires that connect them, you can use other kinds of wires (other languages) to connect them. It's like designing telephones that can work with any kind of wire, including a type of wire that hasn't been invented yet. Today, the devices can work with copper wire or fiber-optic cable. You get a good picture of this separation in Internet Explorer, whose set of document objects can be scripted with either JavaScript or VBScript. The same objects can be connected with either of those two different sets of wiring.

The separation of core language from document objects enables each concept to have its own standards effort and development pace. But even with recommended standards for each factor, each browser maker is free to extend the standards. Furthermore, authors may have to expend more effort to devise one version of a page or script that plays on multiple browsers, unless the script adheres to a common denominator (or uses some other branching techniques to let each browser run its own way).

Core language standard

Keeping track of JavaScript language versions requires a brief history lesson. The first version of JavaScript (in Netscape Navigator 2) was version 1, although that numbering was not part of the language usage. JavaScript was JavaScript. Version numbering became an issue when Navigator 3 was released. The version of JavaScript associated with that Navigator version was JavaScript 1.1. The first appearance of the Navigator 4 generation increased the language version one more notch with JavaScript 1.2.

Microsoft's scripting effort contributes confusion for scripting newcomers. The first version of Internet Explorer to include scripting was Internet Explorer 3. The timing of Internet Explorer 3 was roughly coincidental to Navigator 3. But as scripters soon discovered, Microsoft's scripting effort was one generation behind. Microsoft did not license the JavaScript name. As a result, the company called its language JScript. Even so, the HTML tag attribute that lets you name the language of the script inside the tags could be either JScript or JavaScript for Internet Explorer. Internet Explorer 3 could understand a JavaScript script written for Navigator 2.

During this period of dominance by Navigator 3 and Internet Explorer 3, scripting newcomers were often confused because they expected the scripting languages to be the same. Unfortunately for the scripters, there were language features in JavaScript 1.1 that were not available in the older JavaScript version in Internet Explorer 3. Microsoft improved JavaScript in IE3 with an upgrade to the .dll file that gives IE its JavaScript syntax. However, it was hard to know which .dll is installed in any given visitor's IE3. The situation smoothed out for Internet Explorer 4. Its core language was essentially up to the level of JavaScript 1.2, as in early releases of Navigator 4. Almost all language features that were new in Navigator 4 were understood when you loaded the scripts into Internet Explorer 4. Microsoft still officially called the language JScript.

While all of this jockeying for JavaScript versions was happening, Netscape, Microsoft, and other concerned parties met to establish a core language standard. The standards body is a Switzerland-based organization originally called the European Computer Manufacturer's Association and now known simply as ECMA (commonly pronounced "ECK-ma"). In mid-1997, the first formal language specification was agreed on and published (ECMA-262). Due to licensing issues with the JavaScript name, the body created a new name for the language: ECMAScript.

With only minor and esoteric differences, this first version of ECMAScript was essentially the same as JavaScript 1.1, used in Navigator 3. Both Navigator 4 and Internet Explorer 4 officially supported the ECMAScript standard. Moreover, as happens so often when commerce meets standards bodies, both browsers went beyond the ECMAScript standard. Fortunately, the common denominator of this extended core language is broad, lessening authoring headaches on this front.

JavaScript version 1.3 was implemented in Netscape Navigator 4.06 through 4.7x. This language version is also the one supported in IE5, 5.5, and 6. A few new language features are incorporated in JavaScript 1.5, as implemented in Mozilla-based browsers (including Navigator 6 and later). A few more core language features were added to JavaScript 1.6, first implemented in Mozilla 1.8 (Firefox 1.5, and yet more to JavaScript 1.8 in Firefox 3).

In practice, so many browsers in use today support all but a few leading-edge features of the Mozilla browsers, that JavaScript version numbers are mostly irrelevant. Other compatibility issues with older browsers will likely get in your way before core language problems do. The time has come to forget about elaborate workarounds for the inadequacies of the oldest browsers.

Document object model

If prevalent browsers have been close to one another in core JavaScript language compatibility, nothing could be further from the truth when it comes to the document objects. Internet Explorer 3 based its document object model (DOM) on that of Netscape Navigator 2, the same browser level it used as a model for the core language. When Netscape added a couple of new objects to the model in Navigator 3, the addition caused further headaches for neophyte scripters who expected those objects to appear in Internet Explorer 3. Probably the most commonly missed object in Internet Explorer 3 was the image object, which lets scripts swap the image when a user rolls the cursor atop a graphic — *mouse rollovers,* they're commonly called.

In the level 4 browsers, however, Internet Explorer's DOM jumped way ahead of the object model that Netscape implemented in Navigator 4. The two most revolutionary aspects of IE4 were the ability to script virtually every element in an HTML document and the instant reflow of a page when the content changed. This opened the way for HTML content to be genuinely dynamic without requiring the browser to fetch a rearranged page from the server. NN4 implemented only a small portion of this dynamism, without exposing all elements to scripts or reflowing the page. It introduced a proprietary layering concept that was abandoned at the end of the Navigator 4.x lifetime. Inline content could not change in NN4 as it could in IE4. Suffice it to say that IE4 was an enviable implementation.

At the same time, a DOM standard was being negotiated under the auspices of the World Wide Web Consortium (W3C). The hope among scripters was that after a standard was in place, it would be easier to develop dynamic content for all browsers that supported the standard. The resulting standard — the W3C DOM — formalized the notion of being able to script every element on the page, as in IE4. But it also invented an entirely new object syntax that no browser had used. The race was on for browsers to support the W3C DOM standards.

An arm of the Netscape company called Mozilla.org was formed to create an all-new browser dedicated to supporting industry standards. The engine for the Mozilla browser became the basis for the all-new Navigator 6. It incorporated all of the W3C DOM Level 1 and a good chunk of Level 2. Mozilla 1.01 became the basis for the Netscape 7 browser, whereas Netscape 7.1 was built on the Mozilla 1.4 generation. In the summer of 2003, Netscape's parent company, AOL Time Warner, decided to end further Netscape-branded browser development. The work on the underlying Mozilla browser, however, continues under an independent organization called The Mozilla Foundation.

Mozilla-based browsers, and others using the same engine (such as Firefox and Camino), continue to be upgraded and released to the public. The Mozilla engine arguably offers the most in-depth support for the W3C DOM standards.

Even though Microsoft participated in W3C DOM standards development, IE5 and 5.5 implemented only some of the W3C DOM standard — in some cases, just enough to allow simple cross-browser scripting that adheres to the standard. Microsoft further filled out W3C DOM support in IE6, but chose to omit several important parts. Despite the long time gap between releases of IE6 and IE7, the latter included no additional W3C DOM support — much to the chagrin of web developers. IE8 finally did some significant catching up with the W3C DOM specification, with a switch to put IE8 back into IE7-compatibility mode for support of legacy scripts.

The Apple Safari browser has raced forward in its comparatively short life to offer substantial W3C DOM support. This is especially true of version 2, which was first released as part of Mac OS X version 10.4.

With this seemingly tortuous history of DOM development and browser support leading to the present day, you may wonder how anyone can approach DOM scripting with hope of success. Yet you'd be amazed by how much you can accomplish with today's browsers. You'll certainly encounter compatibility issues along the way, but this book will guide you through the most common problems and equip you to tackle others.

Laying a good foundation with markup

When the HTML markup on a page conforms to uniform public standards, browsers from different manufacturers tend to treat it similarly. However, in order to support the millions of web pages from past years, browsers also take a stab at guessing the author's intent when the markup differs from the specs. Because this sort of "guessing," for the most part, isn't prescribed in the HTML standards, the various browser manufacturers have come up with their own very different solutions. Therefore, you will get more consistent results and build more bullet-proof sites if your markup is easily parsable and error-free.

We encourage you produce markup that conforms to the W3C specification — for example, the HTML 4.01 spec at `http://www.w3.org/TR/html4/`. It's a good idea to rely on tools such as the W3C HTML Validator (`http://validator.w3.org/`) to check your markup against the standard. Beyond that, be consistent in your own work even when the spec is loose — for example, we suggest that you close all tags such as `td` and `li` even if the spec and the Validator don't require it. Examine and mimic the kind of markup produced by JavaScript using DOM methods, and you'll be doing fine.

Cascading Style Sheets

Navigator 4 and Internet Explorer 4 were the first browsers to claim compatibility with a W3C recommendation called *Cascading Style Sheets Level 1 (CSS1)*. This specification provided designers an organized way to customize the look and feel of a document (and thus minimized the HTML in each tag). As implementations go, NN4's had a lot of rough edges, especially when trying to mix style sheets and tables. But IE4 was no angel, either, especially when one compared the results of style sheet assignments as rendered in the Windows and Macintosh versions of the browser (developed by two separate teams).

CSS Level 2 adds more style functionality to the standard; IE6, Mozilla-based browsers, and Safari support a good deal of Level 2 (albeit unevenly) with the latest versions, such as Mozilla 1.8+ and

Safari 2+, and they are beginning to support CSS Level 3 features. Rendering of styled content is more harmonious among browsers, largely thanks to guidelines about how styles should render. Complex layouts, however, still need careful tweaking from time to time because of different interpretations of the standard.

JavaScript plays a role in style sheets in IE4+, Mozilla, and Safari because those browsers' object models permit dynamic modification to styles associated with any content on the page. Style sheet information is part of the object model and therefore is accessible and modifiable from JavaScript.

Standards compatibility modes (DOCTYPE switching)

Both Microsoft and Netscape/Mozilla discovered that they had, over time, implemented CSS features in ways that ultimately differed from the published standards that came later (usually after much wrangling among working-group members). To compensate for these differences and make a clean break to be compatible with the standards, the major browser makers decided to let the page author's choice of `<!DOCTYPE>` header element details determine whether the document was designed to follow the old way (sometimes called *quirks mode*) or the standards-compatible way. The tactic, known informally as *DOCTYPE switching,* is implemented in Internet Explorer 6 and later, Internet Explorer 5 for the Mac, and all Mozilla-based browsers.

Although most of the differences between the two modes are small, there are some significant differences between them in Internet Explorer 6 and later, particularly when styles or DHTML scripts rely on elements designed with borders, margins, and padding. Microsoft's original box model measured the dimensions of elements in a way that differed from the eventual CSS standard.

To place the affected browsers in CSS standards-compatible mode, you should include a `<!DOCTYPE>` element at the top of every document that specifies one of the following statements:

```
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.0 Transitional//EN"
        "http://www.w3.org/TR/REC-html40/loose.dtd">

<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.0 Frameset//EN"
        "http://www.w3.org/TR/REC-html40/frameset.dtd">

<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.0//EN"
        "http://www.w3.org/TR/REC-html40/strict.dtd">

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
        "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Frameset//EN"
        "http://www.w3.org/TR/xhtml1/DTD/xhtml1-frameset.dtd">

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Strict//EN"
        "http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd">

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.1//EN"
        "http://www.w3.org/TR/xhtml11/DTD/xhtml11.dtd">
```

Be aware, however, that older versions of Internet Explorer for Windows, such as Internet Explorer 5 or Internet Explorer 5.5, are ignorant of the standards-compatible mode and

will use the old Microsoft quirks mode regardless of your `<!DOCTYPE>` setting. Still, using the standards-compatible mode DOCTYPE is more likely to force your content and style sheets to render similarly across the latest browsers.

Dynamic HTML and positioning

Perhaps the biggest improvements to the inner workings of the Level 4 browsers from both Netscape and Microsoft revolved around a concept called *Dynamic HTML (DHTML)*. The ultimate goal of DHTML was to enable scripts in documents to control content, content position, and content appearance in response to user actions. To that end, the W3C organization developed another standard for the precise positioning of HTML elements on a page, as an extension of the CSS standards effort. The CSS-Positioning recommendation was later incorporated into the CSS standard, and both are now part of CSS Level 2. With positioning, you can define an exact location on the page where an element should appear, whether the item should be visible, and what stacking order it should take among all the items that might overlap it.

IE4+ adheres to the positioning-standard syntax and makes positionable items subject to script control. Navigator 4 followed the standard from a conceptual point of view, but it implemented an alternative methodology involving an entirely new, and eventually unsanctioned, tag for layers. Such positionable items were scriptable in Navigator 4 as well, although a lot of the script syntax differed from that used in Internet Explorer 4. Fortunately for DHTML authors, Mozilla, through its adherence to the CSS standard, is more syntactically in line with the DHTML style properties employed in IE4+.

Of more interest these days is the ability to modify the inline content of a web page without reloading the entire page. Fundamental standards from the W3C DOM Level 1 are supported by a wide range of browsers, including IE5+, Mozilla, Safari, and Opera. You can accomplish quite a lot using the same basic syntax across all of these browsers. Some challenges remain, however, as you'll see throughout this book.

Developing a Scripting Strategy

How do you create web pages that work well across the board? Browsers representing the latest generation contain a hodgepodge of standards and proprietary extensions. Even if you try to script to a common denominator among today's browsers, your code probably won't take into account the earlier versions of both the JavaScript core language and the browser DOMs.

The true challenge for authors is determining the audience for which scripted pages are intended. Each new browser generation not only brings with it new and exciting features you are probably eager to employ in your pages, but also adds to the fragmentation of the audience visiting a publicly accessible page. It can take months for the latest upgrade of a browser to supplant the previous version among its users, and some people seldom or never upgrade unless the new browser comes via a new computer or operating system upgrade. As a result, web developers are writing for an incredibly mixed audience of browser makes and models, including some of the latest mobile devices that don't support JavaScript. Add to that all the user agents that aren't visual browsers, such as screen readers and search engines. How to cope?

Graceful degradation and progressive enhancement

At this stage in the history of scriptable browsers, most web surfers arrive at our sites with browsers equipped with support for at least simple W3C DOM and DHTML capabilities. But "most" isn't everyone by a long shot, so it is our obligation to apply scripting in the additive, or value-added, manner

known as *progressive enhancement*. By this we mean that your pages should convey their primary information to nonscriptable browsers designed for users with vision or motor-skill impairments, as well as less-feature-rich browsers built into the latest cellular phones. On top of that, your scripting efforts can give visitors with recent scriptable browsers a more enjoyable experience — better interactivity, faster performance, and a more engaging presentation. You will not only be contributing to the state of the art, but also carrying on the original vision of scripting in the browser.

In an early stage of the Web's evolution, many web site developers included the fancy features of the latest browser releases without much concern for folks who hadn't upgraded their browsers or switched from brand X to brand Y. This meant that a lot of new web sites were cosmetically — or, worse, functionally — broken for a lot of visitors. It was common to see banners explaining that "this website is viewed best in" such-and-such a browser, and it was left to the visitor to put up with the mess, or to install a new browser.

Over the years, web site producers have acquired two exciting new features that have changed our approach to browser support: the online business model and the social conscience. Excluding potential web site visitors from both commercial and non-profit sites is recognized as fiscally unwise. Excluding users of assistive technology is regarded as unjust — not to mention actionable in an increasing number of jurisdictions. As web developers, our concern isn't just a few obsolete browsers that can't run JavaScript. There are many other user agents that don't or can't support scripting, including search engines, some mobile devices, and some screen-readers and other assistive UAs. A lot of people simply turn off JavaScript support in their browsers. Some corporate firewalls strip JavaScript out of incoming web pages so that even entirely JavaScript-capable browsers within the organization do not see it or run it. Web stats are all over the map, but some estimates of the percentage of web site visitors who run without JavaScript for all of these reasons are 10% or higher. Even if it were only 1%, it would be significant. Imagine that you're holding the front door for customers at a physical storefront, and you choose to slam the door in the face of one out of every hundred people who approach. How long would you keep your job?

Graceful degradation is an approach to system design that provides fall-backs in case of failure. In web design, this means providing a lower level of appearance or functionality if the user agent can't handle any of the advanced technology that makes up the page. The problem with graceful degradation is the way it's been incorporated into site production. Developers who cut their teeth in the bad old days, and those who were trained by them, continued to build sites primarily for the most advanced and well-equipped browsers and then, as a final step or retrofit, tried to accommodate the rest. This approach adds a lot of work to the final stages of a project for the sake of a minority of users, so in the real world of web design, graceful degradation is often sacrificed due to all-too-common limits on time, money, and altruism. The result is an Internet full of web sites that still fail very *un*gracefully for a significant number of potential visitors.

Progressive enhancement is a newer approach that does justice to graceful degradation. A web site is first designed to run in all user agents, and then enhancements are added to make the user's experience faster or richer if they're using a more sophisticated browser. This ensures essential functionality for every reader (human or machine) and supports the fancy browsers without sacrificing the simpler ones. It puts the vegetable course before the dessert and the horse before the cart. It makes sure the car has a working engine before adding the chrome and the sound system.

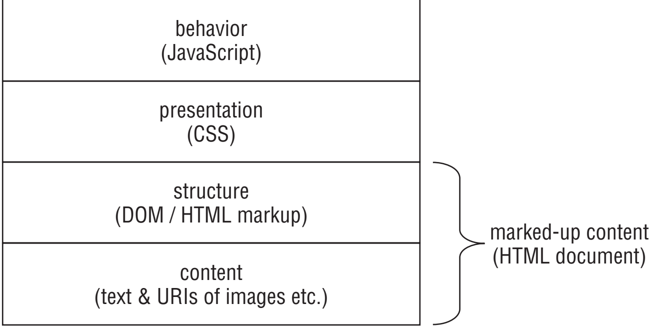
One way we manifest the principle of progressive enhancement in our work is by building pages that work in the absence of JavaScript. This might seem like heresy in a JavaScript "Bible," but the bottom line is that JavaScript is one of many tools we use to accomplish our work. No single tool is so shiny and clever that it should upstage the real star of the show — the web site visitor.

Separation of development layers

Another important principle in modern web design is the separation of layers of development. The main layers we work with are the content of a page (such as text and image names), its structure in HTML markup, its behavior in JavaScript, and its presentation in CSS (see Figure 2-2). The more you can keep these layers separate, the easier it will be to build, modify, and re-use your work.

FIGURE 2-2

Four layers of client-side web development.



Old-school web pages are easy to spot: just look at the HTML source, and you'll see JavaScript and styling attributes embedded in the markup. This is like a house built with the wiring and pipes embedded in cement walls. If you want to change or replace the wiring, you've got a real mess on your hands. These cemented pages are redundant, since identical features on different pages require the same bloated markup to be downloaded each time. For that reason, they're also slower to download.

With separated layers, each component file is fairly trim and fast to download, and if the same style sheet or JavaScript script applies to more than one page, as is often the case, the response time is even faster since the browser caches (stores) files it has already fetched from the server. Web site development and redesign are also made more efficient because several people can work on different layers without stepping on one another's toes. It becomes possible to develop *modules* of markup, script, and style that can more easily be tweaked and re-used for future projects.

Separate development layers aren't unrelated. Just the opposite, in fact: the style sheet and JavaScript code refer to and depend on the HTML markup structure, tags, and attributes. They are hands whose fingers are designed to mesh perfectly, but they are still separate hands.

The first step in separating layers is literally to create separate files for your HTML, JavaScript, and CSS. (The HTML files you'll see in this book are already combinations of markup and content, which, in the everyday world of web production, are often a merger of HTML templates and database fields performed by a server-side script.)

Separation of layers is also an approach we can take to our scripting logic. JavaScript has the ability to write a chunk of cemented markup and text to a document in one operation, but if we separate the new structural elements from their content in our script, we end up with code that is easier to

debug and re-use, and that contains fewer errors. Similarly, JavaScript can directly tweak the styling of an element on a page, changing its color or size or position, but instead, if we simply assign an id or class that is separately defined in the style sheet, then a graphic designer can change that presentation without anyone having to modify the JavaScript.

CHAPTER 3

Selecting and Using Your Tools

IN THIS CHAPTER

How to choose basic JavaScript authoring tools

How to set up your authoring environment

How to enter a simple script to create a web page

In this chapter, you set up a productive script writing and previewing environment on your computer and learn where to find valuable resources on the Web. We also produce sample HTML, JavaScript, and CSS files to demonstrate how to use these tools to create real web pages.

Because of differences in the way various personal computing operating systems behave, we present details of environments for two popular variants: Windows (95 through XP) and Mac OS X. For the most part, your JavaScript authoring experience will be the same regardless of the operating system platform you use — including Linux or Unix. Although there may be slight differences in font designs, depending on your browser and operating system, the information remains the same. Most illustrations of browser output in this book are made from the Windows XP versions of Internet Explorer and Firefox. If you run another browser or version, don't fret if every pixel doesn't match the illustrations in this book.

The Software Tools

The best way to learn JavaScript is to type the HTML and scripting code into documents in a text editor. Your choice of editor is up to you, although we provide some guidelines for choosing.

Choosing a text editor

For the purposes of learning JavaScript in this book, avoid WYSIWYG (What You See Is What You Get) web page authoring tools such as FrontPage and Dreamweaver. These tools may come in handy later for molding your content and layout. But the examples in this book focus more on script content (which you must type anyway), so there isn't much HTML that you have to type. Files for all complete web page listings in this book (except for the tutorial chapters) also appear on the companion CD-ROM.

An important factor to consider in your choice of editor is how easy it is to save standard text files with an `.html` filename extension. In the case of Windows, any program that not only saves the file as text by default, but also enables you to set the extension to `.htm` or `.html`, prevents a great deal of problems. If you use Microsoft Word, for example, the program tries to save files as binary Word files — something that no web browser can load. To save the file initially as a `.txt` or `.html` extension file requires mucking around in the Save As dialog box. This is truly a nuisance.

Perhaps more importantly, a word processor such as Microsoft Word opens with a lot of default settings that may make desktop publishing easier but can frustrate a programmer, such as inserting spaces around words and automatically replacing straight quotes with curly quotes. Setting its defaults to make it programmer-friendly will make it less useful as a word processor.

Finally, we urge you not to create documents in Word and "save them as a web page." This will generate an HTML document that will look much like the word processing document on which it's based, but the actual HTML coding it produces will be bloated and redundant — a far cry from the sleek and elegant code that we hope you will be producing after you read this book. Word just isn't the right tool for this job.

Nothing's wrong with using bare-essentials text editors. In Windows, that includes the WordPad program or a more fully featured product such as Visual Studio or the shareware editor called TextPad. For Mac OS X, the bundled TextEdit application is also fine. Favorites among Mac HTML authors and scripters include BBEdit (Bare Bones Software) and SubEthaEdit (`www.codingmonkeys.de/subethaedit`).

Choosing a browser

The other component that is required for learning JavaScript is the browser. You don't have to be connected to the Internet to test your scripts in the browser. You can perform all testing offline. This means you can learn JavaScript and create cool, scripted web pages with a laptop computer — even on a boat in the middle of an ocean.

The browser brand and version you use are up to you. Because the tutorial chapters in this book teach the W3C DOM syntax, you should be using a recent browser. Any of the following will get you through the tutorial: Internet Explorer 5 or later (Windows or Macintosh); any Mozilla-based browser (including Firefox, Netscape 7 or later, and Camino); Apple Safari; and Opera 7 or later.

Note

Many example listings in Parts III and IV of this book demonstrate language or document object model (DOM) features that work on only specific browsers and versions. Check the compatibility listing for that language or DOM feature to make sure you use the right browser to load the page. ■

Setting Up Your Authoring Environment

To make the job of testing your scripts easier, you want to have your text editor and browser running simultaneously. You need to be able to switch quickly between editor and browser as you experiment and repair any errors that may creep into your code. The typical workflow entails the following steps:

1. Enter HTML, JavaScript, and CSS into the source documents in the text editor.
2. Save them to disk.
3. Switch to the browser.

4. Do one of the following:
   - If this is a new document, open the file through the browser's Open menu.
   - If the document is already loaded, reload the file into the browser.

Steps 2 through 4 are actions you will take frequently. We call this three-step sequence the *save-switch-reload* sequence. You will perform this sequence so often as you script that the physical act will quickly become second nature to you. How you arrange your application windows and effect the save-switch-reload sequence varies according to your operating system.

In web site production, after you tweak your markup, style sheet, and scripts to your liking on your own computer, you'll upload them to your server using an FTP (File Transfer Protocol) program.

There are also online editors, but for now let's keep it simple. One of the advantages of doing your work off-line on your own computer is that you don't even have to have an active Internet connection during this stage of web site development.

Windows

You don't have to have either the editor or browser window maximized (at full screen) to take advantage of them. In fact, you may find them easier to work with if you adjust the size and location of each window so that both windows are as large as possible, while still enabling you to click a sliver of the other's window. Or, you can leave the taskbar visible so you can click the desired program's button to switch to its window (see Figure 3-1). A monitor that displays more than 800×600 pixels certainly helps in offering more screen real estate for the windows and the taskbar.

FIGURE 3-1

Editor and browser window arrangement in Windows XP.

```
function walkChildNodes(objRef, n) {
    var obj
    if (objRef) {
        if (typeof objRef == "string") {
            obj = document.getElementById(objRef)
        } else {
            obj = objRef
        }
    } else {
        obj = (document.body.parentElement) ?
            document.body.parentElement : document.body.parentNode
    }
    var output = ""
    var indent = ""
    var i, group, txt
    if (n) {
        for (i = 0; i < n; i++) {
            indent += "+---"
        }
    } else {
        n = 0
        output += "Child Nodes of <" + obj.tagName
        output += ">\n=====================\n"
    }
    group = obj.childNodes
```

In practice, however, the Windows Alt+Tab task-switching keyboard shortcut makes the job of the save-switch-reload steps outlined earlier a snap. If you run Windows and also use a Windows-compatible text editor (which more than likely has a Ctrl+S file-saving keyboard shortcut), you can effect the save-switch-reload sequence from the keyboard with your the left hand: Ctrl+S (save the source file), Alt+Tab (switch to the browser), and Ctrl+R (reload the saved source file).

As long as you keep switching between the browser and the text editor via Alt+Tab task-switching, either program is always just an Alt+Tab away.

Mac OS X

In Mac OS X, you can change between your text editor and browser applications via the Dock, or, more conveniently, by pressing ⌘+Tab. As long as you stay in those two applications, the other program is only one ⌘+Tab away (see Figure 3-2).

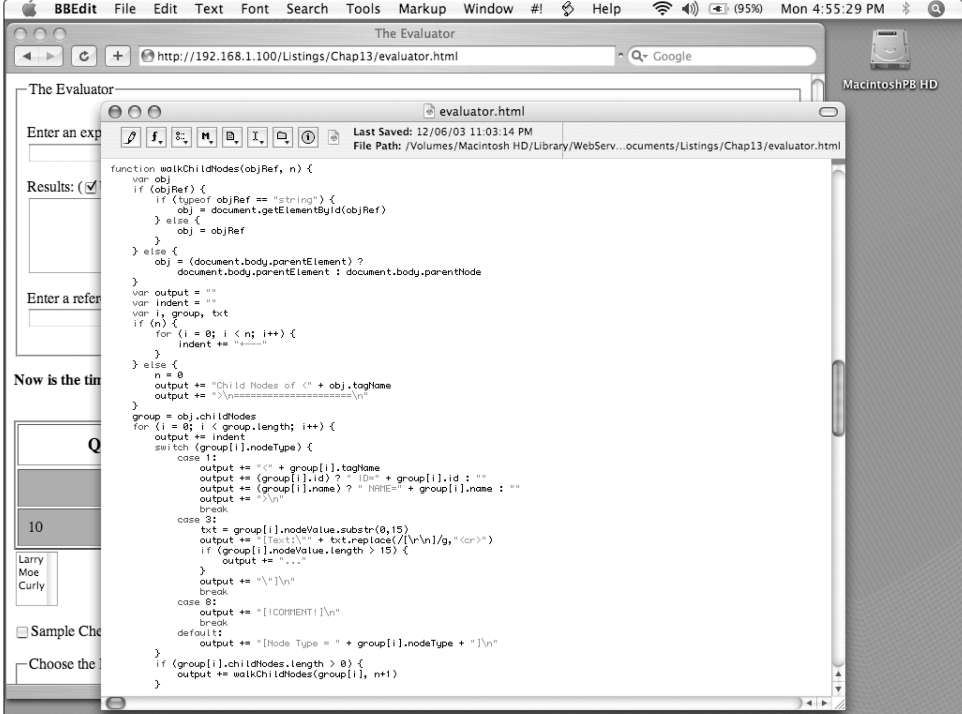
With this setup, the save-switch-reload sequence is a simple affair:

1. Press ⌘+S (save the source file).
2. Press ⌘+Tab (switch to the browser).
3. Press ⌘+R (reload the saved source file).

To return to editing the source file, press ⌘+Tab again.

FIGURE 3-2

Editor and browser window arrangement on the Macintosh screen.



Reloading issues

For the most part, a simple page reload is enough to let you test a revised version of a script right away. But sometimes the browser's cache (with its default settings) can preserve parts of the previous page's attributes when you reload, even though you have changed the source code. To perform a more thorough reload, hold down the Shift key while clicking the browser's Reload/Refresh button. Alternatively, you can turn off the browser's cache in the preferences area, but that setting may negatively affect the overall performance of the browser during your regular web surfing.

Validate, Validate, Validate

You can save yourself hours of debugging by checking to make sure your HTML is valid. If your markup is flawed, chances are your JavaScript and CSS will not work as expected, because they both depend on HTML elements (tags) and their attributes. The more closely your markup matches the industry-standard specs, the more likely it is that you'll get consistent results across browsers that are all approaching the holy grail of web standards conformance. You should always proofread your own code, of course, but an automated validation tool helps for large, complicated pages, and for programmers who are still learning all the rules for correct markup.

The World Wide Web Consortium (W3C), which wrote the HTML specification, has developed just such a validator. It checks a page with the rules specific to the `DOCTYPE` that begins the page. Besides catching our typos, an added advantage of running the Validator is that it helps us learn the fine points of HTML markup. Now repeat after me: The Validator Is My Friend.

The W3C Validator is at `http://validator.w3.org/`. It offers three ways to input your markup — by entering its online URL, by uploading the `.html` file from your computer, and by copying and pasting the markup into the Validator directly. Then, click the Check button and read the results. Often, a single error of markup will result in several items in the Validator error report. If it found any errors in your markup, make the necessary corrections and run your code through the Validator again until you get the green success banner.

Using the Validator will probably make you curious about the HTML specifications. You can read them on the W3C web site:

- **HTML 4.01:** `http://www.w3.org/TR/html4/`
- **HTML5:** `http://www.w3.org/TR/html5/`
- **XHTML 1.0:** `http://www.w3.org/TR/xhtml1/`

As time goes on, you'll discover other useful specs and validators out there, such as those for CSS (Cascading Style Sheets) and web accessibility guidelines:

- **CSS 2.1 Specification:** `http://www.w3.org/TR/CSS21/`
- **CSS Validation Service:** `http://jigsaw.w3.org/css-validator/`
- **Web Content Accessibility Guidelines:** `http://www.w3.org/TR/1999/WAI-WEBCONTENT-19990505/`
- **Web Accessibility Evaluation Tools:** `http://www.w3.org/WAI/ER/tools/`

Creating Your First Script

To demonstrate how we'll use these tools, let's create a classic "Hello, World" page in three stages: first as plain HTML, then augmented with JavaScript, and finally styled with CSS.

For the sake of simplicity, the kind of scripts we're building now are the kind that run automatically, immediately after the browser loads the HTML page. Although all scripting and browsing work here is done offline, the behavior of the page is identical if you place the source file on a server and someone accesses it through the web.

To begin, open your text editor and your browser. Also run Windows File Manager/Macintosh Finder to create a folder in which to save your scripts.

Stage 1: static HTML

Create a new text file and enter the markup in Listing 3-1.

LISTING 3-1

Source Code for hello-world.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Hello, World</title>
   </head>
   <body>
      <h1>Hello, World</h1>
      <p>This is HTML.</p>
   </body>
</html>
```

Save this file to your hard drive as `hello-world.html`, and open it in your browser. Figure 3-3 shows the page as it appears in the browser after you're finished. The precise appearance (or voice, if you're using a screen-reader) may vary slightly from one browser to the next, since at this point we're relying on the default style sheet in the browser to render the page.

The `head` of this page contains two required elements: a `meta` tag that declares the MIME type and character set, and a `title`. The `body` consists of a headline and a paragraph of text, pure and simple.

Stage 2: connecting with JavaScript

Now let's add JavaScript to the page. Create a new text file on your computer and enter Listing 3-2. Be sure and spell everything exactly, including upper- and lowercase:

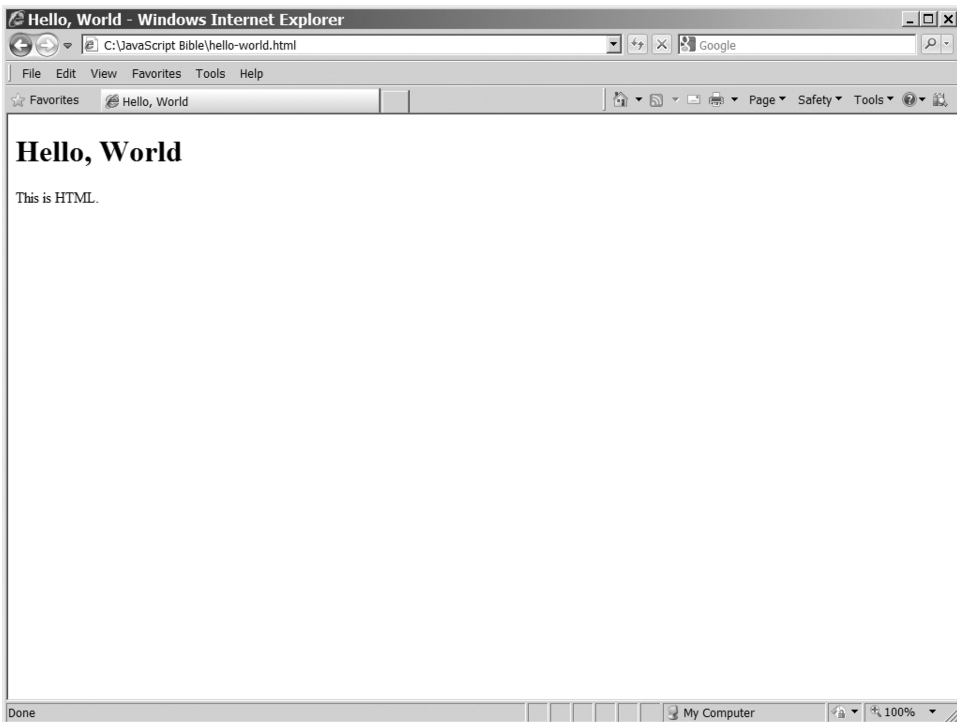
LISTING 3-2

Source Code for hello-world.js

```
var today = new Date();
var msg = "This is JavaScript saying it's now " + today.toLocaleString();
alert(msg);
```

FIGURE 3-3

The static HTML file displayed in a browser.



Save this file as `hello-world.js`. It consists of just three JavaScript statements: the first gets the current date, the second composes a brief message, and the third displays the message.

To enable this JavaScript program to act on your HTML document, add a new `script` tag to the `head` section of the HTML (shown highlighted in Listing 3-3):

LISTING 3-3

Revised Source Code for hello-world.html

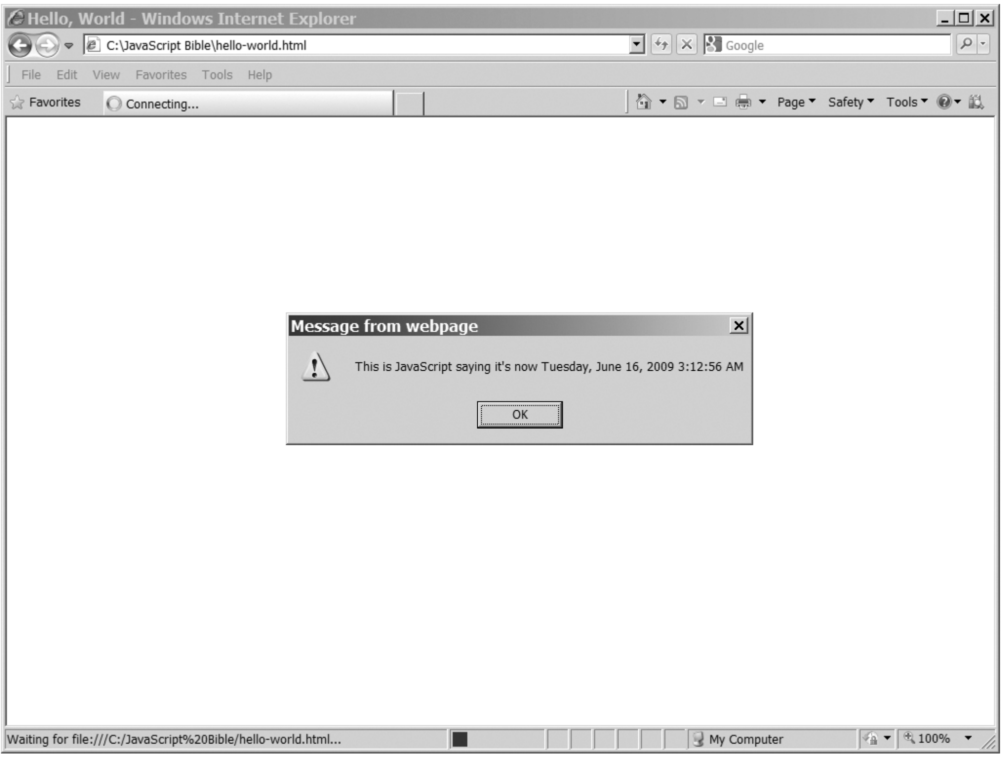
```
...
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Hello, World</title>
      <script type="text/javascript" src="hello-world.js"></script>
   </head>
...
```

The HTML `script` element tells the browser the type and name of the script file to combine with the document. Because the `src` (source) attribute doesn't include a path, the system assumes it's in the same folder as the HTML file. Unlike the `meta` tag, every `<script>` tag must be closed with `</script>`.

When you save the new JavaScript file and the modified HTML file, reload the HTML file in your browser. It should look something like Figure 3-4.

FIGURE 3-4

A JavaScript alert().



The text we passed to `alert()` appears in what's called a *modal dialog*. "Modal" means that you can't do anything more with the application (your browser) until you close the dialog. Notice that the HTML headline and paragraph seem to have disappeared! No worries; they will appear as soon as you click OK on the modal dialog. Why? The browser renders the HTML file from top to bottom. It encounters the `script` tag in the `head` and runs the named JavaScript program before it renders the HTML `body`. In this case, the modal dialog produced by the `alert()` method halts the rendering of the rest of the page until we respond.

Stage 3: styling with CSS

Let's add some styling to the page so that you can see how HTML and CSS interact. Create a new text file on your computer and enter Listing 3-4:

LISTING 3-4

Source Code for hello-world.css

```
h1
{
   font: italic 3em Arial;
}
p
{
   margin-left: 2em;
   font-size: 1.5em;
}
```

Save this file to your hard drive as `hello-world.css`.

This style sheet applies a particular font and color to all the `h1` elements on the page, and a left margin and font-size to all the `p` elements. Of course, in our document, there is only one of each.

To enable this style sheet to affect your HTML document, add a `link` tag to the `head` section of the HTML (shown highlighted in Listing 3-5):

LISTING 3-5

Revised Source Code for hello-world.html

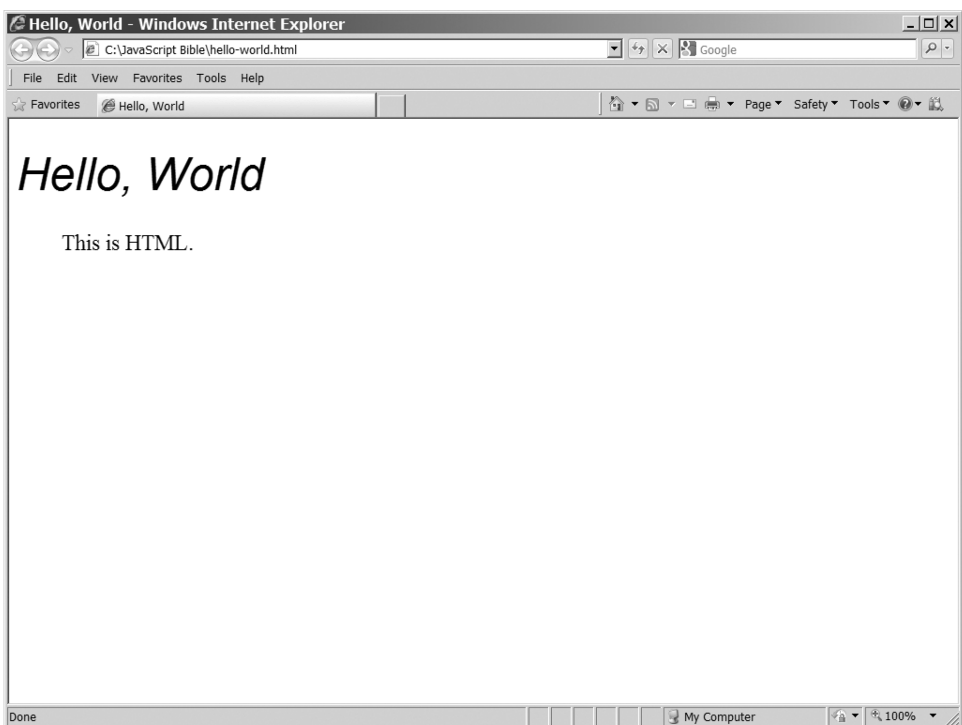
```
...
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Hello, World</title>
      <script type="text/javascript" src="hello-world.js"></script>
      <link type="text/css" rel="stylesheet" href="hello-world.css">
   </head>
...
```

The `link` element tells the browser the type, relationship, and name of the style sheet to combine with the document. Note that, like the `meta` tag and unlike the `script` tag, `link` is an "empty" tag and does not take a separate closing tag. Because the `src` (source) attribute doesn't include a path, the system assumes it's in the same folder as the HTML file. Every `<script>` tag must be closed with `</script>`.

When you save these files and reload the HTML document in your browser (and click OK on that modal dialog), it will look something like Figure 3-5.

FIGURE 3-5

A styled page.



CHAPTER

JavaScript Essentials

When first learning to use JavaScript in the context of the web browser environment, it can be easy to confuse the objects of the JavaScript language with the document objects that we control with JavaScript. It's important to separate the language from the Document Object Model (DOM) to help you make important decisions when designing JavaScript-enhanced pages. You may come to appreciate the separation in the future if you use JavaScript for other object models, such as in server-side programming or scripting Flash animations. All the basics of the language are identical from one context to another; only the objects differ.

This chapter introduces many aspects of the core JavaScript language, particularly as they relate to deploying scripts in a world in which visitors to your pages may use a wide variety of browsers. Along the way, you'll receive additional insights into the language itself. Fortunately, browser differences, as they apply to JavaScript, have lessened considerably as modern browsers continue to inch closer to consistently supporting the JavaScript (ECMAScript) standard. You can find details about the JavaScript core language syntax in Part III.

IN THIS CHAPTER

How to combine JavaScript with HTML

How to accommodate different versions of JavaScript

Language highlights for experienced programmers

Combining JavaScript with HTML

Scriptable browsers offer several ways to include scripts or scripted elements in your HTML documents. Not all approaches are recommended in today's best practices, but it's useful to learn even the old-school techniques so that you can understand legacy code when you come across it on the Web.

<script> tags

We marry JavaScript code to an HTML document using a `<script></script>` tag set that specifies the scripting language

through the `type` attribute. You can have any number of such tag sets in your document. We recommend that all your scripts be external files linked to the HTML:

```
<script type="text/javascript" src="example.js"></script>
```

However, you can also embed JavaScript directly into the HTML by wrapping it in a `<script>...</script>` tag:

```
<script type="text/javascript">
// JavaScript code goes here
</script>
```

There are distinct advantages to linking external JavaScript to HTML rather than embedding the scripts directly in the markup. The principal of *separation of development layers* encourages us to keep different aspects of a document apart, typically in separate, linked files. Doing so facilitates cleaner development, faster downloads, and more modular, re-purposable code that can be much easier to modify than mixtures of technologies cemented together in a single file.

Linking to script libraries (.js files)

The advantages of linking to external JavaScript files become immediately obvious when the same script needs to run on more than one page of a site. If the script were embedded in the HTML markup, each page would be bloated with redundant content, and modifying the script would necessitate repeating the same changes in more than one file. In contrast, linking to an external file adds only a single line to each HTML file, and the external JavaScript file can be modified just once to immediately affect every page that includes it. Another plus is that, by separating the script code from the HTML document, you will not have to worry about comment-hiding or CDATA section tricks (see below).

Such an external script file contains nothing but JavaScript code — no `<script>` tags, no HTML. The script file you create must be a text-only file. Its filename extension can be anything, but the common convention is to use `.js`. To instruct the browser to load the external file at a particular point in your regular HTML file, you add a `src` attribute to the `<script>` tag as follows:

```
<script type="text/javascript" src="example.js"></script>
```

If you load more than one external library, you may include a series of these tag sets in the head of the document.

Notice that the `<script></script>` tag pair is required, even though nothing appears between them. Don't put any script statements between the start and end tags when the start tag contains a `src` attribute.

How you reference the source file in the `src` attribute depends on its physical location and your HTML coding style. In the preceding example, the `.js` file is assumed to reside in the same directory as the HTML file containing the tag. But you can just as easily link to JavaScript files located in other directories on your server or on other domains entirely. Just as with an HTML file, if you want to refer to an absolute URL, the protocol for the file is `http://`.

```
<script type="text/javascript" src="../scripts/example.js"></script>

<script type="text/javascript" src="http://www.example.com/example.js"></script>
```

(A critical prerequisite for using script libraries with your documents is that your web server software must know how to map files with the .js extension to a MIME type of application/x-javascript. Test your web server and, if necessary, arrange for server configuration adjustments. It is rare that a modern server will not correctly recognize .js files.)

When a user views the source of a page that links in an external script library, code from the .js file does not appear in the window, even though the browser treats the loaded script as part of the current document. However, the name or URL of the .js file is plainly visible (displayed exactly as it appears in your source code). Anyone can open that file in their browser (using the http:// protocol) to view the .js file's source code. In other words, an external JavaScript source file is no more hidden from view than JavaScript embedded directly in an HTML file. Nothing that your browser downloads to render a web page can be hidden from view.

Specifying the MIME type & language

Every opening <script> tag should specify the type attribute. script is a generic element indicating that the contained statements are to be interpreted as executable script and not rendered as HTML. The element is designed to accommodate any scripting language that the browser knows — in other words, for which it contains an interpreter. For example, Internet Explorer carries interpreters for both JScript (Microsoft's version of JavaScript) and VBScript.

```
<script type="text/javascript" src="example.js"></script>
<script type="text/vbscript" src="example.vb"></script>
```

Both of these scripts will be interpreted by IE, but a non-VBScript-aware browser such as Mozilla will attempt to interpret only the JavaScript file.

Specifying the language version

It is rarely necessary to specify which version of JavaScript you wish to invoke in your documents. If your script relies on the objects and methods of a recent version of JavaScript that some older browsers won't support, it's better to test for that support directly. For example:

```
// if this browser isn't DOM-aware, exit gracefully
if (!document.getElementById) return;

// now it's safe to use the DOM method
var oExample = document.getElementById("example");
```

However, it isn't always possible to test for the existence of language features at run-time. If the new feature is built into JavaScript's syntax, its mere presence in the script can stop the interpreter from compiling the script to the point where it can't even execute an if-test.

For example, take the E4X syntax introduced in JavaScript 1.6 (see Chapter 20, "E4X — Native XML Processing"):

```
var xAuthor = <name>
                  <first>George</first>
                  <last>Sand</last>
              </name>;
```

If you include this syntax in a script run by a browser that doesn't "know" E4X syntax, the script will simply not run, in some cases with no meaningful error message to alert the visitor or the developer. No code in the same script will run, even if it's within the abilities of the browser.

You can isolate the new syntax with a version-specific `type` attribute for the `script` element:

```
<script src="example-all.js" type="text/javascript"></script>
<script src="example-1-6.js" type="text/javascript;version=1.6"></script>
```

or:

```
<script type="text/javascript">
   // script for all browsers goes here
</script>
<script type="text/javascript;version=1.6">
   // script for browsers that know JavaScript 1.6 and later
</script>
```

Be aware, though, that specifying the version as a special flag is non-standard so not all browsers support it. In the specific case of E4X syntax, Mozilla has introduced another special flag for the `type` attribute: `e4x=1` meaning, essentially, "E4X support = true."

```
<script src="example-e4x.js" type="text/javascript;e4x=1"></script>
```

The practical question then arises: If you have to wall off part of your script from older browsers, what alternative code do you give to those older browsers in place of the new code? And if you're writing that work-around code, why not let that be the only code? What advantage is there in writing the same logic in two different ways in the same script? It's a question to ponder when working with leading-edge language enhancements.

The deprecated language attribute

The `type` attribute is required for the `<script>` tag as of HTML 4, formally published in 1998. Earlier browsers recognized the `language` attribute instead of `type`. The `language` attribute is *deprecated*, which means that it's an outdated feature of the language, has been replaced by newer constructs, and may become obsolete in future versions of HTML. Browsers continue to recognize it in order to support legacy web pages, but there's no reason to use it in industry-standard web sites today. We include it here so that you'll understand it when you encounter it in old markup.

The `language` attribute allowed the scripter to write for a specific minimum version of JavaScript or, in the case of Internet Explorer, other languages such as VBScript. For example, the JavaScript interpreter built into Navigator 3 knows the JavaScript 1.1 version of the language; Navigator 4 and Internet Explorer 4 include the JavaScript 1.2 version. For versions beyond the original JavaScript, you could specify the language version by appending the version number after the language name without any spaces, as in:

```
<script language="JavaScript1.1">...</script>

<script language="JavaScript1.2">...</script>
```

The `type` attribute didn't gain browser support until Internet Explorer 5, Mozilla, and W3C DOM-compatible browsers. If you need to inform even older browsers which language and

version of scripting you're using, you can specify both the `type` and `language` attributes in your `<script>` tags, as older browsers will ignore the `type` attribute:

```
<script type="text/javascript" language="JavaScript1.5">...</script>
```

Of course, if you're depending on features in JavaScript 1.5, you've forgone legacy browsers anyway. In this case, just take the forward-looking approach and test for modern methods at the beginning of the script.

The proprietary for and event attributes

Internet Explorer versions 4 through 7 offered a variation on the `<script>` tag that bound statements of a script to a specific object and an event generated by that object. In addition to the `language` attribute, the tag must include both `for` and `event` attributes (not part of the HTML specification). The value assigned to the `for` attribute was a reference to the desired object. Most often, this was simply the identifier assigned to the object's `id` attribute. The `event` attribute was the event handler name that you wanted the script to respond to. For example, if you designed a script to perform some action upon a `mousedown` event in a paragraph whose ID was `myParagraph`, the script statements were enclosed in the following tag set:

```
<script for="myParagraph" event="onmousedown" type="text/javascript">
...
</script>
```

Statements inside the tag set executed only upon the firing of the event. No function definitions were required.

Because the `for` and `event` attributes were proprietary creations of Microsoft, this way of binding an object's event to a script guaranteed that only Internet Explorer would execute the script when the named event occurred.

Even in its day, the `script for` tag was not a winner. Its attributes constituted a lot of source code overhead for each object's script, so it was never a very efficient technique for linking script statements to multiple objects and events. In addition, non-Internet Explorer and pre-Internet Explorer 4 browsers would execute the script statements as the page loaded, making this proprietary language feature impractical in any cross-browser script.

Old-school inline JavaScript

Back in the bad old days of "tag soup" web development, it was common practice to insert JavaScript statements right in the HTML markup:

```
<select id="nations" name="nations" onchange="doSomething(this);">
```

In that example, the `change` event for the control object `nations` is set to trigger the JavaScript statements provided: a custom function call. We'll show you how this works elsewhere in the book to help you read legacy code, but combining markup and scripting like that today is commonly considered to be "very '90s."

There are many disadvantages to inserting JavaScript into markup this way: it's awkward and expensive to change the markup or the scripting independently when they're this intermeshed; the downloaded markup is unnecessarily bloated and doesn't take full advantage of the centralized

modularity of externally linked scripts; and user agents running versions of JavaScript that can't handle the code are unable to avoid the script.

In a modern page, this markup would be cleaned up to

```
<select id="nations" name="nations">
```

with the event handler assigned entirely in JavaScript with something like

```
AddEvent("nations", "change", doSomething);
```

where the `AddEvent()` function can cater to a variety of event models in different browsers, can be entirely separate from the markup to protect user agents that can't handle scripting, and can be firewalled by defensive if-tests to protect it from legacy JavaScript interpreters that don't play well with modern code.

Accommodating the JavaScript-incapable user agent

There are several categories of user agent that can't or don't support JavaScript, representing, by some accounts, some ten to fifteen percent of all internet usage today. These user agents include search engine spiders, mobile device browsers, browsers inside government and corporate firewalls that strip out script for security reasons, assistive technologies, and browsers in which, for any of a variety of reasons, their users have turned scripting off. There is sure to be a small number of legacy browsers still in use today that cannot run JavaScript or that support very early versions, but the vast majority of non-JavaScript-using internet visitors are using contemporary hardware and software.

It is our responsibility as web developers to acknowledge that JavaScript is an option, not a given, and to ensure that our pages are functional even in its absence. It's our mission to use JavaScript to enhance the visitor's experience and not to supply critical elements without which a page would be broken or dead in the water. We make sure that the HTML markup provides all the fundamental content, hyperlinks, and form fields, and that server-side scripting completes the dialog between client and server that is the core of the HTTP request model. Then, when JavaScript is running, it can morph the page, pretty up the user interface, and quicken the response time. That is the win-win model of modern web scripting.

The question then comes, how can we add JavaScript to an HTML document in a way that leaves the page fully functional when the script interpreter is not running, not present, or packing an obsolete version? Our tactics are several:

- We begin our scripts by testing for the presence of modern DOM methods such as `document.getElementById` in order to turn away obsolete versions of the JavaScript interpreter.
- We export JavaScript to external files and link them to the HTML document with `script` tags. User agents not running a scripting interpreter won't even go there.
- Corollary to the above, we omit JavaScript from event attributes in HTML tags, and instead use JavaScript to assign event handlers to page elements.
- If it is ever unavoidable to include JavaScript in the HTML document itself, enclose the script in HTML comments so that it won't be rendered by not-script-savvy browsers.

Let's take a moment to expand on that last point.

Commenting out script in HTML

Non-scriptable browsers do not know about the <script> tag. Normally, browsers ignore tags that they don't understand. That's fine when a tag is just one line of HTML, but a <script>...</script> tag pair can enclose any number of script statement lines. Old and compact browsers don't know to expect a closing </script> tag. Therefore, their natural inclination is to render any lines they encounter after the opening <script> tag. Seeing JavaScript code spilling out onto a page is sure to confuse or erode the confidence of any visitor.

You can, however, exercise a technique that tricks most non-scriptable browsers into ignoring the script statements: surround the script statements (inside the <script> tag set) with HTML comment markers. An HTML comment begins with the sequence <!— and ends with —>. Therefore, you should embed these comment sequences in your scripts according to the following format:

```
<script type="text/javascript">
<!--
script statements here
//-->
</script>
```

JavaScript interpreters know to ignore a line that begins with the HTML beginning comment sequence <!--, but they need a little help with the ending sequence. The close of the HTML comment starts with a JavaScript comment sequence (//). This tells JavaScript to ignore the line; but a non-scriptable browser sees the ending HTML symbols and begins rendering the page with the next HTML tag or other text in the document. An older browser doesn't know what the </script> tag is, so the tag is ignored and rendering resumes after that.

Commenting out script in XHTML as character data

If your document is marked up with XHTML, the comment syntax is significantly different:

```
<script type="text/javascript">
<!--//--><![CDATA[//><!--
    // script statements here
//--><!]]>
</script>
```

That's quite a mouthful and deserves a bit of explanation.

XHTML parsers are intolerant of < symbols that don't begin elements and & symbols that don't begin HTML entities, yet these characters are commonplace JavaScript operators. The solution is to encase your script statements in what is known as a *CDATA* (pronounced "see-day-tah") section:

```
<![CDATA[
    XHTML permits any character here including < and &
]]>
```

We can then add the HTML comment markers to stop legacy browsers from rendering the script:

```
<script type="text/javascript">
<!--<![CDATA[
```

```
    // script statements here
//--]]>
</script>
```

However, we can't stop here because XHTML also obeys the `<!--` and `-->` comment tags and an XHTML-aware browser will ignore the CDATA section and not execute the script. So, we have to close the comment tag before the CDATA begins in order to satisfy XHTML:

```
<!-- --><![CDATA[
```

and use // comment syntax to make most HTML parsers ignore the rest of that line:

```
<!--//--><![CDATA[
```

Some HTML parsers will treat the line after // as a comment and others will close the comment area with `-->`, so we have to make the CDATA open-tag not show up. The technique we're using is to make the HTML parsers think it's a closed tag

```
<![CDATA[>
```

but to keep XHTML from considering it closed we'll add another comment marker

```
<![CDATA[//>
```

and open the block comment tag once more to stop some browsers from attempting to render the JavaScript code as plain text:

```
<!--//--><![CDATA[//><!--
```

Finally, the CDATA close-tag is commented out for HTML parsers:

```
//--]]>
```

Whew! That's some of the fun web developers get to have when making multiple standards play nicely with one another. How much cleaner to simply export the JavaScript to an external file!

The noscript tag

The `noscript` element is the converse of `script`. A JavaScript-aware browser will render the contents of the `noscript` block if scripting has been turned off or if the browser doesn't support a scripting language invoked by a `script` element in the document. (Significantly, a legacy browser that doesn't support scripting at all and doesn't recognize script-related tags will likewise render the contents of both `script` and `noscript` blocks, which is why we comment out the contents of a `script` block. A `noscript` block will therefore be rendered by all browsers when scripting is not supported.)

You can display any standard HTML within the `noscript` tag set. It is a block-level element that can contain paragraphs, lists, divisions, headings, and so on.

The conventional use of `noscript` is to present HTML content to display in the absence of scripting support — a message such as, "This page would be more interesting if viewed with JavaScript running," for example, or an HTML hyperlink to a page that provides content that would otherwise be inserted by Javascript.

That use of `noscript` has commonly been superseded in recent years by the practice of providing only the non-scripting markup in the HTML, then replacing or enhancing that structure with scripting. Rather than telling visitors that they ought to upgrade their browsers or turn on scripting, we begin with the assumption that they're looking at our pages with a user agent that they need or want to use and give them decent, functional pages; then use scripting to give JavaScript-capable browsers a nicer page. It seems unlikely that there is anyone today using a browser with scripting deliberately turned off, or running behind a corporate firewall that strips out scripting, or using a mobile device with no scripting support, who isn't aware of the additional delights that the internet has to offer with the help of JavaScript. An admonition to upgrade may have been useful advice back in the '90s, but today it seems condescending and redundant.

Listing 4-1 is an example of presenting different content to scriptable and non-scriptable browsers. The HTML includes a plain paragraph that everyone will see and another inside a `noscript` element that will only be seen by user agents that don't support scripting, have JavaScript turned off, or are running an old JavaScript interpreter that's not DOM-aware. The accompanying JavaScript inserts another paragraph that will only be revealed by user agents with running JavaScript interpreters that are aware of the W3C DOM methods `appendChild()` and `createTextNode()`.

LISTING 4-1

Presenting Different Content for Scriptable and Nonscriptable Browsers

HTML: jsb-04-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Presenting Different Content for Scriptable and
      Nonscriptable Browsers</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-04-01.js"></script>
   </head>
   <body>
      <h1>Presenting Different Content for Scriptable and Nonscriptable
      Browsers</h1>

      <p>This text will be revealed to everyone.</p>

      <noscript>
         <p>Only user agents that don't or can't support W3C DOM
         scripting will reveal this text.</p>
      </noscript>

   </body>
</html>
```

continued

LISTING 4-1 *(continued)*

```
JavaScript: jsb-04-01.js
// initialize when the page has loaded
addEvent(window, 'load', addText);

function addText()
{
      // ensure a DOM-aware user agent
      if (!document.appendChild || !document.createTextNode) return;

   // create a text node
   var oNewText = document.createTextNode("Only DOM-aware user agents ↩
running JavaScript will reveal this text.");

   // create a paragraph
   var oParagraph = document.createElement('p');

   // insert the text into the paragraph
   oParagraph.appendChild(oNewText);

   // insert the paragraph at the end of the document
   document.body.appendChild(oParagraph);
}
```

Hiding scripts (not!)

A common question from beginning JavaScript programmers is how to hide scripts from visitors to a page, perhaps to protect a cherished bit of clever code. The short answer is that this isn't possible. In order to run, client-side JavaScript must be downloaded with the page, and therefore is visible in the browser's source view. The URL for an external linked script can simply be pasted into a browser's address bar.

If you are worried about other scripters stealing your scripts, you could include a copyright notice in your source code. Not only are your scripts visible to the world, but so are a thief's scripts. This way, you can easily see when someone lifts your scripts verbatim. Of course, there's nothing stopping someone from copying your script and deleting the notice of ownership.

The most you can hope for along these lines is to *obfuscate* your code, or make it difficult, time-consuming, and tiresome for a human to read. Obfuscation techniques include removing carriage returns and unnecessary spaces and tabs, using meaningless function and variable names, using variables to hold commonly named objects, using Boolean logic in place of `if` and other syntactical branching, writing self-generating code, using recursion, fragmenting logic sequences into multiple nested function calls, and encoding text in decimal, hexadecimal, or octal expressions. At the end of the day, however, global-replacement, careful reading, and patience can expose the logic of any text-based script. The most productive use of a JavaScript obfuscator is simply to produce a "compressed" copy of a script using as few characters as possible for fast download of enormous scripts. However, even that use is questionable since external scripts are cached by the browser after the first download.

If keeping your source code private is a great concern, consider using another programming language that compiles to machine code. Because of the existence of *disassemblers* that turn machine language back into source code, compiling can be viewed as just another form of obfuscation, but it will certainly reduce the number of people willing to put effort into decoding it.

However, it's nearly impossible to conceal anything significant. Even if they can't read your script, good programmers can look at the way your software behaves and write a fresh script that accomplishes much the same thing. The time you take to try to conceal your script could be spent writing new, exciting code!

We suggest that you consider flipping the paradigm on its head. Instead of attempting to conceal your programming code, flaunt it! Add helpful comments to the source code, publish it on your blog and on programming web sites, and otherwise assist as many people as possible to learn about and use it. (Add a Creative Commons license to encourage people to copy your code and keep it free for public use.) If you gain a reputation as a clever and helpful programmer, people will come to you for more.

Scripting for different browsers

Cross-browser compatibility is a concern for every JavaScript programmer. Even though the most recent browsers are doing a decent job of providing a workable lowest common denominator of scriptability, you will still have to consider a range of JavaScript support, from the most advanced browser to the least. Even the differences between the latest Firefox and the latest Internet Explorer are significant. Planning for compatibility begins with deciding on your goals for various classes of user agent.

Building the foundation beneath the towers

The purpose of most web pages can be boiled down to "delivering particular content." Where one web site differs from another is the specific content being delivered and its "look and feel" — the graphic appearance of the page and the style of the user interface with which visitors request further information.

The principal of progressive enhancement guides us first to deliver the content from the server to the client in HTML markup, without relying on JavaScript for core functionality. A web site should be fully usable and navigable, with all its public content exposed to all user agents, including those that don't support scripting . . . such as search engines! After that, we use JavaScript to enhance the visitor's experience and make it faster, easier, more attractive, or more fun in browsers with JavaScript enabled.

One of the consequences of considering JavaScript last instead of first in the planning process is that we'll often discover that much of a web site's functionality that we might have expected to hand over to JavaScript is instead handled perfectly well by other, more universally supported technologies. We should ask JavaScript to perform only those functions that are outside the reach of core browser functionality such as HTML rendering and CSS styling. For example, navigation links should be marked up as functional hyperlinks regardless of whether JavaScript adds any spice to the mix. Multi-level menus, pop-up dialogs, and roll-over image changes can often be implemented using just HTML and CSS, and therefore work for a broader audience.

Ajax (Asynchronous JavaScript and XML) is an interesting case in point. Often developers and even clients will choose Ajax to deliver content just because it's perceived to be sexy technology, but without pausing to consider whether it's really more useful, faster, or more effective than normal page navigation. Reading content from the server takes a certain amount of time regardless; if all the images on a page are already downloaded and therefore cached, it's only the HTML markup that will be the overhead of reading a new page, and that can be the smallest slice of a page. Navigating to individual pages to reveal different content means that visitors can easily bookmark and share links to

specific chunks of content, which isn't normally true of Ajax-retrieved content. Just because we *can* use JavaScript for a particular purpose doesn't mean we have to or should.

Once the core page or site is planned in detail using server-side technologies and HTML/CSS downloads, we can plot out the remainder of the user interface with JavaScript — the sweet dessert that follows the entrée!

JavaScript can be used to add animation to an otherwise static presentation, replace a navigation link with an Ajax download of additional content, augment a button-click editing process with drag-and-drop, fancify a form, and so on. While adding these nice-to-haves, make sure that all the content you're providing through JavaScript is also accessible without scripting. If you find yourself adding critical content to the site that can only been retrieved using JavaScript, you know that you've gone too far. Step back, add the new content to the core web site, then resume your JavaScript planning.

Choosing your battles

Any public web site can, and ultimately will, be viewed using every sort of user agent in existence. Because the range of JavaScript support is so broad — ranging from Early Primitive to Leading Edge — it can be quite challenging, verging on impossible, to write for every browser that's got a JavaScript interpreter. Part of web development planning can therefore be viewed as 'choosing your battles' or a kind of triage — drawing the line between interpreters you'll support and those you won't, and language features you'll use and those you'll avoid. According to this approach, instead of spending time trying to write script that will run in ancient browsers, simply block them from the playing field and focus your attention on developing code for the modern ones.

If, as we recommend, you've engineered your site so that all the core content and functionality are provided by HTML delivered from the server, you won't have to feel negligent if you prevent legacy browsers from trying to run your script. Relax — everyone will be able to use your site. By limiting the JavaScript interpreters you support to the current crop of modern ones and shutting out the older ones, you can save yourself hours of painstaking development work for a small minority of visitors, a decision that can salvage your deadline, your budget, and your sanity.

For example, most of the scripts in this book begin with the simple if-test

```
if (!document.getElementById) return;
```

In other words, "if the JavaScript interpreter running in this browser does not know about the `getElementById` method of the `document` object, stop running this script." This one statement shuts out interpreters that are too old to know about modern Document Object Model methods, allowing you to write most of your code for a single audience. At the other end of the spectrum, you may wish to avoid, for now, using leading-edge JavaScript syntax such as E4X that will stop most current browsers cold in their tracks. The middle ground — ECMAScript 3- and W3C DOM2-aware browsers — constitutes the vast majority in use today, and presents a very comfortable compromise with relatively consistent language support.

In planning your application or web site, it makes far more sense to deliver a single stream of content that can be viewed through all user agents rather than duplicating content in different modes. The latter approach was sometimes used in years past, for a site using frames and a parallel no-frames version, for example. In case you have a notion of creating an application or site that has multiple paths for viewing the same content, don't forget that maintenance chores lie ahead as the site evolves. Will you have the time, budget, and inclination to keep all paths up to date? Despite whatever good intentions a designer of a new web site may have, in our experience, the likelihood that a site will be maintained properly diminishes rapidly with the complexity of the maintenance task.

That said, providing multiple channels does not necessarily mean a duplication of effort. A site may be marked up to navigate to separate pages to deliver different content, but when scripting is supported the site could deliver the same content using Ajax. Since both apparent channels of content come from the server, we could use Ajax to request the same data stream that each stand-alone page requests. When the data is changed on the server, say, by modifying text in a database, both the stand-alone page and the Ajax content injection change accordingly.

Object detection

The methodology of choice by far for implementing browser version branching is *object detection*. The principle is simple: If an object type exists in the browser's object model, it is safe to execute script statements that work with that object.

One example of object detection that you'll see in a lot of older scripts uses the `images` collection. A script can change the `src` attribute of an image — effectively replacing it with another image read from the server — only if the version of JavaScript running in the browser recognizes images as objects. Object models that implement images always include an array of image objects belonging to the `document` object. The `document.images` array always exists, even with a length of zero when no images are on the page. Therefore, if you wrap the image-swapping statements inside an `if` construction that lets browsers pass only if the `document.images` array exists, older browsers simply skip the statements:

```
function imageSwap(imgName, url)
{
   if (document.images)
   {
      document.images[imgName].src = url;
   }
}
```

Object detection works best when you use it to test for the same object you need to use. It can get you into trouble when you use it to make assumptions about browser version and support for language features other than the one being tested.

For example, Internet Explorer 4 introduced a `document` object array called `document.all`, which is used very frequently in building references to HTML element objects. Netscape Navigator 4, however, did not implement that array; instead, it had a document-level array object called `layers`, which was not implemented in Internet Explorer 4. Unfortunately, many scripters used the existence of these array objects not as prerequisites for addressing those objects, but as determinants for the browser version. They set global variables signifying a minimum version of Internet Explorer 4 if `document.all` existed and Netscape Navigator 4 if `document.layers` existed. This was dangerous because there was no way of knowing whether a future version of a browser might adopt the object of the other browser brand or eliminate a language feature. In fact, when the Mozilla-based Netscape version first arrived, it did indeed remove all the layers stuff, replacing it with W3C standards-based features. Tons of scripts on the web used the existence of `document.layers` to branch to Netscape-friendly code that didn't even use `document.layers`. Thus, visitors using Netscape 6 or 7 found that scripts either broke or didn't work, even though the browsers were more than capable of doing the job.

This is why we recommend object detection, not for browser version sniffing, but for object availability branching, as previously shown for images. Moreover, it is safest to implement object detection only when all major browser brands (and the W3C DOM recommendation) have adopted the object so that behavior is predictable wherever your page loads in the future.

Techniques for object detection include testing for the availability of an object's method. A reference to an object's method returns a value, so such a reference can be used in a conditional statement. For example, the following code fragment demonstrates how a function can receive an argument containing the string ID of an element and convert the string to a valid object reference for three different DOMs:

```
function myFunc(elemID)
{
   var obj;
      if (document.getElementById)
      {
         obj = document.getElementById(elemID);
      }
      else if (document.all)
      {
         obj = document.all(elemID);
      }
      else if (document.layers)
      {
         obj = document.layers[elemID];
      }

      if (obj)
      {
         // statements that work on the object
      }
}
```

With this object detection scheme, it doesn't matter which browser brand, version, or operating system support a particular way of changing an element ID to an object reference. Whichever `document` object property or method is supported by the browser (or the first one, if the browser supports more than one), that is the property or method used to accomplish the conversion. If the browser supports none of them, no further statements execute in this function. Keep in mind, however, that the first approach in this example is sufficient (and recommended) as the technique for obtaining all objects from an ID in modern browsers.

If your script wants to check for the existence of an object's property or method, you may also have to check for the existence of the object beforehand, if that object is not part of all browsers' object models. An attempt to reference a property of a nonexistent object in a conditional expression generates a script error. To prevent the error, you can cascade the conditional tests with the help of the && operator. The following fragment tests for the existence of both the `document.body` object and the `document.body.style` property:

```
if (document.body && document.body.style)
{
   // statements that work on the body's style property
}
```

This is the functional equivalent of:

```
if (document.body)
{
```

```
        if (document.body.style)
        {
           // statements that work on the body's style property
        }
}
```

In both examples, if the test for `document.body` fails, JavaScript bypasses the second test.

One potential "gotcha" in using conditional expressions to test for the existence of an object's property is that if the property exists, but its value is zero or an empty string, the conditional test responds the same as it would if the property did not exist. To work around this potential problem, the conditional expression can examine the data type of the value to ensure that the property genuinely exists. A nonexistent property for an object reports a data type of `undefined`. Use the `typeof` operator (discussed in Chapter 22, "JavaScript Operators") to test for a valid property:

```
if (document.body && typeof document.body.scroll != "undefined")
{
   // statements that work on the body's scroll property
}
```

We wholeheartedly recommend designing your scripts to take advantage of object detection in lieu of branching on particular browser name strings and version numbers. Scriptable features are gradually finding their way into browsers embedded in a wide range of nontraditional computing devices. These browsers may not go by the same names and numbering systems that we know today, yet such browsers may be able to interpret your scripts. By testing for browser functionality, your scripts will likely require less maintenance in the future.

Browser version detection

Years ago, before object detection caught on, the commonplace way to pilot a script through the rocky shoals of language support was *browser sniffing*. As described more fully in Chapter 42, "The Navigator and Other Environment Objects," your scripts can examine the `navigator` object to discover which make and model the current browser claims to be. After examining the browser's purported name and version number, a script can branch to different bits of logic specific to the various browsers available at the time. We don't use this technique any more, chiefly because browsers can and do lie about what they are, because browser version sniffing isn't future-proof, and because it's a hack — it tests for one thing in order to act on another.

Browser sniffing is like letting someone fly a jet because they say they're a pilot. They might not actually be a pilot just because they claim to be, and even if they are, they might have gotten their pilot's license before jets were invented. In contrast, with object detection, you find out if they know how to fly the particular aircraft at hand and you let them fly it only if they can — simple, direct, and foolproof.

Designing for Compatibility

Each new major release of a browser brings compatibility problems for page authors. It's not so much that old scripts break in the new versions (well-written scripts rarely break in new versions). The problems center on the new features that attract designers when the designers

forget to accommodate visitors who have not yet advanced to the latest and greatest browser version or who don't share your browser brand preference.

Catering only to the lowest common denominator can more than double your development time, due to the expanded testing matrix necessary to ensure a good working page in all operating systems and on all versions. Decide how important the scripted functionality you employ in a page is for every user. If you want some functionality that works only in a later browser, you may have to be a bit autocratic in defining the minimum browser for scripted access to your page; any lesser browser gets shunted to a simpler presentation of your site's data.

Another possibility is to make a portion of the site accessible to most, if not all, browsers, and restrict the scripting to the occasional enhancement that non-scriptable browser users won't miss. When the application reaches a certain point in the navigation flow, the user needs a more capable browser to get to the really good stuff. This kind of design is a carefully planned strategy that lets the site welcome all users up to a point, but then enables the application to shine for users of, say, W3C DOM–compatible browsers.

The ideal page is one that displays useful content in any browser but whose scripting enhances the experience of the page visitor — perhaps by offering more efficient site navigation or interactivity with the page's content. That is certainly a worthy goal to aspire to. But even if you can achieve this ideal on only some pages, you will reduce the need for defining entirely separate, difficult-to-maintain paths for browsers of varying capabilities.

Regardless of your specific browser compatibility strategy, the good news is that time tends to minimize the problem. Web standards have solidified greatly in the past few years, and browser vendors have made significant strides toward fully supporting those standards.

Dealing with beta browsers

If you have crafted a skillfully scripted web page or site, you may be concerned when a prerelease (or *beta*) version of a browser available to the public causes script errors or other compatibility problems to appear on your page. Do yourself a favor: Don't overreact to bugs and errors that occur in prerelease browser versions. If your code is well written, it should work with any new generation of browser. If the code doesn't work correctly, consider the browser to be buggy. Report the bug (preferably with a simplified test-case script sample) to the browser maker.

One exception to the "it's a beta bug" rule arose in the transition from Netscape Navigator 4 to the Mozilla engine (first released as Netscape Navigator 6). A conscious effort to eliminate a proprietary Netscape Navigator 4 feature (the `<layer>` tag and corresponding scriptable object) caused many Netscape Navigator 4 scripts to break on Moz1 betas (and final release). Had scripters reported the problem to the new browsers' developer (Mozilla), they would have learned about the policy change and planned for the new implementation. It is extremely rare for a browser to eliminate a popular feature so quickly, but it can happen. Stronger web standards have probably minimized the chances of this situation happening again any time soon.

It is often difficult to prevent yourself from getting caught up in a browser maker's enthusiasm for a new release. But remember that a prerelease version is not a shipping version. Users who visit your page with prerelease browsers should know that there may be bugs in the browser. That your code does not work with a prerelease version is not a sin; neither is it worth losing sleep over. Just be sure to connect with the browser's maker either to find out whether the problem will continue in the final release or to report the bug so that the problem doesn't make it into the release version.

Compatibility ratings in reference chapters

With the proliferation of scriptable browser versions since Navigator 2, it is important to know up front whether a particular language or object model, property, method, or event handler is supported in the lowest common denominator for which you are designing. Therefore, in this book, we include frequent compatibility ratings, such as the following example:

Compatibility: WinIE5+, MacIE5+, NN4+, Moz+, Safari+, Opera+, Chrome+

A plus sign after a browser version number means that the language feature was first implemented in the numbered version and continues to be supported in succeeding versions. A minus sign means that the feature is not supported in that browser. The browsers tested for compatibility include Internet Explorer for Windows and Macintosh, Netscape Navigator, Mozilla (including all browsers based on the Mozilla engine), Apple Safari, Opera, and Google Chrome. We also recommend that you print the JavaScript and Browser Object Quick Reference file shown in Appendix A. The file is on the companion CD-ROM in PDF format. This quick reference clearly shows each object's properties, methods, and event handlers, along with keys to the browser version in which each language item is supported. You should find the printout to be valuable as a day-to-day resource.

This is a great place to clarify what we mean by "all browsers based on the Mozilla engine." Once upon a time, *Mozilla* pretty much meant *Netscape*, but those days are long gone. Now there are several viable Mozilla-based browsers that fall under the Moz+ designation in the compatibility charts throughout this book, including Netscape, Firefox, Camino, SeaMonkey, Flock, and others.

Here we're using "Mozilla" to refer to the Gecko (née NGLayout) layout engine. The numbering systems of the individual browser brands are not synchronized to the underlying Mozilla engine versions, making it difficult to know exactly which browser supports what feature. The following table shows which individual browser brands and versions correspond to the Mozilla engine numbering system:

Mozilla	Netscape	Firefox	Camino
m18	6.0		
0.9.2	6.1		
0.9.4	6.2		
1.0.1	7.0		
1.2b		0.1	
1.3a		0.5	
1.4	7.1		
1.5		0.7	
1.7		1.0	
1.7.2	7.2		
1.7.5	8.0–8.1		
1.8		1.5	1.0
1.8.1	9.0	2.0	1.6.5

Mozilla	Netscape	Firefox	Camino
1.9		3.0	2.0
1.9.1		3.5	
1.9.2		3.6	
1.9.3		3.7	
2.0		4.0	

As you can see, Netscape 6.0 and 6.2 were based on Mozilla versions of less than 1. It is rare to see either of these versions "in the wild" these days. The focus, therefore, is on Moz1 and later. Thus, the compatibility charts use Moz1 as the baseline feature set.

In summary, when you see Moz+ in the compatibility charts, it ultimately resolves to Netscape 7 or later, Firefox 1 or later, and Camino 1 or later, to name the most popular Mozilla-based browsers currently in use.

Language Essentials for Experienced Programmers

In this section, experienced programmers can read the highlights about the core JavaScript language in terms that may not make complete sense to those with limited or no scripting experience. Here, then, is the quick tour of the essential issues surrounding the core JavaScript language:

- **JavaScript is a scripting language.** The language is intended for use in an existing *host environment* (for example, a web browser) that exposes objects whose properties and behaviors are controllable via statements written in the language. Scripts execute within the context of the host environment. The host environment controls which, if any, external environmental objects may be addressed by language statements running in the host environment. For security and privacy reasons, web browsers generally afford little or no direct access through JavaScript to browser preferences, the operating system, or other programs beyond the scope of the browser. The exception to this rule is that modern browsers allow deeper client access (with the user's permission) through trust mechanisms such as signed scripts (Mozilla) or trusted ActiveX controls (Microsoft).
- **JavaScript is object based.** Although JavaScript exhibits many syntactic parallels with the Java language, JavaScript is not as pervasively object-oriented as Java. The core language includes several built-in static objects from which working objects are generated. Objects are created through a call to a constructor function for any of the built-in objects plus the `new` operator. For example, the following expression generates a `String` object and returns a reference to that object:

  ```
  new String("Hello");
  ```

  Table 4-1 lists the built-in objects with which scripters come into contact.

TABLE 4-1

JavaScript Built-In Objects

Core Objects	Error Objects	XML Objects	JSON Object
Array[1]	Error[2]	Namespace[4]	JSON[5]
Boolean	EvalError[2]	QName[4]	
Date	RangeError[2]	XML[4]	
Function[1]	ReferenceError[2]	XMLList[4]	
Global	SyntaxError[2]		
Math	TypeError[2]		
Number[1]	URIError[2]		
Object[1]			
RegExp[3]			
String[1]			

[1]Although defined in ECMA Level 1, was first available in NN3 and IE3/J2.
[2]Defined in ECMA Level 3; implemented in Moz1.
[3]Defined in ECMA Level 3; implemented fully in NN4 and IE6.
[4]Defined in E4X; implemented in Mozilla 1.8.1 (Firefox 2.0).
[5]Defined in ECMA Level 5; implemented in Mozilla 1.9.1 (Firefox 3.5).

- **JavaScript is loosely typed.** Variables, arrays, and function return values are not defined to be of any particular data type. In fact, an initialized variable can hold different data type values in subsequent script statements (obviously not good practice but possible nonetheless). Similarly, an array may contain values of multiple types. The range of built-in data types is intentionally limited:
  - Boolean (`true` or `false`)
  - Null
  - Number (double-precision 64-bit format IEEE 734 value)
  - Object (encompassing the `Array` object)
  - String
  - Undefined
  - XML (in E4X)
- **The host environment defines global scope.** Web browsers traditionally define a browser window or frame to be the global context for script statements. When a document unloads, all global variables defined by that document are destroyed.
- **JavaScript variables have either global or local scope.** A global variable is initialized in `var` statements outside of all functions. In a web browser, it typically executes as the document loads. All statements in that document can read or write that global variable. A local variable is also initialized with the `var` operator but inside a function. Only statements inside that function may access that local variable.

- **Scripts sometimes access JavaScript static object properties and methods.** Some static objects encourage direct access to their properties or methods. For example, all properties of the `Math` object act as constant values (for example, `Math.PI`).
- **You can add properties or methods to working objects at will.** To add a property to an object, simply assign a value of any type to it. For example, to add an `author` property to a string object named `myText`, use:

  ```
  myText.author = "Jane";
  ```

  Assign a function reference to an object property to give that object a new method:

  ```
  // function definition
  function doSpecial(arg1)
  {
     // statements
  }
  // assign function reference to method name
  myObj.handleSpecial = doSpecial;
  ...
  // invoke method
  myObj.handleSpecial(argValue);
  ```

  Inside the function definition, the `this` keyword refers to the object that owns the method.
- **JavaScript objects employ prototype-based inheritance.** All object constructors create working objects whose properties and methods inherit the properties and methods defined for the *prototype* of that object. Scripts can add and delete custom properties and methods associated with the static object's prototype so that new working objects inherit the current state of the prototype. Scripts can freely override prototype property values or assign different functions to prototype methods in a working object without affecting the static object prototype. But if inherited properties or methods are not modified in the current working object, any changes to the static object's prototype are reflected in the working object. (The mechanism is that a reference to an object's property works its way up the prototype inheritance chain to find a match to the property name.)
- **JavaScript includes a large set of operators.** You can find most operators that you are accustomed to working with in other languages.
- **JavaScript provides typical control structures.** All versions of JavaScript offer `if`, `if...else`, `for`, and `while` constructions. JavaScript 1.2 (NN4+, IE4+, and all modern mainstream browsers) added `do while` and `switch` constructions. Iteration constructions provide `break` and `continue` statements to modify control structure execution.
- **JavaScript functions may or may not return a value.** There is only one kind of JavaScript function. A value is returned only if the function includes a `return` keyword followed by the value to be returned. Return values can be of any data type.
- **JavaScript functions cannot be overloaded.** A JavaScript function accepts zero or more arguments, regardless of the number of parameter variables defined for the function. All arguments are automatically assigned to the `arguments` array, which is a property of a function object. Parameter variable data types are not predefined.
- **Values are passed by reference and by value.** An object passed to a function is actually a reference to that object, offering full read/write access to properties and methods of that object. But other types of values (including object properties) are passed by value, with no reference

chain to the original object. Thus, the following nonsense fragment empties the text box when the `onchange` event fires:

```
function emptyMe(arg1)
{
   arg1.value = "";
}
...
<input type="text" value="Howdy" onchange="emptyMe(this)">
```

But in the following version, nothing happens to the text box:

```
function emptyMe(arg1)
{
   arg1 = "";
}
...
<input type="text" value="Howdy" onchange="emptyMe(this.value)">
```

The local variable (`arg1`) simply changes from `"Howdy"` to an empty string.

Note

The property assignment event handling technique in the previous example is a deliberate simplification to make the example very brief. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." ■

- **Error trapping techniques depend on JavaScript version.** There was no error trapping in NN2 or IE3. Error trapping in NN3, NN4, and IE4 was event-driven in the web browser object model. JavaScript, as implemented in IE5+ and Mozilla, Safari, and other recent browsers, supports `try-catch` and `throw` statements, as well as built-in error objects that are not dependent on the host environment.
- **Memory management is not under script control.** The host environment manages memory allocation, including garbage collection. Different browsers may handle memory in different ways.
- **Whitespace (other than a line terminator) is insignificant.** Space and tab characters may separate lexical units (for example, keywords, identifiers, and so on).
- **A line terminator is usually treated as a statement delimiter.** Except in very rare constructions, JavaScript parsers automatically insert the semicolon statement delimiter whenever they encounter one or more line terminators (for example, carriage returns or line feeds). A semicolon delimiter is required between two statements on the same physical line of source code. Moreover, string literals may not have carriage returns in their source code (but an escaped newline character (`\n`) may be part of the string).

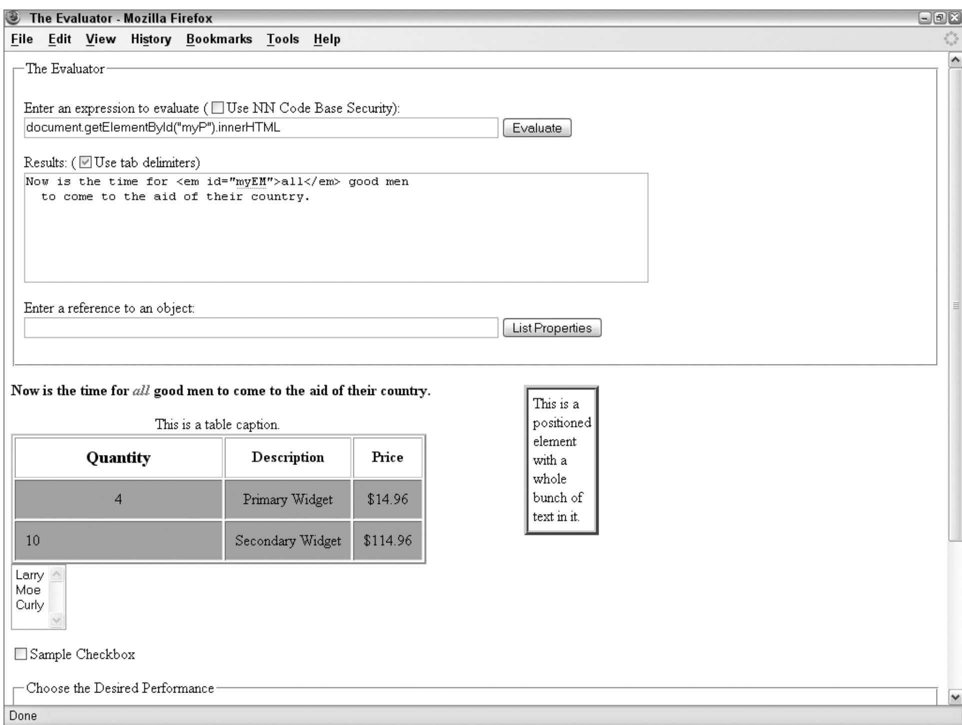
The Evaluator Sr.

The Evaluator Sr. is a tool you can use in succeeding chapters to help you learn both core JavaScript and DOM terminology. The Evaluator provides an interactive workbench to experiment with expression evaluation and object inspection. (In Chapter 8, "Programming Fundamentals, Part I," we will introduce a slimmed-down version we call The Evaluator Jr.)

Figure 4-1 shows the top part of the page. Two important features differentiate this full version from the Jr. version in Chapter 8.

FIGURE 4-1

The Evaluator Sr.



First, you can try some Mozilla secure features if you have Code Base Principles turned on for your browser (see Chapter 49, "Security and Netscape Signed Scripts," on the CD-ROM) and you check the Use Code Base Security check box (Netscape Navigator 4 or later/Moz only). Second, the page has several HTML elements preinstalled, which you can use to explore DOM properties and methods. As with the smaller version, a set of 26 one-letter global variables (`a` through `z`) are initialized and ready for you to assign values for extended evaluation sequences.

Copy the `evaluator.html` and `evaluator.js` files from the companion CD-ROM to a local hard disk and set a bookmark for it in all your test browsers. Feel free to add your own elements to the bottom of the page to explore other objects. We describe a version of The Evaluator for embedding in your projects as a debugging tool in Chapter 48, "Debugging Scripts" (on the CD-ROM), where you can learn more built-in functionality of The Evaluator.

Your First JavaScript Script

IN THIS CHAPTER

Creating a simple application consisting of an HTML page, a JavaScript script, and a CSS style sheet

In this chapter, you write a simple script, the results of which you can see in your JavaScript-compatible browser.

Two common ways of teaching spoken human languages are a) grammar lessons leading to eventual conversation and b) immersion in conversation leading to eventual grammar lessons.

We like b). It's more fun (play enhances learning), you get to see results right away, and it more closely resembles the way we each learned our own native tongue. The grammar's always there to refer to, but let's kick things off to a good start by plunging in and making a little magic happen on the screen.

Don't worry about memorizing every command and detail of syntax discussed in this chapter. Instead, relax and watch how the HTML markup and JavaScript statements become what you see in the browser. The details will soak in more quickly if you're enjoying yourself.

We'll explain each line of code as we go along, although all the methods we use in this first tutorial will be explained in much greater detail later in the book. For now, just enter the scripts as presented and see that they do what they're supposed to do.

What Your First Script Will Do

Our first tutorial script will insert the current date and time into a web page. (This is a further evolution of the "Hello, World" script we showed you in Chapter 3, "Selecting and Using Your Tools.") First, we'll create an HTML page that simply displays static content; then we'll add JavaScript to make it dynamic; and then we'll add styling to jazz it up.

It's worth noting that this sequence — building HTML structure and then adding dynamic JavaScript and CSS for presentation — is not useful merely when learning; it's also a very decent model for everyday, real-world web site production. It's part of a larger sequence of development that might

include information design, graphic design, wireframe and proof-of-concept, HTML markup, server-side scripting, CSS styling, and JavaScript. Although it might be tempting to jump to the scripting first, that's sort of like spreading the icing before the cake is baked. JavaScript, like CSS, needs to know its context — the structure of the page in which it's operating. Also, working in this sequence encourages us to adhere to the principle of progressive enhancement, whereby everyone can get something out of the fundamental page, but those with user agents (such as browsers) with more capabilities can get even more out of it. By starting with the HTML page, we ensure that it's complete and makes sense even without JavaScript.

These days most serious web production includes a server-side scripting language and database, such as PHP and MySQL, to provide the fundamental dynamic content as HTML markup. As server-side scripting is outside the realm of this book, we'll mention it from time to time, but we will otherwise assume a truly static HTML page.

Entering Your First Script

Launch your text editor and browser. You may also want to launch your standard file manager utility to monitor the files that you'll be creating in a folder on your computer.

We'll be working offline throughout this book. All operations will happen locally on your computer and without Internet connectivity. If your browser offers to dial your Internet service provider (ISP) or begins dialing automatically, you can cancel or quit the dialing operation. If the browser's Stop button is active, you can click it to halt any network searching it may try to do. You may receive a dialog-box message or page indicating that the URL for your browser's home page (usually the home page of the browser's publisher — unless you've changed the settings) is unavailable. That's fine. You want the browser open, but you don't need to be connected to your ISP. If you're automatically connected to the Internet through a local area network in your office or school, or through cable modem or DSL, that's also fine. However, you don't need the network connection for now.

Step 1: The HTML document

Figure 5-1 shows our first goal: a simple page with a headline and a paragraph of text. This is what our initial page will look like, allowing for differences in the way various browsers present content by default (in other words, that hasn't yet been styled by us).

Enter the following HTML markup into a new text file and save it (with UTF-8 character encoding) with the name `date-time.html`:

LISTING 5-1

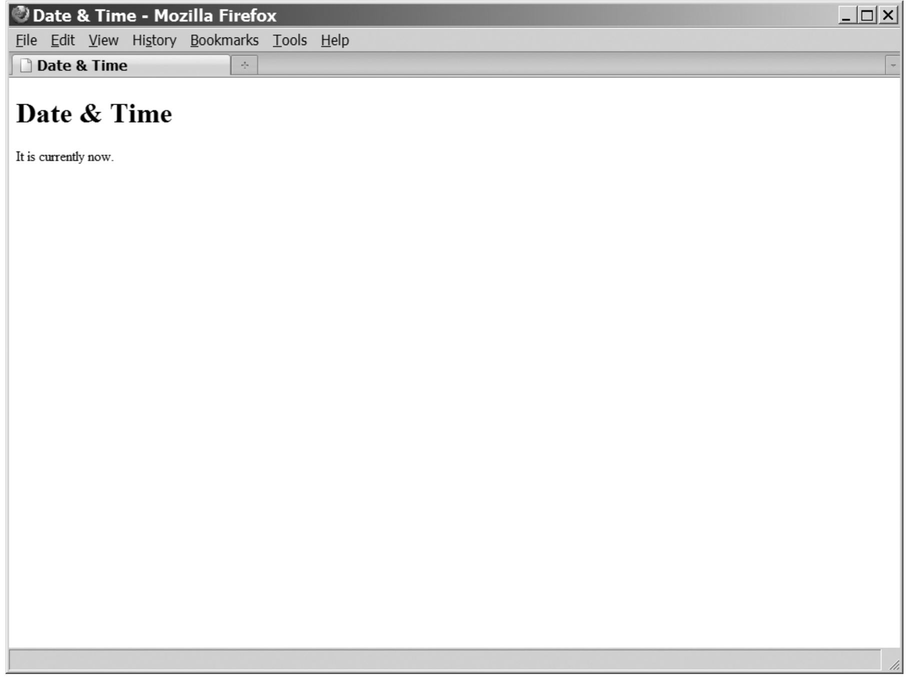
HTML Markup for "Date & Time": date-time.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Date &amp; Time</title>
   </head>
```

```
   <body>
      <h1>Date &amp; Time</h1>
      <p>It is currently <span id="output">now</span>.</p>
   </body>
</html>
```

FIGURE 5-1

Step 1: Static HTML page.



Note

Throughout this book, we will consistently use UTF-8 character encoding for our HTML files. A character encoding tells the browser how to display text characters, and the Unicode standard of UTF-8 is a splendid system that enables us to include virtually any world language in our HTML files. It will serve you well in your web site production.

From the start, get into the habit of saving your files with UTF-8 encoding. Many text editors enable you to choose the encoding in the Save As... dialog, as well as set the default encoding for future files so that you don't have to specify it each time. If your text editor doesn't give you this option, keep using it for now, but start looking around for another editor that will. ■

Now open the document in your browser. You can do this by double-clicking on the file in the file manager screen or by choosing Open or Open File in the File menu of your browser.

If you typed all lines as shown, the document in the browser window should look like the one in Figure 5-1 (with minor differences for your computer's operating system and browser version).

Let's examine the details of the document so that you understand some of the finer points of what the markup is doing.

DOCTYPE

```
<!DOCTYPE html>
```

The DOCTYPE tells the browser how to render the document. Which DOCTYPE you use greatly affects CSS styling and markup validation. The DOCTYPE we're using in this book is the one for HTML5, but you can replace it with either the DOCTYPE for HTML 4.01-Strict for validation purposes:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD HTML 4.01//EN"
   "http://www.w3.org/TR/html4/strict.dtd">
```

or with the one for XHTML 1.0-Strict (along with a few other changes in markup style):

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Strict//EN"
   "http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd">
```

Note

XHTML style, if you intend to follow its conventions, requires all lowercase tags and attribute names. While the listings in this book are HTML, which accepts either upper- or lowercase tags and attributes, we will use lowercase consistently in order to remain compatible with both standards.

XHTML also requires several modifications to the HTML we're using in these examples. For more details on this, see the Introduction. ■

html

The markup continues:

```
<html>
   ...
</html>
```

The entire page will always reside inside the html element, which declares the type of markup. The html element has just two children, head and body.

head

```
<head>
   ...
</head>
```

The head element may contain a variety of child elements that convey information *about* a document but that are not normally rendered as document content. The head must have, at minimum, two children, a meta element defining the character set, and a title:

```
<meta http-equiv="content-type" content="text/html;charset=utf-8">
<title>Date &amp; Time</title>
```

meta tags are a lengthy topic unto themselves. For now, just enter this one exactly as above. HTML5 can accept a shorter version:

```
<meta charset="UTF-8">
```

However, the longer version works for all three markup types (HTML 4.01, HTML5, and XHTML 1.0). Note that the meta tag is "empty" and does not take a closing </meta> tag. All the information it conveys is in its attributes, here http-equiv and content.

title, on the other hand, does require a closing tag; together they surround their content. The title "Date & Time" is entered as Date & Time, using the HTML entity & for the ampersand. There are four characters that must always be converted to HTML entities if they appear in the *content* of the page — attribute values and the text enclosed by tags — in order not to confuse the parsing engine:

```
< &lt;
> &gt;
& &amp;
" &quot;
```

This last one is the straight double quote used in HTML markup, not the curly quotes common in typeset text.

body

```
<body>
   ...
</body>
```

The body element contains the document's content — its structure, text, images, multimedia objects, and so on.

headline

```
<h1>Date &amp; Time</h1>
```

We use the headline tags h1 through h6 to create an outline structure in a document. Ordinarily, a document page will have only one h1 to reiterate the page title, with all other headlines, starting with h2, nested beneath.

In the bad old days, people chose headline tags purely for their default appearance. Today, we use them just as you would use the numbers in a nested outline structure, and we control the appearance of all text from the style sheet.

paragraph

```
<p>It is currently <span id="output">now</span>.</p>
```

Finally, this is the paragraph of text where JavaScript will insert the current date and time. The span element has an ID (output) that JavaScript will use to locate it so that our script can replace the contents of the span with the actual date and time.

So, that's the static HTML page. Even after we plug in the JavaScript, anyone looking at the page with a user agent that doesn't support JavaScript (such as a search engine), or that has it turned off, will

see just what we're seeing here. The page isn't terrifically informative in its current state, but at least it isn't broken. For public web sites, scripting should add value to the page rather than be mission critical.

Step 2: Adding JavaScript

Next, let's create the JavaScript for our page. Now is a good time to instill some good JavaScript habits that will be important to you throughout all your scripting ventures. First, JavaScript is case-sensitive. Therefore, you must type every word in your script with the correct uppercase and lowercase letters. When a line of JavaScript doesn't work, look for the wrong case first. Always compare your typed code against the listings printed in this book and against the various vocabulary entries discussed throughout it.

Second, notice that each JavaScript statement ends in a semicolon. These trailing semicolons — which you can think of as periods at the end of sentences — technically are optional in JavaScript, but we strongly recommend that you use them to remove ambiguity from your scripts. If you someday investigate other programming languages such as PHP, Java, or C++, you'll find that those semicolons are required. All the JavaScript listings in this book use semicolons.

Create a second text file in your editor named `date-time.js` and enter the following script:

Note

A JavaScript comment is any text contained between a double forward slash (//) and the end of the current line, or between slash-asterisk (/*) and asterisk-slash (*/). Comments are ignored by the JavaScript interpreter and are added purely to help human readers understand what's going on in the code. Therefore, you don't have to enter the comments exactly as you see here, but we do recommend that you get in the habit of commenting your code. Other programmers and your own future self will appreciate it! ■

LISTING 5-2

JavaScript Code for "Date & Time": date-time.js

```
// tell the browser to run this script when the page has finished loading
window.onload = insertDateTime;

// insert the date & time
function insertDateTime()
{
      // ensure a DOM-aware user agent
      if (!document.getElementById) return;
      if (!document.createTextNode) return;

   // create a date-time object
   var oNow = new Date();

   // get the current date & time as a string
   var sDateTime = oNow.toLocaleString();

   // point to the target element where we want to insert the date & time
   var oTarget = document.getElementById('output');
```

```
      // make sure the target is found
      if (!oTarget) return;

   // delete everything inside the target
   while (oTarget.firstChild)
   {
      oTarget.removeChild(oTarget.firstChild);
   }

   // use the date-time string to create a new text node for the page
   var oNewText = document.createTextNode(sDateTime);

   // insert the new text into the span
   oTarget.appendChild(oNewText);
}
```

To connect this JavaScript file to the HTML file, we need to add a `script` element to the HTML `head`. Bring `date-time.html` back into your text editor and add the line highlighted below:

```
...
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Date &amp; Time</title>
      <script type="text/javascript" src="date-time.js"></script>
   </head>
...
```

The `script` tag identifies the MIME type of the linked JavaScript file and gives its name (and path, in case it's not located in the same folder as the HTML file itself). This causes the browser to read the JavaScript file as it's building the document page. The JavaScript interpreter within the browser validates and compiles the script, and runs it immediately, even before the rest of the HTML document has been read.

Now let's walk through the JavaScript code line by line so that you can see what it's doing.

Triggering the event

Here's a problem: Our script is going to insert the date and time into a paragraph in the page, but the browser reads and runs our JavaScript code before it's had a chance to read the HTML body. The paragraph into which we want to insert the new content won't even exist yet in the browser's memory when the JavaScript starts running.

Our solution is simply to tell JavaScript not to perform the insertion until the document has been fully read into memory. We do this using the `onload` event. Elements of the page — called *objects* in the Document Object Model (DOM) — can be made sensitive to a number of events, such as the click of a mouse or the press of a key. The `onload` event of the `window` object is triggered when the document finishes loading into the browser.

```
// tell the browser to run this script when the page has finished loading
window.onload = insertDateTime;
```

```
// insert the date & time
function insertDateTime()
{
   ...
}
```

In this case, we're telling JavaScript to call the `insertDateTime()` function when the document has finished loading. The date and time insertion routine that depends on the document having loaded is thus deferred until the browser has the target paragraph in memory.

Ensuring a safe environment

Once the document finishes loading into the browser, the `window.onload` event has been triggered, and the `insertDateTime()` function is called, the first thing the script does is to make sure it's being interpreted by a modern browser that speaks the same language:

```
// ensure a DOM-aware user agent
if (!document.getElementById) return;
if (!document.createTextNode) return;
```

`getElementById()` and `createTextNode()` are two DOM methods we're using in this function that some old JavaScript interpreters won't understand. The exclamation mark (`!`) means "not," and `return` tells JavaScript to stop running the current function; so, the first statement means, "If you aren't aware of the `getElementById()` method for the `document` object, exit this function." If we didn't include these safeguards, a legacy browser or its JavaScript interpreter would likely crash when trying to run the code that follows.

A crash can be as minor as the JavaScript interpreter stopping cold (leaving us with a plain HTML page and no JavaScript functionality at all) or as major as the whole browser freezing up and needing to be rebooted. Neither event is welcome. For many pages, we'll be writing JavaScript to perform several tasks, some of which can be executed by legacy browsers and others that can't. We want to guide the browser around the parts it can't handle, so it will run the parts it can. Preventing old JavaScript versions from crashing on the reefs of modern methods is a hallmark of professional piloting.

We subscribe to the principles of *graceful degradation* and *progressive enhancement*, whereby browsers that can't take advantage of particular features are let down gently and allowed to do the best they can. A fundamental courtesy of scripts that interact with the DOM is to turn away legacy JavaScript interpreters that aren't DOM-aware.

The old-school way of checking for old JavaScript interpreters is *browser-sniffing*, which examines the browser type as reported by the `navigator` object. Unfortunately, these claims of identity can't be relied on. What can be trusted is the JavaScript interpreter's own knowledge of which methods it's capable of executing, and that's the principal safety feature we use today.

Generating the date and time

The text we're going to insert into this document is the current date and time (according to the clock in the user's computer). JavaScript makes this easy: we create a `Date` object and use one of its many methods to produce the string:

```
// create a date-time object
var oNow = new Date();
```

```
// get the current date & time as a string
var sDateTime = oNow.toLocaleString();
```

This code sets the variable `oNow` to a new `Date` object. Once we have that, we use its `toLocaleString()` method to output a text string containing something like:

```
Thursday, August 20, 2009 4:16:05 PM
```

We capture the date and time string in variable `sDateTime`, which we'll use in a moment to output to the page.

The beauty of the `toLocaleString()` method is that it outputs the date and time formatted according to the user's settings and in the user's time zone. If two people run this exact same code at the same moment on opposite sides of the earth, they're likely to get two different dates and times expressed in two different formats and in two different languages. You'll learn a lot more about the Date object in the chapters ahead, particularly Chapter 12, "Strings, Math, and Dates," and Chapter 17,
"The Date Object."

Note

In this example script, `oNow` is a `Date` object and `sDateTime` is a text string. One of the zillion flavors of programming style is the so-called *Systems Hungarian notation* in which each variable name begins with an indication of its type — here `o` for object, `s` for string, `i` for integer, and so on. Naming variables like this is purely optional, and for the programmer's own benefit. JavaScript doesn't care what the names are, as long as no keywords or illegal characters are used. JavaScript is a "dynamically typed" language in which the same variable can be set arbitrarily with numeric, string, Boolean, and object reference values. Some programmers like to maintain only one type of value in each variable to help keep the code easy to manage and debug. Using Hungarian notation can make these artificial variable types easier to remember. ■

Finding the target

The next step is to insert the date and time into the document exactly where we want it. To do that, we need to:

1. Refer to the target `span` element.
2. Delete any text already inside the element.
3. Insert new text inside the element.

To refer to the `output span`, the script uses the industry-standard way to refer to any HTML element that has an ID attribute:

```
// point to the target element where we want to insert the date & time
var oTarget = document.getElementById('output');
```

The first statement locates the target element in the HTML page by its ID (`output`) and stores a reference to that object in variable `oTarget`. The HTML specification mandates that every element ID must be unique on the current page. Even if we accidentally use the same ID more than once on the page, the `getElementById()` method returns only the first instance. So, we know that this method will locate just one element (if it's there at all) — in this case, the span we marked up in the HTML:

```
<p>It is currently <span id="output">now</span>.</p>
```

Notice that when we call `getElementById()`, we specify the element's ID (`output`) but not its tag name (`span`). In the HTML markup we could move the attribute `id="output"` from the `span` to any other element within the page, and our script would attempt to operate on that element instead. If you think about it, that's pretty cool. It means that, even though the markup and the script have to agree about the target element's ID, the script can potentially operate regardless of which tags are used in the markup. It's that kind of flexibility that can make for some truly versatile JavaScript functions down the road.

If we omit or misspell the ID in the markup, `getElementById()` will return a null value. To cover our bases, we test for that:

```
// make sure the target is found
if (!oTarget) return;
```

Similarly to the previous if-tests, this one says, "If the variable `oTarget` doesn't exist or has a null value, return from this function." Adding such reality checks to a script will help make it bulletproof. Developing habits like this will really benefit you when you're juggling dozens of elements on a page or working on pages that have been generated by numerous people and processes.

This is an opportunity to warn the user in case something is seriously wrong — for example:

```
if (!oTarget) return alert("Warning: output element not found");
```

However, since in most cases there's really nothing that a typical web site visitor can do about a problem like this, it might be best for the script to stop quietly or find something else to do, such as notify the web master.

Deleting what's there

Our HTML document comes pre-populated with some text we want to replace:

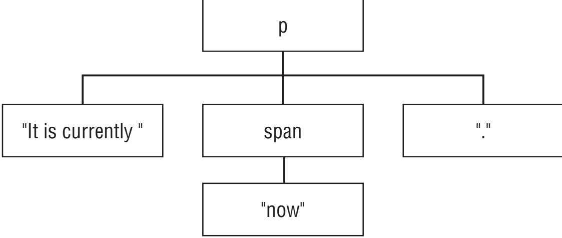
```
<p>It is currently <span id="output">now</span>.</p>
```

We want to delete the text within the `span` and then insert new content. In the DOM that represents the contents of the page, the `span` is the *parent* of everything within it. Right now there's just a single *child* — the word "now" — but we'd like this script to run successfully even if the HTML is later modified to include other markup within the target element.

Figure 5-2 shows that paragraph from a DOM perspective. The `p` element has three children: two text nodes and the span. The span has just one child: a text node containing the value "now".

FIGURE 5-2

A DOM's-eye view of the date and time paragraph before insertion.



To remove the contents of the span, execute a little loop that deletes child elements one at a time, as long as there are any to delete:

```
// delete everything inside the target
while (oTarget.firstChild)
{
   oTarget.removeChild(oTarget.firstChild);
}
```

Given our current markup, this loop will execute just once. A `while` loop will repeat as long as the expression inside the parentheses tests true. When it begins, the property `oTarget.firstChild` is evaluated: Does the object `oTarget` have a first child node? The answer is yes (`true`) because the text node "now" is there. Inside the loop, the `removeChild()` method deletes that first child. Then JavaScript loops and asks the same question again: Does `oTarget.firstChild` exist? The answer is no (`false`), so JavaScript stops processing the `while` loop and resumes execution after the closing brace.

Inserting the date and time

Finally, we create a new node in the DOM that contains the text we want, and insert that into the `span`:

```
   // use the date-time string to create a new text node for the page
   var oNewText = document.createTextNode(sDateTime);

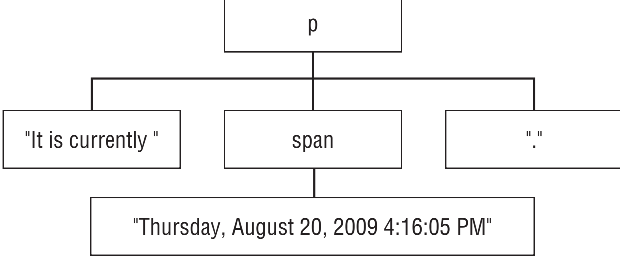
   // insert the new text into the span
   oTarget.appendChild(oNewText);
```

`sDateTime` is the string we generated from the `Date` object a few statements before. We call a method attached to the `document` object that creates a new text node with the date and time string as its value. At this point, the text node isn't yet part of the visible document content; it's waiting in the wings. We bring it on stage using the target element's `appendChild()` method.

The paragraph structure now looks like that shown in Figure 5-3. It's the same structural shape, but the `span` now has a new child.

FIGURE 5-3

The date and time paragraph after insertion.



Debugging

When you've saved the JavaScript file and the HTML file with its script tag, you should be able to load the HTML page into your browser and see the word "now" replaced by the current date and time.

If you can't, take the time now to track down the problem and fix it. In the process, you'll learn important details about JavaScript that will help your future coding go faster and more smoothly.

Proofread the HTML markup and JavaScript code to make sure that they match the preceding listings. The two critical points in the markup will be the `script` tag and its attributes that point to the JavaScript file, and the `span` tag and its ID that JavaScript will look for. In the JavaScript file, make sure that every statement is spelled accurately, including spaces, punctuation, and upper- and lowercase letters.

If you are unsure about the HTML, it's always a good idea to validate it in the W3C HTML Validator, available at `http://validator.w3.org/`. Select either Validate by File Upload to upload the HTML file from your computer or Validate by Direct Input to copy and paste the HTML markup from your text editor into the Validator. At this writing, all the examples in this book with an HTML5 `DOCTYPE` will register one warning: `Using experimental feature: HTML5 Conformance Checker`. This is an informational message, not an error. Your goal is to get a green banner at the top of the Validator results page that says, `This document was successfully checked as HTML5!`

Check your browser's error console to see if it's reporting an error. If so, it will likely tell you the position of the error in the script file.

For further steps, see Chapter 48, "Debugging Scripts."

Step 3: Adding style

Finally, to illustrate how a third component of a typical web page ties in, let's add a simple style sheet to the mix. Style sheets tell the browser how the page should appear — everything from the layout to font choices to background colors.

Create a new text file in your editor, enter the following style sheet script, and save it as `date-time.css`:

LISTING 5-3

CSS Code for "Date & Time": date-time.css

```
@charset "utf-8";

*
{
   margin: 0;
   font-family: sans-serif;
}
h1
{
   font-size: 10em;
   color: #DDF;
```

```
}
p
{
   position: absolute;
   top: 2.5em;
   left: 1.5em;
   font-size: 2em;
   font-weight: bold;
   color: #338;
}
#output
{
   font-style: italic;
   color: #C33;
}
```

To link this style sheet to the HTML file, add a `link` element to the HTML `head`. Bring `date-time.html` back into your text editor and add this line:

```
...
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Date &amp; Time</title>
      <link href="date-time.css" rel="stylesheet" type="text/css" media="all">
      <script type="text/javascript" src="date-time.js"></script>
   </head>
...
```

Save the style sheet, save the modified HTML file, and reload the page in your browser. It should look pretty much like Figure 5-4.

Briefly, the style sheet is a list of rendering rules to be applied to the elements of the page. The basic syntax is as follows:

```
selector { property: value; [...] }
```

Our style sheet begins with a character-encoding directive:

```
@charset "utf-8";
```

Note that this matches the character encoding for the HTML file.

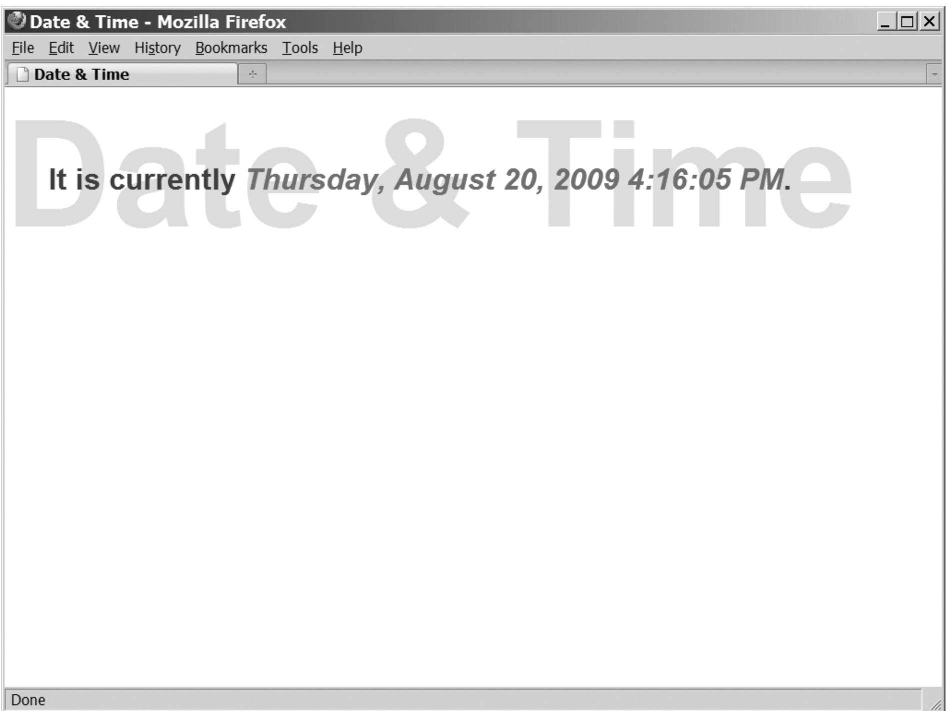
The `*` (wildcard) selector applies to all elements on the page. Here, it zeroes out default margins and sets the font-family for all text.

The `h1` selector sets the headline font size to ten times the base font size (1em = 100% of base) and sets the font color to a pale blue with the RGB (red-green-blue) hexadecimal code of DDF.

The `p` selector applies to all paragraphs on the page (there is only one). The `position`, `top`, and `left` properties allow us to position the paragraph on top of the headline. We set the font weight to bold to make sure it's readable against the pale headline, and the text color to a dark blue with RGB #338.

FIGURE 5-4

Step 3: The styled page.



The `#output` selector applies to the element with an ID of `output`. Here, we change the font-style to italic and the text color to a dark red with RGB #C33. This element also inherits properties from its parent, including the bold font-weight.

To learn more about Cascading Style Sheets (CSS) go to `www.w3.org/Style/CSS/`.

Have Some Fun

Once you get this script working properly, play around with it a bit. Move the `output` ID from one element to another. Change the text that gets inserted. Get comfortable tweaking the markup, the script, and the style sheet to get effects that you want. After each change, save the file and reload the page in your browser to check your progress. Don't be afraid to make mistakes while you're learning. You can always undo a change that goes awry. Remember that play is the best way to learn!

Exercises

1. Perform a single cut-and-paste operation on the HTML markup in Listing 5-1 to cause JavaScript to replace the entire paragraph with the date and time, not just the span. *Hint:* After your edit, the paragraph will still contain text and a `span` element.
2. With the change of markup you've just made, consider the `while` loop in JavaScript Listing 5-2. Write out each step that the loop will take in deleting the contents of the paragraph.
3. Again given the HTML edit you made in Exercise 1, decide which change(s) to the style sheet in Listing 5-3 would be necessary in order to assign the paragraph the same font and color attributes that the span had before.

CHAPTER 6

Browser and Document Objects

In this chapter, you'll see several practical applications of JavaScript and begin to see how a JavaScript-enabled browser turns familiar HTML elements into objects that your scripts control. This tutorial teaches concepts and terminology that apply to modern browsers, with special focus on standards compatibility to equip you to work with today's and tomorrow's browsers. You should study this tutorial in conjunction with any of the following browsers: Internet Explorer 5 or later (Windows or Macintosh), any Mozilla-based browser (Firefox, Netscape 7 or later, or Camino), Apple Safari, or Opera 7 or later.

IN THIS CHAPTER

What client-side scripts do

What happens when a document loads

How the browser creates objects

How scripts refer to objects

What distinguishes one object from another

Scripts Run the Show

If you have authored web pages with HTML, you are familiar with how HTML tags influence the way content is rendered on a page when viewed in the browser. As the page loads, the browser recognizes angle-bracketed tags as formatting instructions. Instructions are read from the top of the document downward, and elements defined in the HTML document appear on-screen in the same order in which they appear in the document's source code. As an author, you do a little work one time and up front — adding the tags to text content — and the browser does a lot more work every time a visitor loads the page into a browser.

Assume for a moment that one of the elements on the page is a text input field inside a form. The user is supposed to enter some text in the text field and then click the Submit button to send that information back to the web server. If that information must be an Internet email address, how do you ensure the user includes the @ symbol in the address?

One way is to have a program running on the web server — such as one written in PHP, ASP, ColdFusion, or a Common Gateway Interface (CGI) language, such as Perl — inspect the submitted form data after the user clicks the Submit button and the form information is transferred to the server. If the user omits or forgets the @ symbol, the server-side program sends the page back to the browser — but this time with an instruction to include the symbol in the

address. Nothing is wrong with this exchange, but it can mean a slight delay for the user in finding out that the address does not contain the crucial symbol. Moreover, the web server has to expend some of its resources to perform the validation and communicate back to the visitor. If the web site is a busy one, the server may try to perform hundreds of these validations at any given moment, probably slowing the response time to the user even more.

Now imagine that the document containing that text input field has some intelligence built into it that makes sure the text-field entry contains the @ symbol before ever submitting one bit (literally!) of data to the server. That kind of intelligence would have to be embedded in the document in some fashion — downloaded with the page's content so it can stand ready to jump into action when called upon. The browser must know how to run that embedded program. Some user action must start the program, perhaps when the user clicks the Submit button. If the program runs inside the browser and detects the lack of the @ symbol, an alert message should appear, to bring the problem to the user's attention. The same program should also be capable of deciding whether the actual submission can proceed or whether it should wait until a valid email address is entered in the field.

This kind of pre-submission data entry validation is but one of the practical ways JavaScript adds intelligence to an HTML document. Considering this example, you might recognize that a script must know how to look into what is typed in a text field; a script must also know how to let a submission continue and how to abort the submission. A browser capable of running JavaScript programs conveniently treats elements such as the text field as *objects*. A JavaScript script controls the action and behavior of objects, most of which you see onscreen in the browser window.

When to Use JavaScript

With so many web-oriented development tools and languages at your disposal, you should focus your client-side JavaScript efforts on tasks for which they are best suited. When faced with a web application task, we look to client-side JavaScript for help with the following requirements:

- **Data entry validation.** If form fields need to be filled out for processing on the server, we let client-side scripts prequalify the data entered by the user.
- **Serverless CGIs.** We use this term to describe processes that, were it not for JavaScript, would be programmed as CGIs on the server, yielding slower performance because of the interactivity required between the program and the user. This includes tasks such as small data collection lookup, modification of images, and generation of HTML in other frames and windows based on user input.
- **Dynamic HTML interactivity.** It's one thing to use DHTML's capabilities to position elements precisely on the page; you don't need scripting for that. But if you intend to make the content dance on the page, scripting makes that happen.
- **CGI prototyping.** Sometimes you want a server-side program to be at the root of your application because it reduces the potential incompatibilities among browser brands and versions. It may be easier to create a prototype of the CGI in client-side JavaScript. Use this opportunity to polish the user interface before implementing the application in your server-side script of choice.
- **Offloading a busy server.** If you have a highly-trafficked web site, it may be beneficial to convert frequently-used CGI processes to client-side JavaScript scripts. After a page is downloaded, the server is free to serve other visitors. Not only does this lighten server load, but users also experience quicker response from the application embedded in the page.

- **Adding life to otherwise-dead pages.** HTML by itself is pretty flat. Adding a blinking chunk of text doesn't help much; animated GIF images more often distract from, rather than contribute to, the user experience at your site. But if you can dream up ways to add some interactive zip to your page, it may engage the user and encourage a recommendation to friends or repeat visits.
- **Creating web pages that "think."** If you let your imagination soar, you may develop new, intriguing ways to make your pages appear "smart." For example, in the application Intelligent "Updated" Flags (Chapter 57 on the CD-ROM), you see how (without a server CGI or database) an HTML page can "remember" when a visitor last came to the page. Then, any items that have been updated since the last visit — regardless of the number of updates you've done to the page — are flagged for that visitor. That's the kind of subtle, thinking web page that best displays JavaScript's powers.

Note

Web pages and applications intended for public access should not rely exclusively on JavaScript to supply critical functions. Make sure that your primary data and web site functionality are accessible to visitors who have JavaScript turned off and to user agents that don't interpret JavaScript, such as search engines and mobile devices. Let your scripting enhance the experience for the majority of visitors who have JavaScript-enabled browsers, but don't let your web site be broken for the rest. ■

The Document Object Model

Before you can truly start scripting, you should have a good feel for the kinds of objects you will be scripting. A scriptable browser does a lot of the work of creating software objects that generally represent the visible objects you see in an HTML page in the browser window. Obvious objects include form controls (text boxes and buttons) and images. However, there may be other objects that aren't so obvious by looking at a page, but that make perfect sense when you consider the HTML tags used to generate a page's content — paragraph objects or frames of a frameset, for example.

To help scripts control these objects — and to help authors see some method to the madness of potentially dozens of objects on a page — the browser makers define a *document object model (DOM)*. In this context, a model is the organization of objects on the page.

Evolution of browser DOMs has caused much confusion and consternation among scripters due to a lack of compatibility across succeeding generations and brands of browsers. Fortunately, the DOM world is stabilizing around a formal specification published by the World Wide Web Consortium (W3C). Today's modern browsers continue to support some of the "old ways" of the earliest DOM because so much existing script code on the Web relies on these traditions continuing to work. (You'll see some of these in Chapter 11, "Forms and Form Elements.") But with the vast majority of browsers in use today supporting the basic W3C DOM syntax and terminology, scripters should aim toward standards compliance whenever possible.

HTML structure and the DOM

An important trend in HTML markup is applying markup solely to define the structure of a document and the context of each piece of content in the document. The days of using only HTML tags to influence the *appearance* of a chunk of text are drawing to a close. It is no longer acceptable to enclose a line of text in, say, an `<h1>` tag because you want the line to appear in the text size and weight that browsers automatically apply to text tagged in that way. An `<h1>` element has a special context

within a document's structure: a first-level heading. In today's HTML world, if you wish to display a stand-alone line of text with a particular style, the text would likely be in a simple paragraph (<p>) tag; the precise look of that paragraph would be under the control of a Cascading Style Sheet (CSS) rule. Current practice even frowns upon the application of <b> and <i> tags to assign boldface and italic styles to a span of text. Instead, surround the text with a contextual tag (such as the <em> element to signify emphasis), and define the CSS style you wish applied to any emphasized text in the document.

The result of applying strict structural design to your HTML tagging is a document that has a well-defined *hierarchy* of elements based on their nesting within one another. For example, a well-formed HTML 4.01 document has the following minimum elements:

- Document type declaration
- HTML
  - Head
    - Character encoding
    - Title
  - Body
    - Block-level content

The HTML markup for this empty document might look like this:

```
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.01//EN"
   "http://www.w3.org/TR/html4/strict.dtd">
<html>
   <head>
      <meta http-equiv="Content-Type" content="text/html;
charset=utf-8">
      <title></title>
   </head>
   <body>
      <p></p>
   </body>
</html>
```

Viewed as a family tree in which every child has just one parent, as shown in Figure 6-1, an HTML document must always have two children, `DOCTYPE` and `html`.

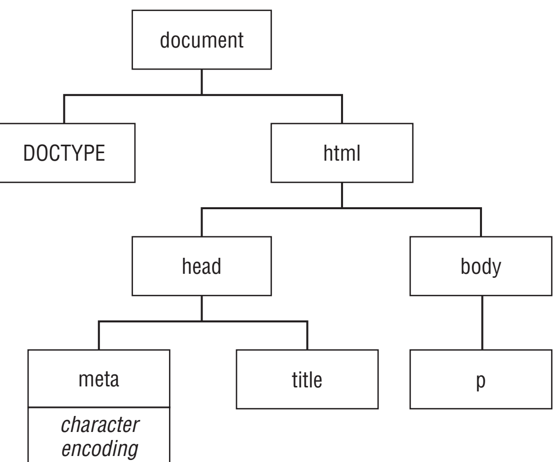
The `DOCTYPE` tells the browser which version of markup is being used, critical information for markup validation and the interpretation of style sheet rules. `html` has two required children, `head` and `body`. The `head` must minimally contain a `meta` element that specifies the character encoding and a `title`, and may also contain a variety of other children such as script and style sheet links. Elements in the `head` ordinarily don't appear as objects on the document page, but tell the browser how to configure the document, and can radically affect its appearance and behavior. The `body` contains the text, images, and other elements that we ordinarily think of as being page content; it must minimally contain at least one block-level element such as a headline, paragraph, or division.

Although we're using the much simpler `DOCTYPE` tag for HTML5 in this book,

```
<!DOCTYPE html>
```

FIGURE 6-1

Element hierarchy of an empty HTML 4.01 document.



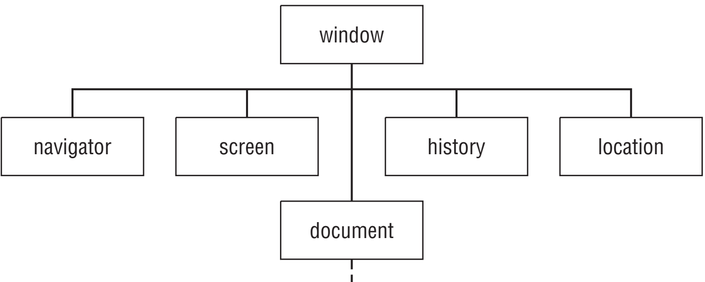
we adhere to the markup requirements for HTML 4.01 so that our HTML markup will validate, to the greatest extent possible, as both HTML 4.01 and HTML5 in order to provide valid examples for whichever branch of markup you choose to pursue.

The DOM in a browser window

As its name implies, the formal DOM focuses primarily on the HTML document and the content nested inside it. From a practical standpoint, however, scripters often need to control the environment that contains the document: the window. The `window` object is the top of the hierarchy that browser scripts work with. The basic structure of the object model in modern browsers (given an empty HTML document) is shown in Figure 6-2.

FIGURE 6-2

Basic object model for all modern browsers.



To give you a sense of the relationships among these top-level objects, the following describes their respective roles:

- `window` **object.** At the very top of the hierarchy is the window. This object represents the content area of the browser window where HTML documents appear. In a multiple-frame environment, each frame is also a window (but don't concern yourself with this just yet). Because all document action takes place inside the window, the window is the outermost element of the object hierarchy. Its physical borders contain the document.
- `navigator` **object.** This is the closest your scripts come to accessing the browser program, primarily to read the browser's claims of brand and version. This object is read-only, protecting the browser from inappropriate manipulation by rogue scripts; however, as you'll see, `navigator` can't be relied on to report the actual make, model, and version of the current browser.
- `screen` **object.** This is another read-only object that lets scripts learn about the physical environment in which the browser is running. For example, this object reveals the numbers of pixels high and wide available in the monitor.
- `history` **object.** Although the browser maintains internal details about its recent history (such as the list available under the Back button), scripts have no access to the details. At most, this object assists a script in simulating a click of the Back or Forward button.
- `location` **object.** This object is the primary avenue to loading a different page into the current window or frame. URL information about the window is available under very controlled circumstances so that scripts cannot track access to other web sites.
- `document` **object.** Each HTML document that gets loaded into a window becomes a `document` object. The `document` object contains the content that you are likely to script. Except for the `html`, `head`, and `body` element objects that are found in every HTML document, the precise makeup and structure of the element object hierarchy of the document depend on the content you put into the document.

When a Document Loads

Programming languages such as JavaScript are convenient intermediaries between your mental image of how a program works and the true inner workings of the computer. Inside the machine, every word of a program code listing influences the transformation and movement of bits (the legendary 1s and 0s of the computer's binary universe) from one RAM storage slot to another. Languages and object models are inside the computer (or, in the case of JavaScript and the DOM, inside the browser's area of the computer) to make it easier for programmers to visualize how a program works and what its results will be. The relationship reminds us of knowing how to drive an automobile from point A to point B without knowing exactly how an internal-combustion engine, steering linkages, and all that other internal "stuff" works. By controlling high-level objects such as the ignition key, gearshift, gas pedal, brake, and steering wheel, we can get the results we need.

Of course, programming is not exactly like driving a car with an automatic transmission. Even scripting requires the equivalent of opening the hood and perhaps knowing how to check the transmission fluid or change the oil. Therefore, now it's time to open the hood and watch what happens to a document's object model as a page loads into the browser.

A simple document

Figure 6-3 shows the HTML and corresponding object model for a document that we'll be adding to in a moment. The figure shows only the `document` object portion; the `window` object and its

other top-level objects (including the `document` object) are always there, even for an empty document. When this page loads, the browser maintains in its memory a map of the objects generated by the HTML tags in the document. The `body` must contain block-level content, but we haven't added that yet.

FIGURE 6-3

Object map of an empty document.

```
<!DOCTYPE ...>
 <html>
  <head>
   <meta ...>
   <title></title>
  </head>
  <body>
   ...
  </body>

Add a paragraph element

Now, we modify the HTML file to include an empty paragraph element and reload the document. Figure 6-4 shows what happens to both the HTML and the object map, as constructed by the browser (changes shown in boldface). Even though no content appears in the paragraph, the `<p>` tags are enough to tell the browser to create that `p` element object. Also note that the `p` element object is contained by the `body` element object in the hierarchy of objects in the current map. In other words, the `p` element object is a *child* of the `body` element object. The object hierarchy matches the HTML tag containment hierarchy.

Add paragraph text

We modify and reload the HTML file again, this time inserting the text of the paragraph between the element's start and end tags, as shown in Figure 6-5. A run of text extending between tags is a special kind of object in the DOM called a *text node*. A text node always has an element acting as its container. Applying the official genealogy metaphor to this structure, this text node is a child of its parent `p` element. We now have a branch of the document object tree that runs several generations: `document` ➪ `html` ➪ `body` ➪ `p` ➪ text node.

Make a new element

The last modification we make to the file is to wrap a portion of the paragraph text in an `<em>` tag to signify emphasis for the enclosed text. This insertion has a large effect on the hierarchy of the `p` element object, as shown in Figure 6-6. The `p` element goes from having a single (text node) child to having three children: two text nodes with an element between them. In the W3C DOM, a text node

cannot have any children and therefore cannot contain an element object. The bit of the text node now inside the `em` element is no longer a child of the `p` element, but a child of the `em` element. That text node is now a grandchild of the `p` element object.

Now that you see how objects are created in memory in response to HTML tags, the next step is to figure out how scripts can communicate with these objects. After all, scripting is mostly about controlling these objects.

FIGURE 6-4

Adding an empty paragraph element.

```
<!DOCTYPE ...>
 <html>
  <head>
   <meta ...>
   <title></title>
  </head>
  <body>
   <p></p>
  </body>
</html>

Adding a text node to the p element object.

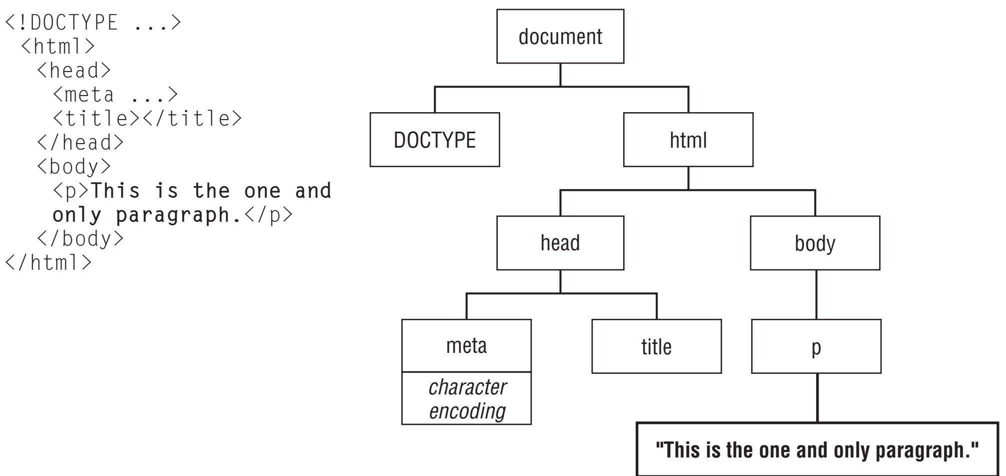

FIGURE 6-6

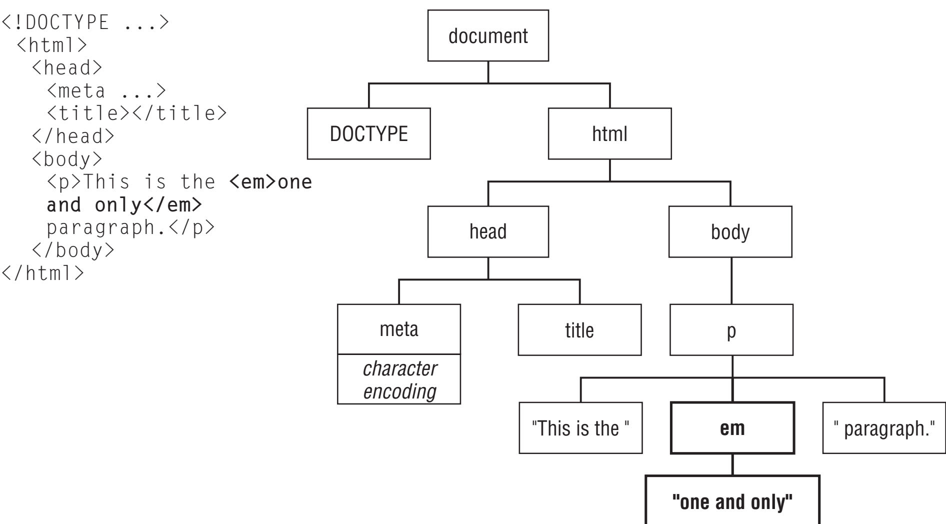
Inserting an element into a text node.



Object References

After a document is loaded into the browser, all of its objects are safely stored in memory in the containment hierarchy structure specified by the browser's DOM. For a script to control one of those objects, there must be a way to communicate with an object and find out something about it (such as "Hey, Mr. Text Field, what did the user type?"). To let your scripts talk to an object, you need a way to refer to that object. That is precisely what an *object reference* in a script does for the browser.

Object naming

The biggest aid in creating script references to objects is assigning a name to every scriptable object in your HTML. In the W3C DOM (and current HTML specification), the way to assign a name to an element is by way of the `id` attribute. This attribute is optional, but if you plan to use scripts to access an element in the page, it is most convenient to assign a name to that element's `id` attribute directly in the HTML code. Here are some examples of `id` attributes added to typical tags:

```
<p id="firstParagraph">

<img id="logo-1" src="images/logo.jpg" alt="Corporate Logo">

<div class="draggable" id="puzzle_piece">
```

The only rules about object IDs (also called *identifiers*) are that they:

- May not contain spaces
- May not contain punctuation except for the underscore, hyphen, period, and colon characters

- Must be inside quotes when assigned to the `id` attribute
- Must not start with a numeric character
- May not occur more than once in the same document

Think of assigning IDs as the same way as sticking name tags on everyone attending a conference meeting. To find a particular conference attendee whose name you know, you could wait at the entrance and scan each name tag until you find the name you're looking for, or you could bump around the attendees at random in the hope that you'll find a known name. But it would be more efficient if you had a way to target an attendee by name immediately — such as broadcasting the name on the public address system to the whole crowd.

Referencing a particular object

The W3C DOM provides that kind of instant access to any named element in the document. Here is the syntax you will use frequently in your browser scripting:

```
window.document.getElementById("elementID")
```

You substitute the ID of the element you wish to reference for `elementID`. For example, if you want to reference the paragraph element whose ID is `firstParagraph`, the reference would be

```
window.document.getElementById("firstParagraph")
```

JavaScript allows us to shorten this by omitting the `window` reference, so we often use this briefer form:

```
document.getElementById("firstParagraph")
```

Be careful! JavaScript is case sensitive. Be sure that you use uppercase for the three uppercase letters in the command and a lowercase *d* at the end, and that you spell the ID itself accurately as well.

The `getElementById()` command belongs to the `document` object, meaning that the entire document's collection of elements is subject to this instantaneous search for a matching ID. The dot — a traditional period character — is the JavaScript way of indicating that the item to the left of the dot (the `document` object here) has the item to the right of the dot (`getElementById()` here) as a resource to call upon whenever needed. Each type of object has a list of such resources, as you'll see in a moment (and as summarized in Appendix A).

id and name Attributes

Prior to the HTML 4.0 specification's introduction of the `id` attribute, scripts could access a handful of elements that also supported the `name` attribute. Elements supporting the `name` attribute are predominantly related to forms, images, and frames. You will see how `name` attributes work in forms in Chapter 11, ''Forms and Form Elements.'' In fact, most browsers still require the `name` attribute for forms and form controls (text fields, buttons, and select lists) for their data to be submitted to a server. It is permissible to assign the same identifier to both the `id` and `name` attributes of an element, and, in fact, in XHTML it is recommended that an `id` and `name` assigned to the same element have the same value. For example:

```
<input type="text" id="firstname" name="firstname" />
```

Node Terminology

W3C DOM terminology uses metaphors to assist programmers in visualizing the containment hierarchy of a document and its content. One concept you should grasp early in your learning is that of a *node;* the other concept is the family relationship among objects in a document.

About nodes

Although the English dictionary contains numerous definitions of *node,* the one that comes closest to its application in the W3C DOM implies a knob or bump on a tree branch. Such nodules on a branch usually lead to one of two things: a leaf or another branch. A leaf is a dead end in that no further branches emanate from the leaf; the branch kind of node leads to a new branch that can itself have further nodes, whether they be leaves or more branches. When you define the structure of an HTML document, you also define a node structure (also called a *node tree*) in which the placement of branches and leaves depends entirely on your HTML elements and text content.

In the W3C DOM, the fundamental building block is a simple, generic node. But inside an HTML document, we work with special kinds of nodes that are tailored to HTML documents. The two types of nodes that scripts touch most often are *element nodes* and *text nodes*. These node types correspond exactly to HTML elements and the text that goes between an element's start and end tags. You've been working with element and text nodes in your HTML authoring, and you may not have even known it.

Look again at the simple document we've just assembled, along with its containment hierarchy diagram in Figure 6-7. All of the boxes representing HTML elements (`html`, `head`, `body`, `p`, and `em`) are element nodes; the three boxes containing the actual text that appears in the rendered document are text nodes. You saw in the transition from one long text node (Figure 6-5) to the insertion of the `em` element (Figure 6-6) that the long text node divided into three pieces. Two text node pieces stayed in the same position in the hierarchy relative to the containing `p` element. We inserted the new `em` element into the tree between the two text nodes and shifted the third text node one level away from the `p` element.

Parents and children

Looking more closely at the p element and its content in Figure 6-7, you can see that element has three child nodes. The first and last are of the text node type, whereas the middle one is an element node. When an element contains multiple child nodes, the sequence of child nodes is entirely dependent upon the HTML source code order. Thus, the first child node of the p element is the text node containing the text "This is the ". The em element has a single child text node as its sole descendant.

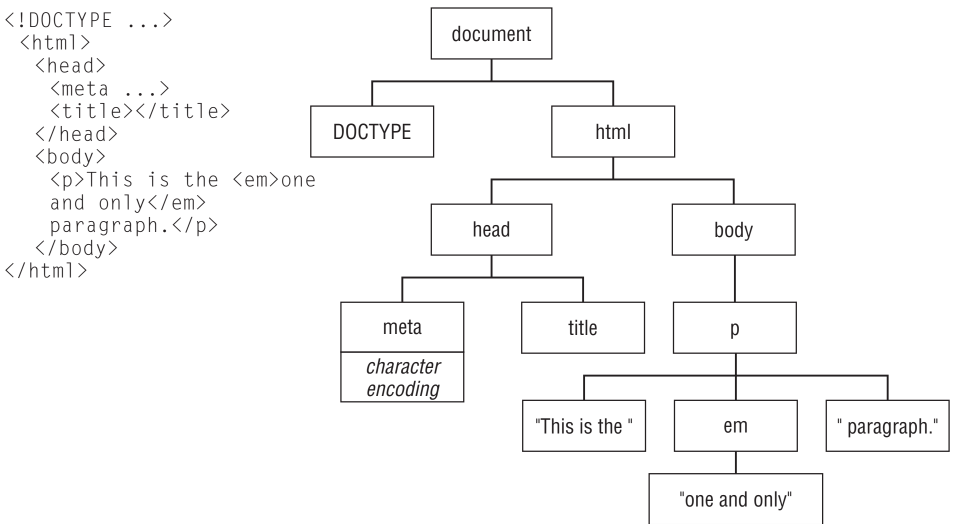
Element node children are not always text nodes; neither do branches always end in text nodes. In Figure 6-7, the `html` element has two child nodes, both of which are element nodes; the `body` element has one child node, the `p` element. A tag in the HTML indicates an element node, whether or not it has any child nodes. By contrast, a text node can never contain another node; it's one of those dead-end leaf type of nodes.

Notice that a child node is always contained by one element node. That container is the *parent* node of its child or children. For example, from the point of view of the `em` element node, it has both one child (a text node) and one parent (the `p` element node). A fair amount of W3C DOM terminology (which you'll meet in Chapter 25, "Document Object Model Essentials") concerns itself with assisting scripts starting at any point in a document hierarchy and obtaining a reference to a related node if necessary. For instance, if a Dynamic HTML script wants to modify the text inside the `em` element

of Figure 6-7, it typically would do so by starting with a reference to the `em` element via the `document.getElementById()` command (assuming that the `em` element has an ID assigned to it) and then modifying the element's child node.

FIGURE 6-7

A simple HTML document node tree.



In case you're wondering, the `document` object at the top of the node tree is itself a node. Its place in the tree is special and is called simply the *document node*. Each loaded HTML document contains a single document node, and that node becomes the scripter's gateway to the rest of the document's nodes. It's no accident that the syntax for referencing an element node — `document.getElementById()` — begins with a reference to the `document` object.

What Defines an Object?

When an HTML tag defines an object in the source code, the browser creates a slot for that object in memory as the page loads. But an object is far more complex internally than, say, a mere number stored in memory. The purpose of an object is to represent some thing. In the browser and its DOM, the most common objects are those that correspond to elements, such as a text input form field, a table element, or the entire rendered body of the document. Outside the pared-down world of the DOM, an object can also represent abstract entities, such as a calendar program's appointment entry or a layer of graphical shapes in a drawing program. It is common for your browser scripts to work with both DOM objects and abstract objects of your own design.

Every type of DOM object is unique in some way, even if two or more objects look identical to you in the browser. Three very important facets of an object define what it is: what it "looks" like, how

it behaves, and how scripts control it. Those three facets are properties, methods, and events (also known as handlers). They will play key roles in your future DOM scripting efforts. The Quick Reference in Appendix A summarizes the properties, methods, and events for each object in the object models implemented in the various browser generations.

Properties

Any physical object you hold in your hand has a collection of characteristics that defines it. A coin, for example, has shape, diameter, thickness, color, weight, embossed images on each side — and any number of other attributes that distinguish it from, say, a feather. Each of those features is called a *property*. Each property has a value of some kind attached to it (even if the value is empty or null). For example, the `shape` property of a coin might be *circle* — in this case, a text value. By contrast, the `denomination` property would most likely be a numeric value.

You may not have known it, but if you've written HTML for use in a scriptable browser, you have set object properties without writing one iota of JavaScript. Tag attributes are the most common way to set an HTML element object's initial properties. For example, the following HTML tag defines an `input` element object that assigns four property values:

```
<input type="button" id="clicker" name="clicker" value="Hit Me...">
```

In JavaScript parlance, then, the `type` property holds the word *button;* the `id` and `name` properties hold the same word, *clicker;* and the `value` property is the text that appears on the button label, *Hit Me* ... . In truth, a button input element has more properties than just these, but you don't have to set every property for every object. Most properties have *default values* that are automatically assigned if nothing special is set in the HTML, or later from a script.

The contents of some properties can change after a document has loaded and the user interacts with the page. Consider the following text input tag:

```
<input type="text" id="donation" name="donation" value="$0.00">
```

The `id` and `name` properties of this object are the same word: `donation`. When the page loads, the text of the `value` attribute setting is placed in the text field — the automatic behavior of an HTML text field when the `value` attribute is specified. But if a user enters some other text into the text field, the `value` property changes — not in the HTML, but in the memory copy of the object model that the browser maintains. Therefore, if a script queries the text field about the content of the `value` property, the browser yields the current setting of the property — which isn't necessarily the one specified by the HTML.

To gain access to an object's property, you use the same kind of dot-notation addressing scheme you saw earlier for objects. A property is a resource belonging to its object, so the reference to it consists of the reference to the object plus one more extension naming the property. Therefore, for the `button` and `text` object tags just shown, references to various properties are

```
document.getElementById("clicker").name
document.getElementById("clicker").value
document.getElementById("entry").value
```

Tip

JavaScript will fail or "abort" if it tries to reference the property of a non-existent element. Therefore, a safer, more bulletproof way of referencing these properties is to first test for the existence of the object:

```
var oClicker = document.getElementById("clicker");
   if (oClicker) var sName = oClicker.name;
```

or

```
var oClicker = document.getElementById("clicker");
   if (!oClicker) return;
var sName = oClicker.name;
```
■

You might wonder what happened to the `window` part of the reference. It turns out that there can be only one document contained in a window, so references to objects inside the document can omit the `window` portion and start the reference with `document`. You cannot omit the `document` object from the reference, however.

Methods

If a property is like a descriptive adjective for an object, a *method* is a verb. A method is all about action related to the object. A method does something either to the object or with the object that affects other parts of a script or document. Methods are commands of a sort whose behaviors are tied to a particular object.

Internet Explorer References

Before the W3C DOM came into existence, Microsoft had created its own way of referencing element objects by way of their `id` attributes. You will find many instances of this syntax in existing code that has been written only for Internet Explorer 4 or later. The syntax uses a construction called `document.all`. Although there are a few different ways to use this construction, the most commonly applied way is to continue the dot notation to include the ID of the element. For example, if a paragraph element's ID is `myParagraph`, the IE-only reference syntax is

```
document.all.myParagraph
```

You can also omit the lead-in parts of the reference and simply refer to the ID of the element:

```
myParagraph
```

Be aware, however, that none of these approaches is supported in the W3C DOM standard. Both the IE-specific and W3C DOM reference syntax styles are implemented in IE5 or later. Also the `document.all.elementId` syntax cannot tolerate some of the valid HTML ID characters, such as hyphen, colon, and period, because JavaScript would interpret them as its own syntax.

Although it's important to be familiar with `document.all` in order to make sense of legacy code, you should stick to W3C DOM methods such as `getElementById()` in your own code to be compatible with forward-looking modern browsers.

Note

Note that the document.all syntax cannot tolerate any hyphens, colons, or periods in the ID. Although these are valid HTML IDs

```
my-paragraph
my.paragraph
my:paragraph
```

the resulting document.all expressions would cause JavaScript to give erroneous results or crash:

```
document.all.my-paragraph
document.all.my.paragraph
document.all.my:paragraph
```

Using the modern standard getElementById() is safer because the ID is always enclosed in quotation marks. ■

An object can have any number of methods associated with it (including none at all). To set a method into motion (usually called *invoking a method*), a JavaScript statement must include a reference to it, via its object, with a pair of parentheses after the method name, as in the following examples:

```
var oForm = document.getElementById("orderForm");
oForm.submit();

var oEntry = document.getElementById("entry");
oEntry.focus();
```

The first is a scripted way of sending a form (named `orderForm`) to a server. The second gives focus to a text field named `entry`.

Sometimes a method requires that you send additional information with it so that it can do its job. Each chunk of information passed with the method is called a *parameter* or *argument* (you can use the terms interchangeably). The `document.getElementById()` method is one that requires a parameter: the identifier of the element object to be addressed for further action. This method's parameter must be in a format consisting of straight text, signified by the quotes around the identifier.

Some methods require more than one parameter. If so, the multiple parameters are separated by commas. For example, modern browsers support a `window` object method that moves the window to a particular *coordinate point* onscreen. A coordinate point is defined by two numbers that indicate the number of pixels from the left and top edges of the screen where the top-left corner of the window should be. To move the browser window to a spot 50 pixels from the left and 100 pixels from the top, the method is

```
window.moveTo(50,100)
```

As you learn more about the details of JavaScript and the document objects you can script, pay close attention to the range of methods defined for each object. They reveal a lot about what an object is capable of doing under script control.

Events

One last characteristic of a DOM object is the *event*. Events are actions that take place in a document, usually as the result of user activity. Common examples of user actions that trigger events include

clicking a button or typing a character in a text field. Some events, such as the act of loading a document into the browser window or experiencing a network error while an image loads, are not so obvious.

Almost every DOM object in a document receives events of one kind or another — summarized for your convenience in the Quick Reference of Appendix A. Your job as scripter is to write the code that tells an element object to perform an action whenever the element receives a particular type of event. The action is simply executing some additional JavaScript code.

A simple way to begin learning about events is to apply one to an HTML element. Listing 4-1 shows a very simple document that displays a single button and a script that applies one event handler to the button. The event's name consists of the type of event (for example, `click`) preceded by the preposition *on* (as in, "on receiving the `click` event ... ": `onclick`).

LISTING 6-1

A Simple Button with an Event Handler

HTML: jsb-06-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>A Simple Button with an Event Handler</title>
      <script type="text/javascript" src="jsb-06-01.js"></script>
   </head>
   <body>
      <form action="">
         <div>
            <button id="clicker">Click me</button>
         </div>
      </form>
   </body>
</html>
```

JavaScript: jsb-06-01.js

```
// tell the browser to run this script when the page has finished loading
window.onload = applyBehavior;

// apply behavior to the button
function applyBehavior()
{
      // ensure a DOM-aware user agent
      if (document.getElementById)
      {
         // point to the button
         var oButton = document.getElementById('clicker');

            // if it exists, apply behavior
            if (oButton)
            {
```

```
                oButton.onclick = behave;
            }
        }
}

// what to do when the button is clicked
function behave(evt)
{
   alert('Ouch!');
}
```

When the browser loads the HTML page, it also loads the linked JavaScript file, compiles it, and begins to execute its instructions. In this case, the only instruction it will actually execute immediately is the `window.onload` statement because all the other statements are inside functions and won't execute until the functions are called by name. Only when the HTML page has finished loading (and when its DOM has been completely built) will our function `applyBehavior()` run. If the JavaScript interpreter that's running is aware of the DOM method `getElementById()`, the function uses it to look up the element with the ID of `clicker`. If found, it applies the onclick behavior to the button, telling it to execute the function `behave()` when clicked. When the user clicks the button, the `behave()` function issues an alert (a popup dialog box) that says, "Ouch!"

Cross-Reference

You will learn about other ways to connect scripting instructions to events in Chapter 25, "Document Object Model Essentials," and Chapter 32, "Event Objects." ■

Exercises

1. Which of the following applications are well suited to client-side JavaScript? Why or why not?
   a. Product catalog page that lets visitors view the product in five different colors
   b. A counter that displays the total number of visitors to the current page
   c. Chat room
   d. Graphical Fahrenheit-to-Celsius temperature calculator
   e. All of the above
   f. None of the above
2. Which of the following element IDs are valid in HTML? For each one that is invalid, explain why.
   a. `lastName`
   b. `company_name`
   c. `1stLineAddress`
   d. `zip code`
   e. `today's_date`
   f. `now:you-hear.this`

3. Using the diagram from Figure 6-7 for reference, draw a diagram of the object model containment hierarchy that the browser would create in its memory for the following HTML. Write the script reference to the first paragraph element using W3C DOM syntax.

```
<!DOCTYPE html>
<html>
<head>
<meta http-equiv="content-type" content="text/html;charset=utf-8">
<title>Search Form</title>
</head>
<body>
<p id="logoPar"><img src="images/logo.jpg" height="90" width="300"
     alt="Logo"></p>
<div id="searchForm">
<form action="cgi-bin/search.pl" method="post">
<div>
<label for="searchText">Search for:</label>
<input type="text" id="searchText" name="searchText">
<input type="submit" value="Search">
</div>
</form>
</div>
</body>
</html>
```

4. Describe at least two characteristics that a text node and an element node have in common; describe at least two characteristics that distinguish a text node from an element node.

5. Write the HTML and JavaScript for a button input element named `Hi`, whose visible label reads `Howdy`, and whose action upon being clicked displays an alert dialog box that says, `Hello to you, too!`

CHAPTER

Scripts and HTML Documents

IN THIS CHAPTER

Where to place scripts in HTML documents

What a JavaScript statement is

What makes a script run

Viewing script errors

Chapter 4, "JavaScript Essentials," covered many of the basics of how to combine JavaScript with HTML documents. This chapter's tutorial reviews how scripts are linked to HTML documents and what comprises a script statement. You also see how script statements can run when the document loads or in response to user action. Finally, you find out where script error information may be hiding.

Connecting Scripts to Documents

We use the `script` element to tell the browser to treat a segment of text as script and not as HTML. Whether our script is an external file linked to the HTML document or embedded directly in the page itself, the `<script>...</script>` tag set encapsulates the script.

Depending on the browser, the `<script>` tag has a variety of attributes you can set that govern the script. One attribute, `type`, advises the browser to treat the code within the tag as JavaScript. Some other browsers accept additional languages (such as Microsoft's VBScript in Windows versions of Internet Explorer). The following setting is one that all modern scriptable browsers accept:

```
<script type="text/javascript" ...>...<script>
```

Be sure to include the ending tag for the script. Your JavaScript program code goes either into an external file specified in the `src` attribute:

```
<script type="text/javascript" src="example.js"><script>
```

or between the two tags:

```
<script  type="text/javascript">
  one or more lines of JavaScript code here
</script>
```

If you forget the closing script tag, the script may not run properly, and the HTML elsewhere in the page may look strange.

The Old language Attribute

Another `<script>` tag attribute, `language`, used to be the way to specify the scripting language for the enclosed code. That attribute allowed scripters to specify the language version. For example, if the scripts included code that required JavaScript syntax available only in version 4 browsers (which implemented JavaScript version 1.2), the `<script>` tag used to be written as follows:

```
<script language="JavaScript1.2">...</script>
```

The `language` attribute was never part of the HTML 4.0 specification and is now falling out of favor. If W3C validation is one of your development concerns, you should be aware that the language attribute does not validate in strict versions of HTML 4.01 or XHTML 1.0. Older browsers that do not know the `type` attribute automatically default to JavaScript anyway. Use only the `type` attribute.

Tag positions

Where do these tags go within a document? The answer is anywhere they're needed in the document. Most of the time, it makes sense to include the tags nested within the `<head>...</head>` tag set; other times, it is essential that you drop the script into a very specific location in the `<body>...</body>` section.

In the following three listings, we demonstrate — with the help of a skeletal HTML document — some of the possibilities of `<script>` tag placement. Later in this lesson, you see why scripts may need to go in different places within a page, depending on the scripting requirements. In each example, we show two `script` tags – one a link to an external script and one for internal embedded scripting – just to show you how they both appear. In practice, it's most likely that you will consistently link only to external scripts.

Listing 7-1 shows the outline of what may be the most common position of a `<script>` tag set in a document: in the `<head>` tag section. Typically, the `head` is a place for tags that influence non-content settings for the page — so-called HTML *directive* elements, such as `<meta>` tags and the document title. It turns out that this is also a convenient place to plant scripts that are called in response to a page load or a user action.

LISTING 7-1

Scripts in the head

```
<html>
   <head>
      <title>A Document</title>
      <script type="text/javascript" src="example.js"></script>
      <script  type="text/javascript">
         //script statement(s) here
         ...
```

```
      </script>
   </head>
   <body>
   </body>
</html>
```

On the other hand, if you need a script to run as the page loads so that the script generates content in the page, the script goes in the `<body>` portion of the document, as shown in Listing 7-2.

LISTING 7-2

A Script in the body

```
<html>
   <head>
      <title>A Document</title>
   </head>
   <body>
      <script type="text/javascript" src="example.js"></script>
      <script  type="text/javascript">
         //script statement(s) here
         ...
      </script>
   </body>
</html>
```

It's also good to know that you can place an unlimited number of `<script>` tag sets in a document. For example, Listing 7-3 shows a script in both the `head` and `body` portions. This document needs the `body` script, perhaps to create some dynamic content as the page loads, but the document also contains a button that needs a script to run later. That script is stored in the `head` portion.

LISTING 7-3

Scripts in the head and body

```
<html>
   <head>
      <title>A Document</title>
      <script type="text/javascript" src="example.js"></script>
      <script  type="text/javascript">
         //script statement(s) here
         ...
      </script>
   </head>
   <body>
      <script type="text/javascript" src="example.js"></script>
```

continued

LISTING 7-3 *(continued)*

```
      <script  type="text/javascript">
         //script statement(s) here
         ...
      </script>
   </body>
</html>
```

Handling non-JavaScript browsers and XHTML

Only browsers that include JavaScript know to interpret the lines of code between the `<script>...</script>` tag pair as script statements rather than HTML text for display in the browser. This means that a pre-JavaScript browser or a simplified browser in a cell phone would not only ignore the tags, but also treat the JavaScript code as page content. The results can be disastrous to a page.

On the other hand, you don't have to worry about non-JavaScript browsers trying to execute externally linked scripts. That's one of the advantages of linking rather than embedding your scripts. The problem only arises when JavaScript code is embedded in the HTML document.

You can reduce the risk of older, non-JavaScript browsers displaying the script lines by enclosing the script lines between HTML comment symbols, as shown in Listing 7-4. Most nonscriptable browsers ignore the content between the `<!--` and `-->` comment tags, whereas scriptable browsers ignore the opening comment symbol when it appears inside a `<script>` tag set.

LISTING 7-4

Hiding Scripts from Most Old Browsers

```
<script  type="text/javascript">
<!--
   //script statement(s) here
   ...
// -->
</script>
```

The odd construction right before the ending script tag needs a brief explanation. The two forward slashes are a JavaScript comment symbol. This symbol is necessary because JavaScript otherwise tries to interpret the components of the ending HTML symbol (`-->`). Therefore, while the forward slashes tell JavaScript to skip the line entirely, a non-scriptable browser simply treats those slash characters as part of the entire HTML comment to be ignored.

Although it's no longer really necessary to hide JavaScript in this way from older browsers, there are instances when a different type of hiding may be required. XML is more frequently being used to feed content to the browser, and often this is done using XHTML. In the XML world, all special characters need to be enclosed in a `CDATA` section, or else the file may be parsed incorrectly; at the very least, it will fail validation. Again, the trick is to enclose your script, but this time it will look like

Listing 7-5. You'll notice again that immediately before the closing script tag the JavaScript comment hides the closing of the CDATA section from JavaScript itself.

LISTING 7-5

Hiding Scripts From XML Parsers

```
<script  type="text/javascript">
<![CDATA[
   //script statement(s) here
   ...
//]]>
</script>
```

Despite the fact that these techniques are often called *script hiding,* they do not conceal the scripts from human readers. All client-side JavaScript scripts are part of, or accompany, the HTML document, and they download to the browser just like all the other assets that make up the page. You can view the JavaScript source as easily as you can view the HTML document source. Do not be fooled into thinking that you can hide your scripts from prying eyes. Some developers *obfuscate* their scripts by removing all carriage returns and using nonsensical variable and function names, but this only slows down (and doesn't stop) any inquisitive visitor from reading and understanding the code.

Since it's not possible to truly hide your JavaScript programming from the public, you might as well flaunt it: sign the scripts you're proud of, include a copyright or Creative Commons notice of authorship in script comments, and encourage people who admire the script to come to you for more.

JavaScript Statements

Virtually every line of code in an externally linked file or that sits within a `<script>...</script>` tag pair is a JavaScript *statement* (except for HTML comment tags). To be compatible with the habits of experienced programmers, JavaScript accepts a semicolon at the end of every statement (the computer equivalent of a period at the end of a sentence). This semicolon is optional, but we strongly recommend that you use it consistently to avoid ambiguity. The carriage return at the end of a statement suffices for JavaScript to know that the statement has ended. It is possible, however, that in the future the semicolon will be required, so it's a good idea to get into the semicolon habit now.

A statement must be in the script for a purpose. Therefore, every statement does something relevant to the script. The kinds of things that statements do are

- Define or initialize a variable
- Assign a value to a property or variable
- Change the value of a property or variable
- Define or invoke an object's method
- Define or invoke a function routine
- Make a decision

If you don't yet know what all of these things mean, don't worry; you will, by the end of this tutorial. The point we want to stress is that each statement contributes to the scripts you write. The only statement that doesn't perform any explicit action is the *comment*. A pair of forward slashes (no space between them) is the most common way to include a single-line comment in a script:

```
// this is a one-line comment

var a = b;   // this comment shares a line with an active statement
```

Multiple-line comments can be enclosed in slash-asterisks:

```
/*
  Any number of lines are comments if they are
  bracketed by slash-asterisks
*/
```

You add comments to a script for the benefit of yourself and other human readers. They usually explain in plain language what a statement or group of statements does. The purpose of including comments is to remind you how your script works six months from now, or to help out another developer who needs to read your code.

When Script Statements Execute

Now that you know where scripts go in a document, it's time to look at when they run. Depending on what you need a script to do, you have four choices for determining when a script runs:

- While a document loads
- Immediately after a document loads
- In response to user action
- When called upon by other script statements

The determining factor is how the script statements are positioned in a document.

While a document loads: immediate execution

Listing 7-5 is a variation of your first script from Chapter 5, "Your First JavaScript Script." In this version, the script writes the current date and time to the page while the page loads. The `document.write()` method is a common way to write dynamic content to the page *during* loading. We call the kinds of statements that run as the page loads *immediate statements*. Care must be taken when you code scripts using `document.write()`. Once the page completes loading, any further `document.write()` statements create a new page, overwriting all the content you have carefully written.

LISTING 7-6

HTML Page with Immediate Script Execution

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Date &amp; Time: Immediate Execution</title>
```

```
  </head>
  <body>
    <h1>Date &amp; Time: Immediate Execution</h1>
    <p>It is currently <span id="output">
    <script type="text/javascript">
      <!-- hide from old browsers
      var oNow = new Date();
      document.write(oNow.toLocaleString());
      // end script hiding -->
    </script>
    </span>.</p>
  </body>
</html>
```

In recent years, the use of `document.write()` has become mildly controversial. At the very least, it encourages bad structure in your document, mixing script with HTML. Good structure cleanly separates style (style sheets) and behavior (JavaScript) from the HTML markup. One issue with `document.write()` centers around the increased use of XML to feed content to the browser. XML documents must be well-formed. If a `document.write()` statement closes an element opened outside of it, or opens a new element, the XML document will fail to load because the browser will perceive it as malformed.

Another issue with `document.write()` centers around the DOM, especially with XHTML documents (which are served as XML). The use of `document.write()` means that the content will not be included in the DOM. The very important short story is that you will not be able to further manipulate such content with your JavaScript programs, limiting your dynamic response to the visitor's actions on your web page. This is an interesting conundrum because you might often choose to use `document.write()`, as we do in several examples in this book, to provide dynamic content, based on the browser environment, as the page loads.

Deferred scripts

The other three ways that script statements run are grouped together into what we call *deferred scripts*. To demonstrate these deferred script situations, we must introduce you briefly to a concept covered in more depth in Chapter 9, "Programming Fundamentals, Part II": the function. A *function* defines a block of script statements summoned to run some time after those statements load into the browser. Functions are clearly visible inside a `<script>` tag because each function definition begins with the word `function` followed by the function name (and parentheses). After a function is loaded into the browser (commonly in the `head` portion so that it loads early), it stands ready to run whenever called upon.

Run after loading

One of the most common times a function is called on to run is immediately after a page loads. Scripts using industry-standard DOM methods would fail if we attempted to operate on page elements before they appeared in the DOM, so we ask the browser to run the script only after the page has finished loading. The `window` object has an event handler property called `onload`. Unlike most event handlers, which are triggered in response to user action (for example, clicking a button), the

window's onload event handler fires the instant that all of the page's components (including images, Java applets, and embedded multimedia) are loaded into the browser.

There are two cross-browser ways to connect the onload event handler to a function: via an object event property or an HTML event attribute. The object event property we prefer is shown in Listing 7-6. The assignment of the event handler is executed in immediate mode and attaches the desired function call to the load event of the window object. At this early point in page rendering, only the window object can be guaranteed to exist in the DOM.

In old-school web development, the window.onload event assignment was written right into the HTML, with the <body> element standing in to represent the window. Therefore, you can include the onload event attribute in the <body> tag, as shown in Listing 7-7. Recall from Chapter 6, "Browser and Document Objects," that an event handler can run a script statement directly. However, if the event handler must run several script statements, it is usually more convenient to put those statements in a function definition and then have the event handler *invoke* that function. That's what happens in Listing 7-7: When the page completes loading, the onload event handler triggers the done() function. That function (simplified for this example) displays an alert dialog box.

LISTING 7-7

Running a Script from the onload Event Handler

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>An old-school HTML-based onload script</title>
      <script type="text/javascript">
         function done()
         {
            alert("The page has finished loading.");
         }
      </script>
   </head>
   <body onload="done()">
      <h1>An old-school HTML-based onload script</h1>
      <p>Here is some body text.</p>
   </body>
</html>
```

Don't worry about the curly braces or other oddities in Listing 7-7 at this point. Focus instead on the structure of the document and the flow. The entire page loads without running any script statements, although the page loads the done() function in memory so that it is ready to run at a moment's notice. After the document loads, the browser fires the onload event handler, which causes the done() function to run. Then the user sees the alert dialog box.

Although the HTML event attribute approach dates back to the earliest JavaScript browsers, the trend these days is to separate HTML markup from specifics of style (style sheets) and behavior (scripts). To the scripter's rescue come the equivalent event handler properties of objects. To get the onload

attribute out of the <body> tag, you can instead assign the desired JavaScript function to the object's event as a property, as in:

```
window.onload = done;
```

Such statements typically go near the end of scripts in the head portion of the document. Note, too, that in this version, the right side of the statement is merely the function's name, with no quotes or parentheses. Because it is easier to learn about event handlers when they're specified as HTML attributes, most examples in this tutorial continue with that approach. We needed to show you the property version, however, because you will see a lot of real-life code using that format.

Run by user

Getting a script to execute in response to a user action is very similar to the preceding example for running a deferred script right after the document loads. Commonly, a script function is defined in the head portion, and an event handler in, say, a form element calls upon that function to run. Listing 7-8 includes a script that runs when a user clicks a button.

LISTING 7-8

Running a Script from User Action

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>An onclick script</title>
      <script type="text/javascript">
         function alertUser()
         {
            alert("Ouch!");
         }
      </script>
   </head>
   <body>
      Here is some body text.
      <form>
         <input type="text" name="entry">
         <input type="button" name="oneButton"
                value="Press Me!" onclick="alertUser()">
      </form>
   </body>
</html>
```

Not every object must have an event handler defined for it, as shown in Listing 7-8 — only the ones for which scripting is needed. No script statements execute in Listing 7-8 until the user clicks the

button. The `alertUser()` function is defined as the page loads, and it waits to run as long as the page remains loaded in the browser. If it is never called upon to run, there's no harm done.

Called by another function

The last scenario for when script statements run also involves functions. In this case, a function is called upon to run by another script statement. Before you see how that works, it helps to read the next lesson, Chapter 8, "Programming Fundamentals, Part I." Therefore, we will hold off on this example until later in the tutorial.

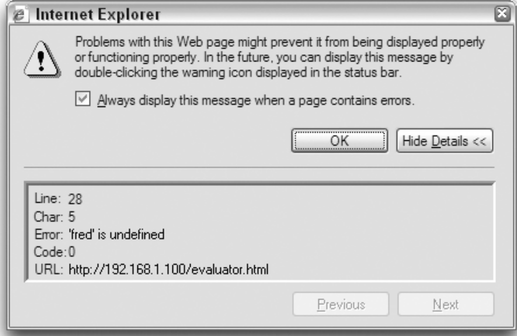
Viewing Script Errors

In the early days of JavaScript in browsers, script errors displayed themselves in very obvious dialog boxes. These boxes were certainly helpful for scripters who wanted to debug their scripts. However, if a bug got through to a page served up to a nontechnical user, the error alert dialog boxes were not only disruptive, but also scary. To prevent such dialog boxes from disturbing unsuspecting users, the browser makers tried to diminish the visual impact of errors in the browser window. Unfortunately for scripters, it is often easy to overlook the fact that your script contains an error because the error message is not so obvious.

Not only does each browser have a different way of displaying error messages, but the display can differ from version to version. The method to display errors in each of the major browsers is covered in the section "Error Message Notification" in Chapter 48, "Debugging Scripts" on the CD-ROM. While you need to read that section before testing your code, we've included a sample error dialog box as it appears in IE5+ (see Figure 7-1) and one as it appears in Mozilla 1.4+ (see Figure 7-2). Keep in mind that script-error dialog boxes are not necessarily displayed by default in these and other browsers. You have to train yourself to monitor the status bar when a page loads and after each script runs.

FIGURE 7-1

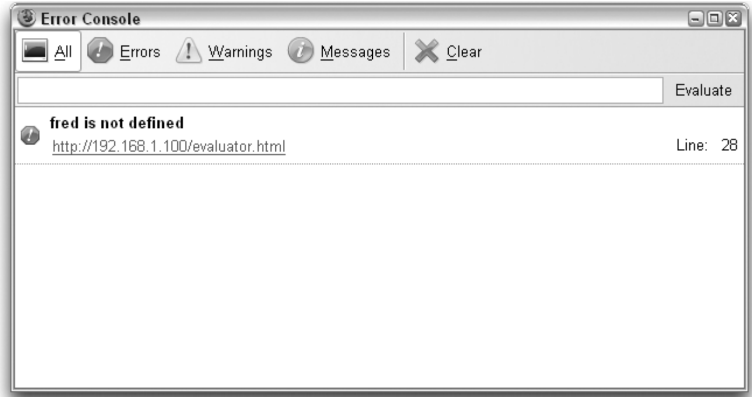
The expanded IE error dialog box.



Understanding error messages and doing something about them is a very large subject, the complete discussion of which is in reserved for Chapter 48. During this tutorial, however, you can use the error messages to see whether you mistyped a script from a listing in the book.

FIGURE 7-2

The Mozilla 1.4 JavaScript console window.



Scripting versus Programming

You may get the impression that scripting is easier than programming. *Scripting* simply sounds easier or more friendly than *programming*. In many respects, this is true. One of our favorite analogies is the difference between a hobbyist who builds model airplanes from scratch and a hobbyist who builds model airplanes from commercial kits. The "from scratch" hobbyist carefully cuts and shapes each piece of wood and metal according to very detailed plans before the model starts to take shape. The commercial kit builder starts with many prefabricated parts and assembles them into the finished product. When both builders are finished, you may not be able to tell which airplane was built from scratch and which one came out of a box of components. In the end, both builders used many of the same techniques to complete the assembly, and each can take pride in the result.

Thanks to implementations of the document object model (DOM), the browser gives scripters many prefabricated components with which to work. Without the browser, you'd have to be a pretty good programmer to develop your own application from scratch that served up content and offered user interaction. In the end, both authors have working applications that look equally professional.

Beyond the DOM, however, real programming nibbles its way into the scripting world. That's because scripts (and programs) work with more than just objects. Earlier in this lesson, we said that each statement of a JavaScript script does "something", and that "something" involves data of some kind. *Data* is the information associated with objects or other pieces of information that a script pushes around from place to place with each statement.

Data takes many forms. In JavaScript, the common incarnations of data are numbers, text (called *strings*), objects (derived from the object model or created with script), and `true` and `false` (called *Boolean values*).

Each programming or scripting language determines numerous structures and limits for each kind of data. Fortunately for newcomers to JavaScript, the universe of knowledge necessary for working with data is smaller than in a language such as Java or C++. At the same time, what you learn

about data in JavaScript is immediately applicable to future learning you may undertake in any other programming language; don't believe for an instant that your efforts in learning scripting will be wasted.

Because, deep down, scripting *is* programming, you need to have a basic knowledge of fundamental programming concepts to consider yourself a good JavaScript scripter. In the next two lessons, we set aside most of our discussion about the DOM and focus on the programming principles that will serve you well in JavaScript and future programming endeavors.

Exercises

1. Write the complete script tag set for a script whose lone statement is

   ```
   document.write("Hello, world.");
   ```

2. Build an HTML document, and include the answer to the previous question, such that the page executes the script as it loads. Open the document in your browser to test the results.
3. Add a comment to the script in the previous answer that explains what the script does.
4. Create an HTML document that displays an alert dialog box immediately after the page loads, and displays a different alert dialog box when the user clicks a form button.
5. Carefully study the document in Listing 7-9. Without entering and loading the document, predict
   - **a.** What the page looks like without further styling
   - **b.** How users interact with the page
   - **c.** What the script does

   Then type the listing as shown into a text editor. Observe all capitalization and punctuation. Do not type a carriage return after the = sign in the `upperMe` function statement; let the line word-wrap as it does in the following listing. It's okay to use a carriage return between attribute name/value pairs, as shown in the first `<input>` tag. Save the document as an HTML file, and load the file into your browser to see how well you did.

LISTING 7-9

How Does This Page Work?

```
<!DOCTYPE html>
<html>
   <head>
   <meta http-equiv="content-type" content="text/html;charset=utf-8">
   <title>Text Object Value</title>
      <script type="text/javascript">
         function upperMe()
         {
            document.getElementById("output").value =
            document.getElementById("input").value.toUpperCase();
         }
```

```
    </script>
  </head>

  <body>
    Enter lowercase letters for conversion to uppercase:<br>
    <form name="converter">
      <input type="text" name="input" id="input"
             value="sample" onchange="upperMe()" /><br />
      <input type="text" name="output" id="output" value="" />
    </form>
  </body>
</html>
```

CHAPTER

8

Programming Fundamentals, Part I

The tutorial breaks away from HTML and documents for a while, as you begin to learn programming fundamentals that apply to practically every scripting and programming language you will encounter. Here, you start learning about variables, expressions, data types, and operators — things that might sound scary if you haven't programmed before. Don't worry. With a little practice, you will become quite comfortable with these terms and concepts.

IN THIS CHAPTER

What variables are and how to use them

Why you must learn how to evaluate expressions

How to convert data from one type to another

How to use basic operators

What Language Is This?

The language you're studying is called JavaScript. But the language has some other names that you may have heard. JScript is Microsoft's name for the language. By leaving out the *ava,* the company doesn't have to license the Java name from its trademark owner: Sun Microsystems.

A standards body called ECMA (pronounced "ECK-ma") now governs the specifications for the language (no matter what you call it). The document that provides all of the details about the language is known as *ECMA-262* (it's the 262nd standard published by ECMA). Both JavaScript and JScript are ECMA-262 compatible. Some earlier browser versions exhibit very slight deviations from ECMA-262 (which came later than the earliest browsers). The most serious discrepancies are noted in the core language reference in Part III of this book.

Working with Information

With rare exceptions, every JavaScript statement you write does something with a hunk of information — *data.* Data may be text information displayed onscreen by a JavaScript statement or the on/off setting of a radio button in a form. Each single piece of information in programming is also called a *value.* Outside of programming, the term *value* usually connotes a number of some kind; in the programming world, however, the term is not as restrictive.

A string of letters is a value. A number is a value. The setting of a checkbox (whether it is checked or not) is a value.

In JavaScript, a value can be one of several types. Table 8-1 lists JavaScript's formal data types, with examples of the values you will see displayed from time to time.

TABLE 8-1

JavaScript Value (Data) Types

Type	Example	Description
String	`"Howdy"`	A series of characters inside quote marks
Number	`4.5`	Any number not inside quote marks
Boolean	`true`	A logical true or false
Null	`null`	Devoid of any content, but a value just the same
Object		A software thing that is defined by its properties and methods (arrays are also objects)
Function		A function definition

A language that contains these few data types simplifies programming tasks, especially those involving what other languages consider to be incompatible types of numbers (integers versus real or floating-point values). In some definitions of syntax and parts of objects later in this book, we make specific reference to the type of value accepted in placeholders. When a string is required, any text inside a set of quotes suffices.

You will encounter situations, however, in which the value type may get in the way of a smooth script step. For example, if a user enters a number into a form's text input field, the browser stores that number as a string value type. If the script is to perform some arithmetic on that number, you must convert the string to a number before you can apply the value to any math operations. You see examples of this later in this lesson.

Variables

Cooking up a dish according to a recipe in the kitchen has one advantage over cooking up some data in a program. In the kitchen, you follow recipe steps and work with real things: carrots, milk, or a salmon filet. A computer, on the other hand, follows a list of instructions to work with data. Even if the data represents something that looks real, such as the text entered into a form's input field, once the value gets into the program, you can no longer reach out and touch it.

In truth, the data that a program works with is merely a collection of bits (on and off states) in your computer's memory. More specifically, data in a JavaScript-enhanced web page occupies parts of the computer's memory set aside for exclusive use by the browser software. In the olden days, programmers had to know the numeric address in memory (RAM) where a value was stored to retrieve a copy of it for, say, some addition. Although the innards of a program have that level of complexity, programming languages such as JavaScript shield you from it.

The most convenient way to work with data in a script is to first assign the data to a *variable*. It's usually easier to think of a variable as a basket that holds information. How long the variable holds the information depends on a number of factors. But the instant a web page clears the window (or frame), any variables it knows about are discarded.

Creating variables

You have a couple of ways to create a variable in JavaScript, but one way covers all cases properly. Use the `var` keyword, followed by the name you want to give that variable. Therefore, to *declare* a new variable called `myAge`, the JavaScript statement is

```
var myAge;
```

That statement lets the browser know that you can use that variable later to hold information or to modify any of the data in that variable.

To assign a value to a variable, use one of the *assignment operators*. The most common one by far is the equal sign. For example, if you want to assign a value to the `myAge` variable at the same time that you declare it (a combined process known as *initializing the variable*), use that operator in the same statement as the `var` keyword:

```
var myAge = 45;
```

On the other hand, if you declare a variable in one statement and later want to assign a value to it, the sequence of statements is

```
var myAge;
myAge = 45;
```

Use the `var` keyword for declaration or initialization — typically only once for the life of any variable name in a document.

A JavaScript variable can hold any value type. Unlike many other languages, you don't have to tell JavaScript during variable declaration what type of value the variable will hold. In fact, the value type of a variable can change during the execution of a program. (This flexibility drives experienced programmers crazy because they're accustomed to assigning both a data type and a value to a variable.)

Naming variables

Choose the names you assign to variables with care. You'll often find scripts that use vague variable names, such as single letters. Other than a few specific circumstances where using letters is a common practice (for example, using `i` as a counting variable in repeat loops in Chapter 9), you should use names that truly describe a variable's contents. This practice can help you follow the state of your data through a long series of statements or jumps, especially for complex scripts.

A number of restrictions help instill good practice in assigning names. First, you cannot use any reserved keyword as a variable name. That includes all keywords currently used by the language and all others held in reserve for future versions of JavaScript. The designers of JavaScript, however, cannot foresee every keyword that the language may need in the future. By using the kind of single words that currently appear in the list of reserved keywords (see Appendix C, on the CD-ROM), you always run a risk of a future conflict.

To complicate matters, a variable name cannot contain space characters. Therefore, one-word variable names are fine. Should your description really benefit from more than one word, you can use one of

two conventions to join multiple words as one. One convention is to place an underscore character between the words; the other is to start the combination word with a lowercase letter and capitalize the first letter of each subsequent word within the name — referred to as *CamelCase* or *interCap* format. Both of the following examples are valid variable names:

```
my_age
myAge
```

Our preference is for the second version; it is easier to type and easier to read. In fact, because of the potential conflict with future one-word keywords, using multiword combinations for variable names is a good idea. Multiword combinations are less likely to appear in the list of reserved words.

Variable names have a couple of other important restrictions. Avoid all punctuation symbols except for the underscore character. Also, the first character of a variable name cannot be a numeral. If these restrictions sound familiar, it's because they're similar to those for HTML element identifiers described in Chapter 6.

Expressions and Evaluation

Another concept closely related to the value and variable is *expression evaluation* — perhaps the most important concept in learning how to program a computer.

We use expressions in our everyday language. Remember the theme song of "The Beverly Hillbillies"?:

Then one day he was shootin' at some food
And up through the ground came a-bubblin' crude
Oil, that is. Black gold. Texas tea.

At the end of the song, you find four quite different references (crude, oil, black gold, and Texas tea). They all mean oil. They're all *expressions* for oil. Say any one of them, and other people know what you mean. In our minds, we *evaluate* those expressions to mean one thing: oil.

In programming, a variable always evaluates to its contents, or value. For example, after assigning a value to a variable, such as

```
var myAge = 45;
```

any time the variable is used in a statement, its value (`45`) is automatically applied to whatever operation that statement calls. Therefore, if you're 15 years my junior, I can assign a value to a variable representing your age based on the evaluated value of `myAge`:

```
var yourAge = myAge - 15;
```

The variable, `yourAge`, evaluates to 30 the next time the script uses it. If the `myAge` value changes later in the script, the change has no link to the `yourAge` variable because `myAge` evaluated to `45` when it was used to assign a value to `yourAge`.

Expressions in scripts

You probably didn't recognize it at the time, but you have seen how expression evaluation came in handy in several scripts in previous chapters. Let's look at one in particular — from

Listing 5-6 — where a script writes dynamic text to the page as the page loads. Recall the second `document.write()` statement:

```
document.write(" of " + navigator.appName + ".");
```

Testing JavaScript Evaluation

You can begin experimenting with the way JavaScript evaluates expressions with the help of The Evaluator Jr. (see Figure 8-1), an HTML page you can find on the companion CD-ROM. (The Senior version is introduced in Chapter 4, ''JavaScript Essentials.'') Enter any JavaScript expression into the top text box, and either press Enter/Return or click the Evaluate button.

FIGURE 8-1

The Evaluator Jr. for testing expression evaluation.

The Evaluator Jr. has 26 variables (lowercase `a` through `z`) predefined for you. Therefore, you can assign values to variables, test comparison operators, and even do math here. Using the `age` variable examples

continued

continued

from earlier in this chapter, type each of the following statements in the upper text box, and observe how each expression evaluates in the Results field. Be sure to observe case sensitivity in your entries. The trailing semicolons are optional in The Evaluator.

```
a = 45;
a;
b = a - 15;
b;
a - b;
a > b;
```

To start over, click the Reload/Refresh button.

The `document.write()` method (remember, JavaScript uses the term *method* to mean *command*) requires a parameter in the parentheses: the text string to be displayed on the web page. The parameter here consists of one expression that joins three distinct strings:

```
" of "
navigator.appName
"."
```

The plus symbol is one of JavaScript's ways of joining strings. Before JavaScript can display this line, it must perform some quick evaluations. The first evaluation is the value of the `navigator.appName` property. This property evaluates to a string of the name of your browser. With that expression safely evaluated to a string, JavaScript can finish the job of joining the three strings in the final evaluation. The evaluated string expression is what ultimately appears on the web page.

Expressions and variables

As one more demonstration of the flexibility that expression evaluation offers, this section shows you a slightly different route to the `document.write()` statement. Rather than join those strings as the direct parameter to the `document.write()` method, you can gather the strings in a variable and then apply the variable to the `document.write()` method. Here's how that sequence looks, as you simultaneously declare a new variable and assign it a value:

```
var textToWrite = " of " + navigator.appName + ".";
document.write(textToWrite);
```

This method works because the variable, `textToWrite`, evaluates to the combined string. The `document.write()` method accepts that string value and does its display job. As you read a script or try to work through a bug, pay special attention to how each expression (variable, statement, object property) evaluates. As you learn JavaScript (or any language), you will end up scratching your head from time to time because you haven't stopped to examine how expressions evaluate when a particular kind of value is required in a script.

Data Type Conversions

We mentioned earlier that the type of data in an expression can trip up some script operations if the expected components of the operation are not of the right type. JavaScript tries its best to perform internal conversions to head off such problems, but JavaScript cannot read your mind. If your intentions differ from the way JavaScript treats the values, you won't get the results you expect.

A case in point is adding numbers that may be in the form of text strings. In a simple arithmetic statement that adds two numbers, you get the expected result:

```
3 + 3          // result = 6
```

But if one of those numbers is a string, JavaScript leans toward converting the other value to a string — thus turning the plus sign's action from arithmetic addition to joining strings. Therefore, in the statement

```
3 + "3"        // result = "33"
```

the stringness of the second value prevails over the entire operation. The first value is automatically converted to a string, and the result joins the two strings. Try this yourself in The Evaluator Jr.

If you take this progression one step further, look what happens when another number is added to the statement:

```
3 + 3 + "3"    // result = "63"
```

This might seem totally illogical, but there is logic behind this result. The expression is evaluated from left to right. The first plus operation works on two numbers, yielding a value of `6`. But as the `6` is about to be added to the `3`, JavaScript lets the stringness of the `3` rule. The `6` is converted to a string, and two string values are joined to yield `63`.

Most of your concern about data types will focus on performing math operations like the ones here. However, some object methods also require one or more parameters of particular data types. Although JavaScript provides numerous ways to convert data from one type to another, it is appropriate at this stage of the tutorial to introduce you to the two most common data conversions: string to number and number to string.

Converting strings to numbers

As you saw in the preceding section, if a numeric value is stored as a string — as it is when entered into a form text field — your scripts may have difficulty applying that value to a math operation. The JavaScript language provides two built-in functions to convert string representations of numbers to true numbers: `parseInt()` and `parseFloat()`.

There is a difference between integers and floating-point numbers in JavaScript. *Integers* are always whole numbers, with no decimal point or numbers to the right of a decimal. *Floating-point numbers,* on the other hand, have fractional values to the right of the decimal. By and large, JavaScript math operations don't differentiate between integers and floating-point numbers: A number is a number. The only time you need to be cognizant of the difference is when a method parameter requires an integer because it can't handle fractional values. For example, parameters to the `scroll()` method of a window require integer values of the numbers of pixels vertically and horizontally that you want to scroll the window. That's because you can't scroll a window a fraction of a pixel onscreen.

To use either of these conversion functions, insert the string value you wish to convert as a parameter to the function. For example, look at the results of two different string values when passed through the `parseInt()` function:

```
parseInt("42")        // result = 42
parseInt("42.33")     // result = 42
```

Even though the second expression passes the string version of a floating-point number to the function, the value returned by the function is an integer. No rounding of the value occurs here (although other math functions can help with that if necessary). The decimal and everything to its right are simply stripped off.

The `parseFloat()` function returns an integer if it can; otherwise, it returns a floating-point number, as follows:

```
parseFloat("42")       // result = 42
parseFloat("42.33")    // result = 42.33
```

Because these two conversion functions evaluate to their results, you simply insert the entire function wherever you need a string value converted to a number. Therefore, modifying an earlier example in which one of three values was a string, the complete expression can evaluate to the desired result:

```
3 + 3 + parseInt("3")  // result = 9
```

Converting numbers to strings

You'll have less need for converting a number to its string equivalent than the other way around. As you saw in the previous section, JavaScript gravitates toward strings when faced with an expression containing mixed data types. Even so, it is good practice to perform data type conversions explicitly in your code to prevent any potential ambiguity. The simplest way to convert a number to a string is to take advantage of JavaScript's string tendencies in addition operations. By adding an empty string to a number, you convert the number to its string equivalent:

```
("" + 2500)           // result = "2500"
("" + 2500).length    // result = 4
```

In the second example, you can see the power of expression evaluation at work. The parentheses force the conversion of the number to a string. A *string* is a JavaScript object that has properties associated with it. One of those properties is the `length` property, which evaluates to the number of characters in the string. Therefore, the length of the string `"2500"` is `4`. Note that the `length` value is a number, not a string.

Operators

You will use lots of *operators* in expressions. Earlier, you used the equal sign (=) as an assignment operator to assign a value to a variable. In the preceding examples with strings, you used the plus symbol (+) to join two strings. An operator generally performs some kind of calculation (operation) or comparison with two values (the value on each side of an operator is called an *operand*) to reach a third value. This lesson briefly describes two categories of operators: arithmetic and comparison. Chapter 22, "JavaScript Operators," covers many more operators, but after you understand the basics here, the others are easier to grasp.

Arithmetic operators

It may seem odd to talk about text strings in the context of arithmetic operators, but you have already seen the special case of the plus (+) operator when one or more of the operands is a string. The plus operator instructs JavaScript to *concatenate* (pronounced "kon-KAT-en-eight"), or join, two strings together precisely where you place the operator. The string concatenation operator doesn't know about words and spaces, so the programmer must make sure that any two strings to be joined have the proper word spacing as part of the strings, even if that means adding a space:

```
firstName = "John";
lastName = "Doe";
fullName = firstName + " " + lastName;
```

JavaScript uses the same plus operator for arithmetic addition. When both operands are numbers, JavaScript knows to treat the expression as an arithmetic addition rather than a string concatenation. The standard math operators for addition, subtraction, multiplication, and division (+, -, *, /) are built into JavaScript.

Comparison operators

Another category of operator helps you compare values in scripts — whether two values are the same, for example. These kinds of comparisons return a value of the Boolean type: `true` or `false`. Table 8-2 lists the comparison operators. The operator that tests whether two items are equal consists of a pair of equal signs to distinguish it from the single-equal-sign assignment operator.

TABLE 8-2

JavaScript Comparison Operators

Symbol	Description
==	Equals
!=	Does not equal
>	Is greater than
>=	Is greater than or equal to
<	Is less than
<=	Is less than or equal to

Comparison operators come into greatest play in the construction of scripts that make decisions as they run. A cook does this in the kitchen all the time: If the sauce is too watery, add a bit of flour. You see comparison operators in action in Chapter 22.

Exercises

1. Which of the following are valid variable declarations or initializations? Explain why each one is or is not valid. If an item is not valid, how do you fix it so that it is?
   a. `my_name = "Cind";`
   b. `var how many = 25;`
   c. `var zipCode = document.getElementById("zip").value`
   d. `var 1address = document.("address1").value;`
2. Assume that the following statements operate rapidly in sequence, where each statement relies on the result of the one before it. For each of the statements in the sequence, write down how the `someVal` expression evaluates after the statement executes in JavaScript.

```
var someVal = 2;
someVal = someVal + 2;
someVal = someVal * 10;
someVal = someVal + "20";
someVal = "Robert";
```

3. Name the two JavaScript functions that convert strings to numbers. How do you give the function a string value to convert to a number?
4. Type and load the HTML page and script shown in Listing 8-1. Enter a three-digit number in the top two fields, and click the Add button. Examine the code, and explain what is wrong with the script. How do you fix the script so that the proper sum is displayed in the output field?

LISTING 8-1

What's Wrong with This Script?

HTML: jsb-08-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Making Sums</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-08-01.js"></script>
   </head>
   <body>
      <h1>Making Sums</h1>
      <form action="addit.php">
         <p><input type="text" id="inputA" name="inputA" value="0"></p>
         <p><input type="text" id="inputB" name="inputB" value="0"></p>
         <p><input type="button" id="add" name="add" value="Add"></p>
         <p><input type="text" id="output" name="output"></p>
      </form>
   </body>
</html>
```

JavaScript: jsb-08-01.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to critical elements
      var oInputA = document.getElementById('inputA');
      var oInputB = document.getElementById('inputB');
      var oButton = document.getElementById('add');
      var oOutput = document.getElementById('output');

         // if they all exist...
         if (oInputA && oInputB && oButton && oOutput)
         {
            // apply behaviors
            addEvent(oButton, 'click', addIt);
         }
   }
}

// add two input numbers & display result
function addIt()
{
   var value1 = document.getElementById("inputA").value;
   var value2 = document.getElementById("inputB").value;

   document.getElementById("output").value = value1 + value2;
}
```

5. What does the term *concatenate* mean in the context of JavaScript programming?

CHAPTER

Programming Fundamentals, Part II

Your tour of programming fundamentals continues in this chapter with subjects that have more intriguing possibilities. For example, we show you how programs make decisions and why a program must sometimes repeat statements over and over. Before you're finished here, you also will learn how to use one of the most powerful information holders in the JavaScript language: the array.

IN THIS CHAPTER

How control structures make decisions

How to define functions

Where to initialize variables efficiently

What those darned curly braces are all about

The basics of data arrays

Decisions and Loops

Every waking hour of every day, you make decisions of some kind; most of the time, you probably don't even realize it. Don't think so? Well, look at the number of decisions you make at the grocery store, from the moment you enter the store to the moment you clear the checkout aisle.

No sooner do you enter the store than you are faced with a decision. Based on the number and size of items you intend to buy, do you pick up a hand-carried basket or attempt to extricate a shopping cart from the metallic conga line near the front of the store? That key decision may have impact later, when you see a special offer on an item that is too heavy to put in the handbasket.

Next, you head for the food aisles. Before entering an aisle, you compare the range of goods stocked in that aisle with items on your shopping list. If an item you need is likely to be found in this aisle, you turn into the aisle and start looking for the item; otherwise, you skip the aisle and move to the head of the next aisle.

Later, you reach the produce section in search of a juicy tomato. Standing in front of the bin of tomatoes, you begin inspecting them one by one — picking one up, feeling its firmness, checking the color, looking for blemishes or signs of pests. You discard one, pick up another, and continue this process until one matches the criteria you set in your mind for an acceptable morsel. Your last stop in the store is the checkout aisle. "Paper or plastic?" the clerk asks. One more decision to make. What you choose affects how you get the groceries from the car to the kitchen, as well as your recycling habits.

During your trip to the store, you go through the same kinds of decisions and repetitions that your JavaScript programs encounter. If you understand these frameworks in real life, you can look into the JavaScript equivalents and the syntax required to make them work.

Control Structures

In the vernacular of programming, the kinds of statements that make decisions and loop around to repeat themselves are called *control structures*. A control structure directs the execution flow through a sequence of script statements based on simple decisions and other factors.

An important part of a control structure is the *condition*. Just as you may travel different routes to work depending on certain conditions (for example, nice weather, nighttime, whether you're attending a soccer game), so, too, does a program sometimes have to branch to an execution route if a certain condition exists. Each condition is an expression that evaluates to `true` or `false` — one of those Boolean data types mentioned in Chapter 8. The kinds of expressions commonly used for conditions are expressions that include a comparison operator. You do the same in real life: If it is true that the outdoor temperature is less than freezing, you put on a coat before going outside. In programming, the comparisons are strictly comparisons of numeric values and character strings.

JavaScript provides several kinds of control structures for different programming situations. Three of the most common control structures you'll use are `if` constructions, `if...else` constructions, and `for` loops.

Chapter 21 covers in great detail other common control structures you should know. For this tutorial, however, you need to learn about the three common ones just mentioned.

if constructions

The simplest program decision is to follow a special branch or path of the program if a certain condition is true. Formal syntax for this construction follows. Items in italics get replaced in a real script with expressions and statements that fit the situation.

```
if (condition)
{
   statement[s] if true
}
```

Don't worry about the curly braces yet. Instead, get a feel for the basic structure. The keyword, `if`, is a must. Between the parentheses goes an expression that evaluates to a Boolean (true/false) value. This is the condition being tested as the program runs past this point. If the condition evaluates to `true`, one or more statements inside the curly braces execute before the program continues with the next statement after the closing brace. If the condition evaluates to `false`, the statements inside the curly braces are ignored, and processing continues with the next statement after the closing brace.

The following example assumes that a variable, `myAge`, has had its value set earlier in the script (exactly how is not important for this example). The conditional expression compares the value `myAge` against a numeric value of 13:

```
if (myAge < 13)
{
   alert("You are not yet a teenager.");
}
```

In this example, the data type of the value inside myAge must be a number so that the proper comparison (via the <, or less than, comparison operator) does the right thing. For all instances of myAge less than 13, the nested statement inside the curly braces runs and displays the alert to the user. After the user closes the alert dialog box, the script continues with whatever statement follows the entire if construction.

if . . . else constructions

Not all program decisions are as simple as the one shown for the if construction. Rather than specifying one detour for a given condition, you might want the program to follow either of two branches depending on that condition. It is a fine but important distinction. In the plain if construction, no special processing is performed when the condition evaluates to false. But if processing must follow one of two special paths, you need the if...else construction. The formal syntax definition for an if...else construction is as follows:

```
if (condition)
{
   statement[s] if true
}
else
{
   statement[s] if false
}
```

Everything you know about the condition for an if construction applies here. The only difference is the else keyword, which provides an alternative path for execution to follow if the condition evaluates to false.

As an example, the following if...else construction determines how many days are in February for a given year. To simplify the demo, the condition simply tests whether the year divides equally by 4. (True testing for this value includes special treatment of end-of-century dates, but we're ignoring that for now.) The % operator symbol is called the *modulus operator* (covered in more detail in Chapter 22). The result of an operation with this operator yields the remainder of division of the two values. If the remainder is zero, the first value divides evenly by the second.

```
var febDays;
var theYear = 2010;
   if (theYear % 4 == 0)
   {
      febDays = 29;
   }
   else
   {
      febDays = 28;
   }
```

The important point to see from this example is that by the end of the if...else construction, the febDays variable is set to either 28 or 29. No other value is possible. For years evenly divisible by 4, the first nested statement runs. For all other cases, the second statement runs. Then processing picks up with the next statement after the if...else construction.

Repeat Loops

Repeat loops in real life generally mean the repetition of a series of steps until some condition is met, thus enabling you to break out of that loop. Such was the case earlier in this chapter, when you looked through a bushel of tomatoes for the one that came closest to your ideal tomato. The same can be said for driving around the block in a crowded neighborhood until a parking space opens up.

A *repeat loop* lets a script cycle through a sequence of statements until some condition is met. For example, a JavaScript data validation routine might inspect every character that you enter in a form text field to make sure that each one is a number. Or, if you have a collection of data stored in a list, the loop can check whether an entered value is in that list. When that condition is met, the script can break out of the loop and continue with the next statement after the loop construction.

The most common repeat loop construction used in JavaScript is called the `for` loop. It gets its name from the keyword that begins the construction. A `for` loop is a powerful device because you can set it up to keep track of the number of times the loop repeats itself. The formal syntax of the `for` loop is as follows:

```
for ([initial expression]; [condition]; [update expression])
{
   statement[s] inside loop
}
```

The square brackets mean that the item is optional. However, until you get to know the `for` loop better, we recommend designing your loops to use all three items inside the parentheses. The *initial expression* portion usually sets the starting value of a counter variable. The *condition* — the same kind of condition you saw for `if` constructions — defines the condition that forces the loop to stop going around and around. Finally, the *update expression* is a statement that executes each time all the statements nested inside the construction complete running.

A common implementation initializes a counting variable, `i`; increments the value of `i` by 1 each time through the loop; and repeats the loop until the value of `i` exceeds some maximum value, as in the following:

```
for (var i = startValue; i <= maxValue; i++)
{
   statement[s] inside loop
}
```

Placeholders `startValue` and `maxValue` represent any numeric values, including explicit numbers or variables holding numbers. In the update expression is an operator we have not presented yet. The ++ operator adds 1 to the value of `i` each time the update expression runs at the end of the loop. If `startValue` is 1, the value of `i` is 1 the first time through the loop, 2 the second time through, and so on. Therefore, if `maxValue` is 10, the loop repeats itself 10 times (in other words, as long as `i` is less than or equal to 10). Generally speaking, the statements inside the loop use the value of the counting variable in their execution. Later in this lesson, we show how the variable can play a key role in the statements inside a loop. At the same time, you will see how to break out of a loop prematurely and why you may need to do this in a script.

Functions

In Chapter 7, you saw a preview of the JavaScript function. A *function* is a definition of a set of deferred actions. Functions are invoked by event handlers or by statements elsewhere in the script.

Whenever possible, good functions are designed for reuse in other documents. They can become building blocks you use over and over again.

If you have programmed before, you can see parallels between JavaScript functions and other languages' subroutines. But unlike some languages that distinguish between procedures (which carry out actions) and functions (which carry out actions and return values), only one classification of routine exists for JavaScript. A function is capable of returning a value to the statement that invoked it, but this is not a requirement. When a function does return a value, the calling statement treats the function call like any expression — plugging in the returned value right where the function call is made. We will show some examples in a moment.

Formal syntax for a function is as follows:

```
function functionName ( [parameter1]...[,parameterN] )
{
   statement[s]
}
```

Names you assign to functions have the same restrictions as names you assign to HTML elements and variables. You should devise a name that succinctly describes what the function does. We tend to use multiword names with the CamelCase or interCap (internally capitalized) format that start with a verb because functions are action items, even if they do nothing more than get or set a value.

Another practice to keep in mind as you start to create functions is to keep the focus of each function as narrow as possible. It is possible to generate functions that are literally hundreds of lines long. Such functions are usually difficult to maintain and debug. Chances are that you can divide the long function into smaller, more tightly focused segments.

Function parameters

In Chapter 4, you saw how an event handler invokes a function by calling the function by name. A typical call to a function, including one that comes from another JavaScript statement, works the same way: A set of parentheses follows the function name.

You also can define functions so that they receive parameter values from the calling statement. Listing 9-1 shows a simple script in which a statement passes text data to a function at the same time that it calls the function.

LISTING 9-1

Calling a Function from an Event Handler

HTML: jsb-09-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Passing a Parameter to a Function</title>
      <script type="text/javascript" src="jsb-09-01.js"></script>
   </head>
```

continued

LISTING 9-1 *(continued)*

```
   <body>
      <h1>Passing a Parameter to a Function</h1>
   </body>
</html>
```

JavaScript: jsb-09-01.js

```
// display a personalized greeting
function greeting(sName)
{
   alert("Hello, " + sName + "!");
}

greeting("Chris");
```

Parameters (also known as *arguments*) provide a mechanism for handing off a value from one statement to another by way of a function call. If no parameters occur in the function definition, both the function definition and the call to the function have only empty sets of parentheses (as shown in Chapter 4, Listing 4-2).

When a function receives parameters, it assigns the incoming values to the variable names specified in the function definition's parentheses. Consider the following script segment:

```
function sayHelloFirst(a, b, c)
{
   alert("Say hello, " + a);
}
sayHelloFirst("Gracie", "George", "Harry");
sayHelloFirst("Larry", "Moe", "Curly");
```

After the function is defined in the script, the next statement calls that very function, passing three strings as parameters. The function definition automatically assigns the strings to variables `a`, `b`, and `c`. Therefore, before the `alert()` statement inside the function ever runs, `a` evaluates to `"Gracie"`, `b` evaluates to `"George"`, and `c` evaluates to `"Harry"`. In the `alert()` statement, only the `a` value is used, and the alert reads

```
Say hello, Gracie
```

When the user closes the first alert, the next call to the function occurs. This time through, different values are passed to the function and assigned to `a`, `b`, and `c`. The alert dialog box reads

```
Say hello, Larry
```

Unlike other variables that you define in your script, function parameters do not use the `var` keyword to initialize them. They are automatically initialized whenever the function is called.

Variable scope

Speaking of variables, it's time to distinguish between variables that are defined outside and those that are defined inside functions. Variables defined outside of functions are called *global variables;* those defined inside functions with the `var` keyword are called *local variables.*

A global variable has a slightly different connotation in JavaScript than it has in most other languages. For a JavaScript script, the globe of a global variable is the current document loaded in a browser window or frame. Therefore, when you initialize a variable as a global variable, it means that all script statements in the page (including those inside functions) have direct access to that variable's value via the variable's name. Statements can retrieve and modify global variables from anywhere in the script. In programming terminology, this kind of variable is said to have *global scope* because every statement on the page can see it.

It is important to remember that the instant a page unloads itself, all global variables defined in that page disappear from memory forever. If you need a value to persist from one page to another, you must use other techniques to store that value (for example, as a global variable in a framesetting document, as described in Chapter 27, "Window and Frame Objects," or in a cookie, as described in Chapter 29, "The Document and Body Objects." Although the `var` keyword is usually optional for initializing global variables, we strongly recommend that you use it for all variable initializations to guard against future changes to the JavaScript language.

In contrast to the global variable, a local variable is defined inside a function. You already saw how parameter variables are defined inside functions (without `var` keyword initializations). But you can also define other variables with the `var` keyword (absolutely required for local variables; otherwise, they become recognized as global variables). The scope of a local variable is only within the statements of the function. No other functions or statements outside functions have access to a local variable.

Local scope allows for the reuse of variable names within a document. For most variables, we strongly discourage this practice because it leads to confusion and bugs that are difficult to track down. At the same time, it is convenient to reuse certain kinds of variable names, such as `for` loop counters. These are safe because they are always reinitialized with a starting value whenever a `for` loop starts. In order to nest one `for` loop inside another, you need to specify a different loop-counting variable in the nested loop.

To demonstrate the structure and behavior of global and local variables — and show you why it can get confusing to reuse most variable names inside a script — Listing 9-2 defines two global variables and a local one. For the purposes of this illustration, we intentionally use bad form by initializing a local variable that has the same name as a global variable.

LISTING 9-2

Global and Local Variable Scope Demonstration

HTML: jsb-09-02.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Global and Local Variable Scope</title>
```

continued

LISTING 9-2 *(continued)*

```
      <script type="text/javascript" src="jsb-09-02.js"></script>
   </head>
   <body>
      <h1>Global and Local Variable Scope</h1>
   </body>
</html>
```

JavaScript: jsb-09-02.js

```
var Boy = "Charlie Brown";   // global
var Dog = "Snoopy";        // global

// using improper design to demonstrate a point
function demo()
{
   // local variable with the same name as a global
   var Dog = "Gromit";

   alert(Dog + " does not belong to " + Boy + ".");
}

// use global variables
alert(Dog + " belongs to " + Boy + ".");

// use global & local variables
demo();
```

When the page loads, the script initializes the two global variables (`Boy` and `Dog`) and defines the `demo()` function in memory. Inside the function, a local variable is initialized with the same name as one of the global variables: `Dog`. In JavaScript, such a local initialization overrides the global variable for all statements inside the function. (But note that if we had omitted the `var` keyword from the local initialization, the variable `Dog` inside the function would have referred to the global variable — i.e., `"Gromit"`.)

The script displays two `alert` dialogs. The first to appear concatenates the two global variables to display:

```
Snoopy belongs to Charlie Brown.
```

The second dialog, invoked by calling the function `demo()` in the last line of the script, occurs inside the `demo()` function and therefore uses the local variable `Dog` instead of the global one:

```
Gromit does not belong to Charlie Brown.
```

Curly Braces

Despite the fact that you probably rarely — if ever — use curly braces (`{ }`) in your writing, there is no mystery to their usage in JavaScript (and many other languages). Curly braces enclose blocks of

statements that belong together. Although they do assist humans who are reading scripts in knowing what's going on, curly braces also help the browser know which statements belong together. You always must use curly braces in matched pairs.

You use curly braces most commonly in function definitions and control structures. In the function definition in Listing 9-2, curly braces enclose three statements (including the comment line) that make up the function definition. The closing brace lets the browser know that whatever statement comes next is a statement outside the function definition.

Physical placement of curly braces is not critical. (Neither is the indentation style you see in the code we provide.) The following function definitions are treated identically by scriptable browsers:

```
function sayHiToFirst(a, b, c)
{
   alert("Say hello, " + a);
}
function sayHiToFirst(a, b, c) {
   alert("Say hello, " + a);
}

function sayHiToFirst(a, b, c) {alert("Say hello, " + a);}
```

Throughout this book, we use the style shown in the first example because we find that it makes lengthy and complex scripts easier to read — especially scripts that have many levels of nested control structures. However, this aspect of scripting style is highly personal and varies from one programmer to another — even among the co-authors of this book!

Arrays

The JavaScript array is one of the most useful data constructions you have available to you. You can visualize the structure of a basic array as though it were a single-column spreadsheet. Each row of the column holds a distinct piece of data, and each row is numbered. Numbers assigned to rows are in strict numerical sequence, starting with zero as the first row. (Computers tend to start counting with zero.) This row number is called an *index*. To access an item in an array, you need to know the name of the array and the index for the row. Because index values start with zero, the total number of items of the array (as determined by the array's `length` property) is always one more than the highest index value of the array. More advanced array concepts enable you to create the equivalent of an array with multiple columns (described in Chapter 18). For this tutorial, we stay with the single-column basic array.

Data elements inside JavaScript arrays can be any data type, including objects. And unlike a lot of other programming languages, JavaScript allows different rows of the same array to contain different data types.

Creating an array

An array is stored in a variable, so when you create an array, you assign the new array object to the variable. (Arrays are objects that belong to the core JavaScript language rather than to the document object model [DOM].) A special keyword — `new` — preceding a call to the JavaScript function that generates arrays creates space in memory for the array. An optional parameter to the `Array()` function enables you to specify at the time of creation how many elements (rows) of data eventually will occupy the array. JavaScript is very forgiving about this because you can change the size of an array

at any time. Therefore, if you omit a parameter when generating a new array, your script incurs no penalty.

To demonstrate the array creation process, we create an array that holds the names of the 50 U.S. states plus the District of Columbia (a total of 51). The first task is to create that array and assign it to a variable of any name that helps us remember what this collection of data is about:

```
var USStates = new Array(51);
```

At this point, the `USStates` array is sitting in memory like a 51-row table with no data in it. To fill the rows, we must assign data to each row. Addressing each row of an array requires a special way of indicating the index value of the row: square brackets after the name of the array. The first row of the `USStates` array is addressed as:

```
USStates[0]
```

To assign the string name of the first state of the alphabet to that row, use a simple assignment operator:

```
USStates[0] = "Alabama";
```

To fill in the rows, include a statement for each row:

```
USStates[0] = "Alabama";
USStates[1] = "Alaska";
USStates[2] = "Arizona";
USStates[3] = "Arkansas";
...
USStates[50] = "Wyoming";
```

(Note that the 51st array element has an index of 50 because we're starting with 0, not 1.)

Therefore, if you want to include a table of information from which a script can look up information without accessing the server, you include the data in the script in the form of an array creation sequence. When the script loads into the browser and the statements run, the data collection array is built and ready to go. Despite what appears to be the potential for a lot of statements in a document for such a data collection, the amount of data that must download for typical array collections is small enough not to affect page loading severely — even for dial-up users. In Chapter 18, you also see some syntax shortcuts for creating arrays that reduce source code character counts.

Accessing array data

The array index is the key to accessing an array element. The name of the array and an index in square brackets evaluates to the content of that array location. For example, after the `USStates` array is built, a script can display an alert with Alaska's name in it with the following statement:

```
alert("The largest state is " + USStates[1] + ".");
```

Just as you can retrieve data from an indexed array element, you can change the element by reassigning a new value to any indexed element in the array.

Parallel arrays

Now we show you why the numeric index methodology works well in JavaScript. To help with the demonstration, we generate another array that is parallel with the `USStates` array. This new array is also 51 elements long, and it contains the year in which the state in the corresponding row of `USStates` entered the Union. That array construction looks like the following:

```
var stateEntered = new Array(51);
stateEntered [0] = 1819;
stateEntered [1] = 1959;
stateEntered [2] = 1912;
stateEntered [3] = 1836;
...
stateEntered [50] = 1890;
```

In the browser's memory, then, are two data tables that you can visualize as looking like the model in Figure 9-1. We can build more arrays that are parallel to these for items such as the postal abbreviation and capital city. The important point is that the zeroth element in each of these tables applies to Alabama, the first state in the `USStates` array.

FIGURE 9-1

Visualization of two related parallel data tables.

USStates		stateEntered
"Alabama"	[0]	1819
"Alaska"	[1]	1959
"Arizona"	[2]	1912
"Arkansas"	[3]	1836
⋮	⋮	⋮
"Wyoming"	[50]	1890

If a web page included these data tables and a way for a user to look up the entry date for a given state, the page would need a way to look through all the `USStates` entries to find the index value of the one that matches the user's entry. Then that index value could be applied to the `stateEntered` array to find the matching year.

For this demo, the page includes a text entry field in which the user types the name of the state to look up. This methodology is fraught with peril unless the script performs some error checking in case the user makes a mistake. Let's not assume that the user always types a valid state name; instead, let's gracefully handle the circumstance in which they don't. (Don't ever assume that user input is valid in your web site's pages.) An event handler from either the text field or a clickable button calls a function that looks up the state name, fetches the corresponding entry year, and displays an alert message with the information. The function is as follows:

```
function getStateDate()
{
   var selectedState = document.getElementById("entry").value;
   for (var i = 0; i < USStates.length; i++)
   {
```

```
         if (USStates[i] == selectedState)
         {
            break;
         }
      }

      if (i < USStates.length)
      {
         alert(selectedState + " entered the Union in " + stateEn-
tered[i] + ".");
      }
      else
      {
         alert("Sorry, '" + selectedState + "' isn't a US state.");
      }
}
```

In the first statement of the function, we grab the value of the text box and assign the value to a variable, `selectedState`. This is mostly for convenience, so that we can use this shorter variable name later in the script. In fact, the usage of that value is inside a `for` loop, so the script is marginally more efficient because the browser doesn't have to evaluate that long reference to the text field each time through the loop.

The key to this function is in the `for` loop. Here is where we combine the natural behavior of incrementing a loop counter with the index values assigned to the two arrays. Specifications for the loop indicate that the counter variable, `i`, is initialized with a value of zero. The loop is directed to continue as long as the value of `i` is less than the length of the `USStates` array. Remember that the length of an array is always one more than the index value of the last item. Therefore, the last time the loop runs is when `i` is 50, which is both less than the length of 51 and equal to the index value of the last element. Each time after the loop runs, the counter increments by 1 (`i++`).

Nested inside the `for` loop is an `if` construction. The condition tests the value of an element of the array against the value typed by the user. Each time through the loop, the condition tests a different row of the array, starting with row zero. In other words, this `if` construction can be performed dozens of times before a match is found, but each time, the value of `i` is 1 larger than in the previous try.

The equality comparison operator (==) is fairly strict when it comes to comparing string values. Such comparisons respect the case of each letter. In our example, the user must type the state name exactly as it is stored in the `USStates` array for the match to be found. In Chapter 12, you learn about some helper methods that eliminate case and sensitivity in string comparisons.

When a match is found, the statement nested inside the `if` construction runs. The `break` statement is designed to help control structures bail out if the program needs it. For this application, it is imperative that the `for` loop stop running when a match for the state name is found. When the `for` loop breaks, the value of the `i` counter is fixed at the row of the `USStates` array containing the entered state. We need that index value to find the corresponding entry in the other array. Even though the counting variable, `i`, is initialized in the `for` loop, it is still alive and in the scope of the function for all statements after the initialization. That's why we can use it to extract the value of the row of the `stateEntered` array in the final statement that displays the results in an alert message.

If the entered state name doesn't match any of the values in the `USStates` array, the counter variable `i` increments to the length of the array (51) and the `for` loop terminates, leaving `i` equal to 51. From

that we can easily tell whether we successfully found a state name match and display an error message if no match was found.

This application of a `for` loop and array indexes is a common one in JavaScript. Study the code carefully, and be sure you understand how it works. This way of cycling through arrays plays a role not only in the kinds of arrays you create in your code, but also in the arrays that browsers generate for the DOM.

Document objects in arrays

If you look at the `document` object portions of the Quick Reference in Appendix A, you can see that the properties of some objects are listed with square brackets after them. These are indeed the same kind of square brackets you just saw for array indexes. That's because when a document loads, the browser creates arrays of like objects in the document. For example, if your page includes two `<form>` tag sets, two forms appear in the document. The browser maintains an array of `form` objects for that document. References to those forms are

```
document.forms[0]
document.forms[1]
```

You can also capture this array using the DOM method `getElementsByTagName()`:

```
var aForms = document.getElementsByTagName('form');
```

and then refer to the form array items with:

```
aForms[0]
aForms[1]
```

Index values for objects are assigned according to the loading order of the objects. In the case of `form` objects, the order is dictated by the order of the `<form>` tags in the document. This indexed array syntax is another way to reference forms in an object reference. You can still use a form's identifier (`id` attribute) if you prefer — and we heartily recommend using object names wherever possible, because even if you change the physical order of the objects in your HTML, references that use names still work without modification. But if your page contains only one form, you can use the reference types interchangeably, as in the following examples of equivalent references to the `length` property of a form's `elements` array (the `elements` array contains all the form controls in the form):

```
document.getElementById("entryForm").elements.length
document.forms[0].elements.length
document.getElementsByTagName('form')[0].elements.length
```

In examples throughout this book, you can see that we often use the array type of reference to simple forms in simple documents. But in our production pages, we almost always use named references.

Exercises

1. With your newly acquired knowledge of functions, event handlers, and control structures, use the script fragments from this chapter to complete the page that has the lookup table for all the states and the years they entered into the union. If you do not have a reference book for the dates, use different year numbers, starting with 1800 for each entry. In the page, create a text entry field for the state and a button that triggers the lookup in the arrays.

2. Examine the following function definition. Can you spot any problems with the definition? If so, how can you fix the problems?

```
function format(ohmage)
{
   var result;
   if ohmage >= 1e6
   {
      ohmage = ohmage / 1e6;
      result = ohmage + " Mohms";
   }
   else
   {
      if (ohmage >= 1e3)
         ohmage = ohmage / 1e3;
         result = ohmage + " Kohms";
      else
         result = ohmage + " ohms";
}
alert(result);
```

3. Devise your own syntax for the scenario of looking for a ripe tomato at the grocery store, and write a `for` loop using that object and property syntax.
4. Modify Listing 9-2 so that it does not reuse the `Dog` variable inside the function.
5. Given the following table of data about several planets of our solar system, create a web page that enables users to enter a planet name and, at the click of a button, have the distance and diameter appear either in an alert box or (as extra credit) in separate fields of the page.

Planet	Distance from the Sun	Diameter
Mercury	36 million miles	3,100 miles
Venus	67 million miles	7,700 miles
Earth	93 million miles	7,920 miles
Mars	141 million miles	4,200 miles

CHAPTER

10

Window and Document Objects

IN THIS CHAPTER

What the window object does

How to access key window object properties and methods

How to trigger script actions after a document loads

The purposes of the location and navigator objects

How the document object is created

How to access key document object properties and methods

Now that you have exposure to programming fundamentals, it is easier to demonstrate how to script objects in documents. Starting with this lesson, the tutorial turns back to the Document Object Model (DOM), diving more deeply into the objects you will place in many of your documents.

Top-Level Objects

As a refresher, study the hierarchy of top-level objects in Figure 10-1. This chapter focuses on objects of this level that you'll frequently encounter in your scripting: `window`, `location`, `navigator`, and `document`. The goal is not only to equip you with the basics so you can script simple tasks, but also to prepare you for the in-depth examinations of each object and its properties, methods, and event handlers, that you will find in Part IV, "Document Objects Reference." We introduce only the basic properties, methods, and events for objects in this tutorial. Examples in Part IV of the book assume that you know the programming fundamentals covered here in Part II.

The window Object

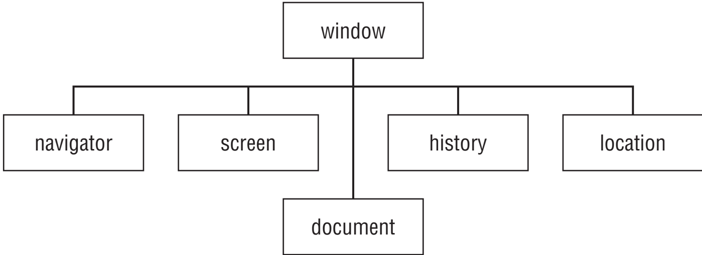
At the top of the object hierarchy is the `window` object. This object gains that exalted spot in the object food chain because it is the master container for all content you view in the web browser. As long as a browser window is open — even if no document is loaded in the window — the `window` object is defined in the current model in memory.

In addition to the content part of the window where documents go, a window's sphere of influence includes the dimensions of the window and all the stuff that surrounds the content area. The area where scrollbars, toolbars, the status bar, and (non-Macintosh) menu bar live is known as a window's *chrome*. Not every browser has full scripted control over the chrome of the main browser window,

but you can easily script the creation of additional windows sized the way you want and with only the chrome elements you wish to display.

FIGURE 10-1

The top-level browser object model for all scriptable browsers.



Although the discussion of frames comes in Chapter 13, "Scripting Frames and Multiple Windows," we can now safely say that each frame is also considered a `window` object. If you think about it, that makes sense, because each frame can hold a different document. When a script runs in one of those documents, it regards the frame that holds the document as the `window` object in its view of the object hierarchy.

As you will learn in this chapter, the `window` object is a convenient place for the DOM to attach methods that display modal dialog boxes and adjust the text that displays in the status bar at the bottom of the browser window. A `window` object method enables you to create a separate window that appears onscreen. When you look at all of the properties, methods, and events defined for the `window` object (see Chapter 27, "Window and Frame Objects"), it should be clear why they are attached to window objects: Visualize their scope and the scope of a browser window.

Note

In the modern crop of browsers, the user is given the choice of opening web pages either in new *tabs* within one browser or in new *browser windows*, which are separate copies of the browser program on the desktop. JavaScript does not exert any control whatsoever over this choice, which remains the user's prerogative. Browser windows and browser tabs are both identically `window` objects to JavaScript. Efforts to control features such as window size and the appearance of toolbars will either fail or will frustrate the user's attempts to make their browser conform to their own personal usability standards. In other words, if you don't want to irritate web site visitors, don't try to mess with their settings. Trust users to manage their browsers. Focus your creative energies on the content and style of the page, not the window chrome. ■

Accessing window properties and methods

You can word script references to properties and methods of the `window` object in several ways, depending more on whim and style than on specific syntactical requirements. The most logical and common way to compose such references includes the `window` object in the reference:

```
window.propertyName
window.methodName([parameters])
```

A window object also has a synonym when the script doing the referencing points to the window that houses the document. The synonym is self. Then the reference syntax becomes

```
self.propertyName
self.methodName([parameters])
```

You can use these initial reference object names interchangeably, but we tend to reserve the use of self for more complex scripts that involve multiple frames and windows. The self moniker more clearly denotes the current window holding the script's document, and can make the script more readable — by us and by others.

Back in Chapter 6, "Browser and Document Objects," we indicated that because the window object is always there when a script runs, you can omit it from references to any objects inside that window. Therefore, the following syntax models assume properties and methods of the current window:

```
propertyName
methodName([parameters])
```

In fact, as you will see in a few moments, some methods may be more understandable if you omit the window object reference. The methods run just fine either way.

Creating a window

A script does not create the main browser window. A user does that by virtue of launching the browser or by opening a URL or file from the browser's menus (if the window is not already open). But a script can generate a large number of subwindows when the main window is open (and that window contains a document whose script needs to open subwindows).

The method that generates a new window is window.open(). This method contains up to three parameters that define window characteristics: the URL of the document to load, its name for target attribute reference purposes in HTML tags, and physical appearance (size and chrome contingent). We don't go into the details of the parameters here (they're covered in great depth in Chapter 27), but we do want to expose you to an important concept involved with the window.open() method.

Consider the following statement, which opens a new window to a specific size and with an HTML document from the same server directory that holds the current page:

```
var subWindow = window.open("define.html","def","height=200,width=300");
```

The important thing to note about this statement is that it is an assignment statement. Something gets assigned to that variable subWindow. What is it? It turns out that when the window.open() method runs, it not only opens that new window according to specifications set as parameters, but also evaluates to a reference to that new window. In programming parlance, the method is said to *return a value* — in this case, a genuine object reference. The value returned by the method is assigned to the variable.

Now your script can use that variable as a valid reference to the second window. If you need to access one of its properties or methods, you must use that reference as part of the complete reference. For example, to close the subwindow from a script in the main window, use this reference to the close() method for that subwindow:

```
subWindow.close();
```

If you issue `window.close()`, `self.close()`, or just `close()` in the main window's script, the method closes the main window (after confirming with the user), but not the subwindow. To address another window, then, you must include a reference to that window as part of the complete reference. This has an impact on your code because you probably want the variable holding the reference to the subwindow to be valid as long as the main document is loaded into the browser. For that to happen, the variable has to be initialized as a global variable, rather than inside a function (although you can set its value inside a function). That way, one function can open the window while another function closes it.

Listing 10-1 is a page that has a button for opening a blank new window and a button for closing that window from the main window. To view this demonstration, shrink your main browser window to less than full screen. Then, when the new window is generated, reposition the windows so you can see the smaller, new window when the main window is in front. (If you lose a window behind another, use the browser's Window menu to choose the hidden window.) The key point of Listing 10-1 is that the `newWindow` variable is defined as a global variable so that both the `makeNewWindow()` and `closeNewWindow()` functions have access to it. When a variable is declared with no value assignment, its initial value is `null`. A `null` value is interpreted to be the same as `false` in a condition, whereas the presence of any nonzero value is the same as `true` in a condition. Therefore, in the `closeNewWindow()` function, the condition tests whether the window has been created before issuing the subwindow's `close()` method. Then, to clean up, the function sets the `newWindow` variable to `null` so that another click of the Close button doesn't try to close a nonexistent window.

Note

The property assignment event-handling technique employed throughout the code in this chapter, and much of the book, is `addEvent()`, a cross-browser event handler explained in detail in Chapter 32, "Event Objects."

The `addEvent()` function is part of the script file `jsb-global.js`, located on the accompanying CD-ROM in the `Content/` folder where it is accessible to all chapters' scripts. ■

References to Window Objects

HTML: jsb-10-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Window Open &amp; Close</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-10-01.js"></script>
   </head>
   <body>
      <h1>Window Open &amp; Close</h1>
      <form>
         <p>
            <input type="button" id="create-window" value="Create New Window">
            <input type="button" id="close-window" value="Close New Window">
         </p>
      </form>
```

```
   </body>
</html>
```

JavaScript: jsb-10-01.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to critical elements
      var oButtonCreate = document.getElementById('create-window');
      var oButtonClose = document.getElementById('close-window');

         // if they all exist...
         if (oButtonCreate && oButtonClose)
         {
            // apply behaviors
            oButtonCreate.onclick = makeNewWindow;
            oButtonClose.onclick = closeNewWindow;
         }
   }
}

var newWindow;

function makeNewWindow()
{
   newWindow = window.open("","","height=300,width=300");
}

function closeNewWindow()
{
   if (newWindow)
   {
      newWindow.close();
      newWindow = null;
   }
}
```

window Properties and Methods

The three methods for the `window` object described in this section have an immediate impact on user interaction by displaying dialog boxes of various types. They work with all scriptable browsers. You can find extensive code examples in Part IV for each property and method. You can also experiment with the one-statement script examples by entering them in the top text box of The Evaluator Jr. (from Chapter 8, "Programming Fundamentals, Part I").

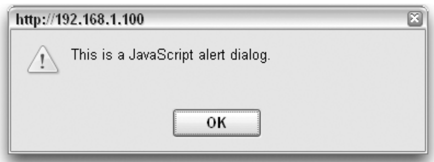
One of the first questions that new scripters ask is how to customize the title bars, sizes, and button labels of these dialog boxes. Each browser maker dictates how these dialogs are labeled. Because tricksters have tried to use these dialog boxes for nefarious purposes over the years, browser makers now go to great lengths to let users know that the dialog boxes emanate from web page scripts. Scripters cannot alter the user interfaces of these dialog boxes.

window.alert() method

We use the `alert()` method many times in this tutorial. This window method generates a dialog box that displays whatever text you pass as a parameter (see Figure 10-2). A single OK button (whose label you cannot change) enables the user to dismiss the alert.

FIGURE 10-2

A JavaScript alert dialog box.



All three dialog-box methods are good cases for using a `window` object's methods without the reference to the window. Even though the `alert()` method technically is a `window` object method, no special relationship exists between the dialog box and the window that generates it. In production scripts, we usually use the shortcut reference:

```
alert("This is a JavaScript alert dialog.");
```

window.confirm() method

The second style of dialog box presents two buttons (Cancel and OK in most versions on most platforms) and is called a confirm dialog box (see Figure 10-3). More important, this is one of those methods that returns a value: `true` if the user clicks OK or `false` if the user clicks Cancel. You can use this dialog box and its returned value as a way to have a user make a decision about how a script progresses.

FIGURE 10-3

A JavaScript confirm dialog box (IE7/WinXP style).

Because the method always returns a Boolean value, you can use the evaluated value of the entire method as a condition statement in an `if` or `if...else` construction. For example, in the following

code fragment, the user is asked about starting the application over. Doing so causes the `index.html` page to load into the browser.

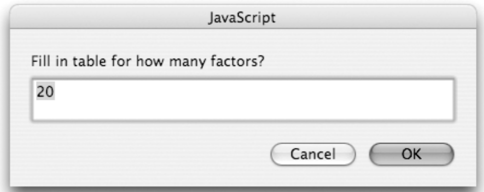
```
if (confirm("Are you sure you want to start over?"))
{
    location.href = "index.html";
}
```

window.prompt() method

The final dialog box of the `window` object, the prompt dialog box (see Figure 10-4), displays a message that you set and provides a text field for the user to enter a response. Two buttons, Cancel and OK, enable the user to dismiss the dialog box with two opposite expectations: canceling the entire operation or accepting the input typed in the dialog box.

FIGURE 10-4

A JavaScript prompt dialog box (Safari 2 style).



The `window.prompt()` method has two parameters. The first is the message that acts as a prompt to the user. You can suggest a default answer in the text field by including a string as the second parameter. If you don't want any default answer to appear, include an empty string (two double quotes without any space between them).

This method returns one value when the user clicks either button. A click of the Cancel button returns a value of `null`, regardless of what the user types in the field. A click of the OK button returns a string value of the typed entry. Your scripts can use this information in conditions for `if` and `if...else` constructions. A value of `null` is treated as `false` in a condition. It turns out that an empty string is also treated as `false`. Therefore, a condition can easily test for the presence of real characters typed in the field to simplify a conditional test, as shown in the following fragment:

```
var answer = prompt("What is your name?","");
if (answer)
{
   alert("Hello, " + answer + "!");
}
```

In this example, the only time the `alert()` method is called is when the user enters something in the prompt dialog box and clicks the OK button.

load event

The `window` object reacts to several system and user events, but the one you will probably use most often is the event that fires as soon as everything in a page finishes loading. This event waits for

images, Java applets, and data files for plug-ins to download fully to the browser. It can be dangerous to script access to elements of a document object while the page loads because if the object has not loaded yet (perhaps due to a slow network connection or server), a script error results. The advantage of using the `load` event to invoke functions is that you are assured that all document objects are in the browser's DOM.

The `load` event handler can be applied to the `window` object in several ways, depending on the browser and the circumstances:

```
window.addEventListener('load', functionName, false);
window.attachEvent('onload', functionName);
```

where `functionName` is the function you've written that you want to run as soon as the page has downloaded. (For a cross-browser event-adding function, see Chapter 32.) `addEventListener` and `attachEvent` can be called multiple times to add more than one function to the list to be executed when the page has loaded.

You can also apply the behavior directly to the element:

```
window['onload'] = functionName;
window.onload = functionName;
```

However, this usage dictates that there will be only one function to run when the page is loaded, replacing any event handler already assigned to the `window` object.

In old-school legacy web pages, you'll sometimes find the window event handler applied to the `body` element right in the HTML:

```
<body onload="functionName()">
```

(Even though you will come to associate the `<body>` tag's attributes with the `document` object's properties, it is the `window` object's event handlers that go inside the tag.) This embedding of JavaScript into the fabric of the HTML is considered poor usage today for several reasons: it doesn't let browsers that can't handle the scripting fail gracefully, it makes the HTML file heavier than it has to be, and it makes both the script and the markup messier and more time-consuming to modify. Separation of layers is the way to go.

Cross-Reference

For more on the `window.onload` event, see Chapter 27, "Window and Frame Objects." ■

The location Object

Sometimes an object in the hierarchy represents something that doesn't seem to have the kind of physical presence that a window or a button does. That's the case with the `location` object. This object represents the URL loaded into the window. This differs from the `document` object (discussed later in this lesson): the document is the content of the page, while the location is its URL (Uniform Resource Locator or address).

A URL consists of many components that define the address and method of data transfer for a file. Pieces of a URL include the protocol (such as `http:`) and the hostname (such as `www.example.com`). You can access all these items as properties of the `location` object. For the

most part, though, your scripts will be interested in only one property: the `href` property, which defines the complete URL.

Setting the `location.href` property is the primary way your scripts navigate to other pages:

```
location.href = "http://www.example.com/contact.html";
```

For pages outside the domain of the current page, you need to specify the complete URL. You can generally navigate to a page in your own web site by specifying a relative URL (that is, relative to the currently loaded page) rather than the complete URL with protocol and host information.

```
location.href = "contact.html";   // relative URL
```

If the page to be loaded is in another window or frame, the window reference must be part of the statement. For example, if your script opens a new window and assigns its reference to a variable named `newWindow`, the statement that loads a page into the subwindow is

```
newWindow.location.href = "http://www.example.com";
```

The navigator Object

Despite a name reminiscent of the Netscape Navigator-branded browser, the `navigator` object is implemented in all scriptable browsers. All browsers also implement a handful of properties that reveal the same kind of information that browsers send to servers with each page request. Thus, the `navigator.userAgent` property returns a string with numerous details about the browser and operating system. For example, a script running in Internet Explorer 8 in Windows XP receives the following value for the `navigator.userAgent` property:

```
Mozilla/4.0 (compatible; MSIE 8.0; Windows NT 5.1)
```

The same script running in Firefox 3.5.2 on a Macintosh reveals the following `userAgent` details:

```
Mozilla/5.0 (Macintosh; U; PPC Mac OS X 10.4; en-US; rv:1.9.1.2)
    Gecko/20090729 Firefox/3.5.2
```

Cross-Reference

See Chapter 42, "Navigator and Other Environment Objects" (on the CD), for more details about the `navigator` object and the meaning of the values returned by its properties. Unfortunately, it cannot be trusted to accurately report the actual user agent make, model, and version. It once was used extensively to branch script execution according to various browser versions. Chapter 25, "Document Object Model Essentials," describes more modern ways to detect the capabilities of the browser. ■

The document Object

The `document` object holds the real content of the page. Properties and methods of the `document` object generally affect the look and content of the document that occupies the window. As you saw in Chapter 5, "Your First JavaScript Script," all W3C DOM-compatible browsers allow script access

to the text contents of a page when the document has loaded. You've also seen that DOM methods let a script create content dynamically after the page has loaded. Many `document` object properties are arrays of other objects in the document, which provide additional ways to reference these objects (over and above the `document.getElementById()` method).

Accessing a `document` object's properties and methods is straightforward, as shown in the following syntax examples:

```
[window.]document.propertyName
[window.]document.methodName([parameters])
```

The `window` reference is optional when the script is accessing the `document` object that contains the script. If you want a preview of the long list of `document` object properties of IE or a Mozilla-based browser, enter `document` in the object text box of The Evaluator Jr. and press Enter/Return. The object's properties, current values, and value types appear in the Results box (as well as methods in Mozilla). Following are some of the most commonly used properties and methods of the `document` object.

document.getElementById() method

You met the `document.getElementById()` method in Chapter 5 when learning about the syntax for referencing element objects. This W3C DOM method is one you will use a lot. Get to know its finger-twisting name well. Be sure to honor the upper- and lowercase spelling of this all-important method.

The sole parameter of this method is a quoted string containing the ID of the element you wish to reference. The Evaluator Jr. page from Chapter 8 (and in the listings on the CD-ROM) has several element objects with IDs, including `input`, `output`, and `inspector`. Type this method in the top text box with each ID, as in the following example:

```
document.getElementById("output")
```

The method returns a value, which you typically preserve in a variable for use by subsequent script statements — for example:

```
var oneTable = document.getElementById("salesResults");
```

After the assignment statement, the variable represents the element object, allowing you to get and set its properties or invoke whatever methods belong to that type of object.

document.getElementsByTagName() method

`getElementsByTagName()` is a handy method for collecting an array of page elements that share the same tag name. For example, to get a list of all of the images on the page, we could call:

```
var aImages = document.getElementsByTagName('img');
```

Referring to an image by its position in an array of all images can be challenging — for example, if we want to work with an image gallery on a page that also contains miscellaneous images before and after the gallery. One of the advantages of using `getElementsByTagName()` is that it can gather a collection within any container element on the page:

```
HTML:

<div id="gallery">
   <h2>My Gallery</h2>
   <img src="bat.jpg" alt="bat">
   <img src="cat.jpg" alt="cat">
   <img src="hat.jpg" alt="hat">
</div>

JavaScript:

var oGallery = document.getElementById('gallery');
var aCollection = oGallery.getElementsByTagName('img');
```

The array `aCollection()` in this example then contains the three image objects (but not, of course, the `h2` element). As you'll recall from the discussion of arrays in Chapter 9, "Programming Fundamentals, Part II," an index number inside an array's square brackets points to one of the elements in the array. To find out how many objects are in the collection, use

```
aCollection.length
```

Each object can be accessed by its offset into the array:

```
oImage = aImages[0];   // first image
oImage = aImages[1];   // second image
```

Other applications of this method might be to collect all the items in a list, all the hyperlinks (anchors) in a text block, or all the multimedia objects on a page.

document.forms[] property

Implemented back in pre-DOM days, the `document.forms` property of the document object contains an array of all `form` element objects in the document. Compare these two expressions:

```
var aForms = document.forms;
var aForms = document.getElementsByTagName('form');
```

One important difference is that the `document.forms` collection enables us to reference a particular form directly by its name, not just by its offset in the array. It isn't always practical to refer to a form by its index number. A dynamic web page might contain a varying number of forms depending on context, so the position of any one form on the page might change with circumstances. For example, a Search form that sits in the header chrome of every page of a web site might be suppressed on the Advanced Search page; a Join List form might be suppressed on the Contact page; and a page listing workshops might blossom with registration forms for selected workshops.

Scriptable browsers let you refer to a form more directly by its name or ID (that is, the identifier assigned to either the `name` or `id` attribute of the `<form>` tag):

```
<form id="formId" name="formName" ...>
```

The first way is by using the `getElementById()` method:

```
document.getElementById("formId")
```

The second way uses array syntax, applying the form's name or ID as a string index value of the array:

```
document.forms["formId"]
document.forms["formName"]
```

A third, even shorter way to refer to a `form` object by name is to append the name as a property of the `document` object, as in:

```
document.formName
```

However, this last technique works only if the `name` attribute omits several characters that are legal in HTML element names but illegal in JavaScript object names such as hyphen (`-`), period (`.`), and colon (`:`). (For more on this point, see Chapter 6.)

Any of these methodologies reaches the same object. We will primarily be using the DOM methods `getElementById()` and `getElementsByTagName()` throughout this book; however, the `document.forms` collection syntax, which dates back to the earliest scriptable browsers, is still valid in the most modern versions.

document.images[] property

Just as a document keeps track of forms in a special array property, the `document` object maintains a collection (array) of images inserted into the document by way of `<img>` tags. Images referenced through the `document.images` array may be reached by either numeric or string index of the `img` element's name. Just as with forms, the `name` attribute value is the identifier you use for a string index.

The presence of the `document.images` property indicates that the browser supports image objects and therefore scripting techniques such as image-swapping. Thus, you can use the existence of the property as a test condition to make sure the browser supports images as objects before attempting to perform any script action on an image. To do so, surround statements that deal with images with an `if` construction that verifies the property's existence, as follows:

```
if (document.images)
{
    // statements dealing with img objects
}
```

Older browsers skip the nested statements, preventing them from displaying error messages to their users.

In a typical, complex web page today, there are images in different sections used for very different purposes, and it doesn't often make sense to collect all the images on a page in a single array. In cases like this, it might be more convenient to use the DOM method `getElementsByTagName()` instead (see above).

document.createElement() and document.createTextNode() methods

Adding a new element to an HTML document consists of, at minimum, two steps:

1. Create the new element for the document.
2. Insert it exactly where you want it within the tree structure of the page.

The `document.createElement()` method lets you create a brand-new element object in the browser's memory. To specify the element you wish to create, pass the tag name of the element as a string parameter of the method:

```
var newElem = document.createElement("p");
```

You may also want to add some attribute values to the element, which you may do by assigning values to the newly created object's properties, even before the element becomes part of the document.

```
newElem.setAttribute("class", "intro");
```

This element can be inserted wherever you want in the document — for example, at the end:

```
document.body.appendChild(newElem);
```

These three lines of code generate a paragraph at the end of the document body:

```
<body>
...
<p class="intro"></p></body>
```

As you saw in the object hierarchy illustrations in Chapter 6, "Browser and Document Objects," an element object frequently needs text content between its start and end tags. The W3C DOM way to create that text is to generate a brand new text node via the `document.createTextNode()` method and populate the node with the desired text. For example:

```
var newText = document.createTextNode("Greetings to all.");
newElem.appendChild(newText);
```

resulting in:

```
<body>
...
<p class="intro">Greetings to all.</p></body>
```

As you can see, the act of creating an element or text node does not by itself influence the document node tree. You must invoke one of the various insertion or replacement methods to place the new text node in its element and place the element in the document, as you learned how to do in Chapter 5.

document.write() method

The `document.write()` method is another way of writing content to a document. It has the advantage of being "quick and dirty," but it also has several disadvantages:

- `document.write()` can add a piece of a web page only while the page is loading into the browser the first time. Any subsequent invocation of the method replaces the entire page.
- Because `document.write()` will insert any old block of text into the document, it enables sloppy programming habits and malformed markup, encourages the mixture of markup with content in scripting, and does not encourage the separation of development layers (structure from content).
- `document.write()` does not work with XHTML, a document type that doesn't permit its content to be modified during the initial parsing.

For these reasons we do not recommend that you use `document.write()` in your own code, though it's still useful to understand how it works in order to be able to read legacy code.

The `document.write()` method operates both in immediate scripts to create content in a page as it loads and in deferred scripts that create new content in the same window or in a different window. The method requires one string parameter, the HTML content to be written to the window or frame. Such string parameters can be variables or any other expressions that evaluate to a string. Very often, the written content includes HTML tags.

Bear in mind that after a page loads, the browser's *output stream* automatically closes. After that, any `document.write()` method issued to the current page opens a new stream that immediately erases the current page (along with any variables or other values in the original document). Therefore, if you wish to replace the current page with script-generated HTML, you need to accumulate that HTML in a variable and perform the writing with just one `document.write()` method. You don't have to clear a document explicitly and open a new data stream; one `document.write()` call does it all.

One last piece of housekeeping advice about the `document.write()` method involves its companion method, `document.close()`. Your script must close the output stream when it finishes writing its content to the window (either the same window or another). After the last `document.write()` method in a deferred script, be sure to include a `document.close()` method. Failure to do this may cause images and forms not to appear. Also, any `document.write()` method invoked later will only append to the page, rather than clear the existing content to write anew.

To demonstrate the `document.write()` method, we show two versions of the same application. One writes to the same document that contains the script; the other writes to a separate window. Type the code for each document in a new text editor file, save them, and open the `.html` file in your browser.

Listing 10-2 creates a button that assembles new HTML content for a document, including HTML tags for new document title and color attributes for the `<body>` tag. An operator in the listing that may be unfamiliar to you is +=. It appends a string on its right side to whatever string is stored in the variable on its left side. This operator is a convenient way to accumulate a long string across several separate statements. With the content gathered in the `newContent` variable, one `document.write()` statement blasts the entire new content to the same document, obliterating all vestiges of the content of Listing 10-2. The `document.close()` statement, however, is required to close the output stream properly. When you load this document and click the button, notice that the document title in the browser's title bar changes accordingly. As you click back to the original and try the button again, notice that the dynamically written second page loads much faster than even a reload of the original document.

LISTING 10-2

Using document.write() on the Current Window

HTML: jsb-10-02.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Writing to Same Doc</title>
```

```
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-10-02.js"></script>
   </head>
   <body>
      <h1>Writing to Same Doc</h1>
      <form>
         <p>
            <input type="button" id="rewritePage" value="Replace Content">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-10-02.js

```
// replace the page with new markup
function reWrite()
{
 // assemble content for new window
 var newContent = '<!DOCTYPE html>';
 newContent += '<html>';
 newContent += '<head>';
 newContent += '<meta http-equiv="content-type"
    content="text/html;charset=utf-8">';
 newContent += '<title>A New Doc</title>';
 newContent += '<style type="text/css">';
 newContent += 'body { background-color: aqua; }';
 newContent += '</style>';
 newContent += '</head>';
 newContent += '<body>';
 newContent += '<h1>This document is brand new.</h1>';
 newContent += '<p>Click the Back button to see the original document.</p>';
 newContent += '</body>';
 newContent += '</html>';

 // write HTML to new window document
 document.write(newContent);
 document.close(); // close layout stream
}

// apply behaviors when document has loaded
function initialize()
{
 // do this only if the browser can handle DOM methods
 if (document.getElementById)
 {
    // point to the button
    var oButtonRewrite = document.getElementById('rewritePage');

       // if it exists...
       if (oButtonRewrite)
       {
```

continued

LISTING 10-2 *(continued)*

```
            // apply event handler
            addEvent(oButtonRewrite, 'click', reWrite);
        }
  }
}

// initialize when the page has loaded
addEvent(window, 'load', initialize);
```

In Listing 10-3, the situation is a bit more complex because the script generates a subwindow to which an entirely script-generated document is written.

Note

You will have to turn off pop-up window blocking temporarily to run this script. ■

To keep the reference to the new window alive across both functions, the `newWindow` variable is declared as a global variable. As soon as the page loads, the `onload` event handler invokes the `makeNewWindow()` function. This function generates a blank subwindow. We added a property to the third parameter of the `window.open()` method that instructs the status bar of the subwindow to appear.

A button in the page invokes the `subWrite()` method. The first task it performs is to check the `closed` property of the subwindow. This property returns `true` if the referenced window is closed. If that's the case (if the user closed the window manually), the function invokes the `makeNewWindow()` function again to reopen that window.

With the window open, new content is assembled as a string variable. As with Listing 10-2, the content is written in one blast (although this isn't necessary for a separate window), followed by a `close()` method. But notice an important difference: Both the `write()` and `close()` methods explicitly specify the subwindow.

LISTING 10-3

Using document.write() on Another Window

HTML: jsb-10-03.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Writing to Subwindow</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-10-03.js"></script>
   </head>
   <body>
      <h1>Writing to Subwindow</h1>
      <form>
```

```
         <p>
            <input type="button" id="writeSubwindow" value="Write to Subwindow">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-10-03.js

```
var newWindow;

function makeNewWindow()
{
   newWindow = window.open("","","status,height=200,width=300");
}

function subWrite()
{
    // make new window if someone has closed it
    if (!newWindow || newWindow.closed)
    {
       makeNewWindow();
    }

 // bring subwindow to front
 newWindow.focus();

 // assemble content for new window
 var newContent = '<!DOCTYPE html>';
 newContent += '<html>';
 newContent += '<head>';
 newContent += '<meta http-equiv="content-type"
     content="text/html;charset=utf-8">';
 newContent += '<title>A New Doc</title>';
 newContent += '<style type="text/css">';
 newContent += 'body { background-color: aqua; }';
 newContent += '</style>';
 newContent += '</head>';
 newContent += '<body>';
 newContent += '<h1>This document is brand new.</h1>';
 newContent += '</body>';
 newContent += '</html>';

 // write HTML to new window document
 newWindow.document.write(newContent);

 // close layout stream
 newWindow.document.close();
}

// apply behaviors when document has loaded
function initialize()
{
```

continued

LISTING 10-3 *(continued)*

```
  // do this only if the browser can handle DOM methods
  if (document.getElementById)
  {
     // point to the button
     var oButtonRewrite = document.getElementById('writeSubwindow');

        // if it exists...

        if (oButtonRewrite)
        {
           // apply event handler
           addEvent(oButtonRewrite, 'click', subWrite);
        }
  }
}

// initialize when the page has loaded
addEvent(window, 'load', initialize);
addEvent(window, 'load', makeNewWindow);
```

The next logical step after the document level in the object hierarchy is the form. That's where you will spend the next lesson.

Exercises

1. Which of the following references are valid, and which are not? Explain what is wrong with the invalid references.
   a. `window.document.form[0]`
   b. `self.entryForm.submit()`
   c. `document.forms[2].name`
   d. `document.getElementByID("firstParagraph")`
   e. `newWindow.document.write("Howdy")`
2. Write the JavaScript statement that displays an (annoying) dialog box welcoming visitors to your web page.
3. Write the JavaScript statement that executes while the page loads to display the same message from Question 2 to the document as an `<h1>`-level headline on the page.
4. Create a page that prompts the user for his or her name as the page loads (via a dialog box) and then welcomes the user by name in the body of the page.
5. Create a page with any content you like, but one that automatically displays a dialog box after the page loads to show the user the URL of the current page.

CHAPTER 11

Forms and Form Elements

IN THIS CHAPTER

What the form object represents

How to access key form object properties and methods

How text, button, and select objects work

How to submit forms from a script

How to pass information from form elements to functions

Most interactivity between a web page and the user takes place inside a form. That's where a lot of the interactive HTML stuff lives for every browser: text fields, buttons, checkboxes, option lists, and so on.

In this chapter, we discuss how to locate forms and their controls in the document tree, how to change them, how to examine the user's input, and how to submit a form or suppress submission if the input doesn't validate.

The Form object

A form and the input controls that go inside it are DOM objects with unique properties that other objects in the document don't have. For example, a form object has an `action` property that tells the browser where to send input values when a form is submitted. A `select` control (drop-down list) has a `selectedIndex` property that tells us which option has been selected by the user.

Our first step is to point to the form on the page. Here are three ways of doing this, all referring to the following abbreviated snippet of a page that contains three forms:

```
<div id="header">
   <form id="search" action="...">...</form>
   <form id="join-list" action="...">...</form>
</div>
   ...
   <form id="contact" action="...">...</form>
   ...
```

1. The DOM method `getElementById()`, as described in previous chapters, gives us a handle on a single, specific element on the page if we know its `id` attribute:

   ```
   var oForm = document.getElementById('search');
   ```

In practice, using `getElementById()` suffices most of the time because web pages generally contain one or a very small number of unique forms which accomplish very different tasks; assigning them unique IDs in the markup is a natural.

2. The DOM method `getElementsByTagName()` delivers an array or collection of form objects with a given tag name:

```
var aForms = document.getElementsByTagName('form');
var oForm = aForms[0];  // get the first form on the page
```

As always, JavaScript arrays begin with the first item having an index of zero, so our collection of three forms can be addressed as array elements 0, 1, and 2.

It's worth pondering the usefulness of working with a collection of all the forms on a page. In order to locate a specific form from the collection, we would have to know its position among all the forms on the page (which could change in a rich, dynamic site) or we'd have to cycle through them looking for an identifier (which suggests using `getElementById()` in the first place).

One of the cool things about `getElementsByTagName()` is that it can give us a collection of objects within a particular parent other than the `document` element itself:

```
var oHeader = document.getElementById('header');
var aForms = oHeader.getElementsByTagName('form');
var oForm = aForms[0];
```

In this example, we're collecting all the forms in the "header" section of the document only.

Or imagine a page listing a series of workshops, each of which has its own separate registration form. We could collect an array of all those registration forms by first pointing to their parent `div` without worrying about other miscellaneous forms on the page confusing the mix.

3. The syntax `document.forms` is another way of collecting all the forms on the page that pre-dates today's DOM methods but is still supported by modern browsers, so as not to break legacy web sites.

```
var aForms = document.forms;
// then point to one form:
var oForm = aForms[0];
// or:
var oForm = aForms["search"];
// or:
var oForm = aForms.search;
```

Using this original "DOM Level 0" syntax, we can reference a `form` object either by its position in the array of forms contained in a document or by name (if you assign an identifier to the `id` or `name` attribute inside the `<form>` tag). If only one form appears in the document, it is still a member of an array (a one-element array) and is referenced as follows:

```
document.forms[0]
```

Or use the string of the element's name as the array index:

```
document.forms[formName]
```

Notice that the array reference uses the plural version of the word, followed by a set of square brackets containing the index number (zero is always first) or name of the element. Alternatively, you can use the form's name (not as a quoted string) as though it were a property of the `document` object:

```
document.formName
```

However, this last syntax works only if the form `id` or `name` doesn't include characters such as hyphens, periods, or colons that would confuse JavaScript. For example, the second form in our sample HTML above has the `id` of `join-list`:

```
var oForm = document.forms.join-list;
```

This looks to JavaScript like we're trying to subtract the value of a variable named `list` from a `form` object with the `id` of `join`. This statement would either stop JavaScript cold or produce a result of `NaN` (Not a Number). As a general rule, we recommend that you use syntax that puts element names in quotes.

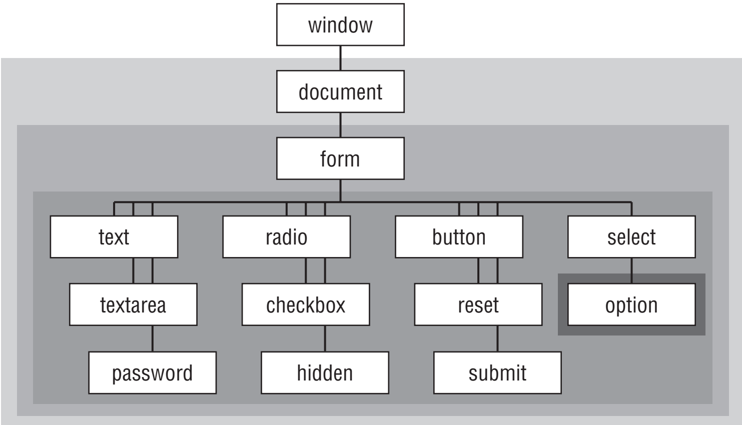
Because there are so many ways to arrive at a `form` object, we'll often represent them in further examples with the label `formObject`.

Form as object and container

Because the modern DOM is backward-compatible with many of yesterday's conventions, the form object finds itself the matriarch of two different family trees at the same time. The modern DOM Level 2 specifies that the form is the parent of all of its child nodes, both element and text nodes, whereas the older DOM Level 0 makes the form the container for all of its form control objects only (`input`, `select`, `button`, and `textarea` elements). Figure 11-1 shows the structure of this DOM 0 hierarchy and its place relative to the `document` object. You'll see the effect this structure has on the way you reference form control elements in a moment.

FIGURE 11-1

DOM Level 0 hierarchy for forms and controls.



Let's illustrate the difference by diagramming the following snippet of HTML:

LISTING 11-1

Sample form markup

```
<form action="search.php" method="post">
   <p>
      <label for="inputSearch">Search for:</label>
      <input id="inputSearch" name="inputSearch" type="text" value="">
      <input id="submit" type="submit" value="Search">
   </p>
</form>
```

Figure 11-2 shows the DOM Level 2 tree for this markup. Note that it represents the entire content of that segment of the document. The carriage returns, tabs, and spaces between elements are text nodes (represented here by the shorthand `"[whitespace]"`).

FIGURE 11-2

DOM Level 2 tree for a typical form.

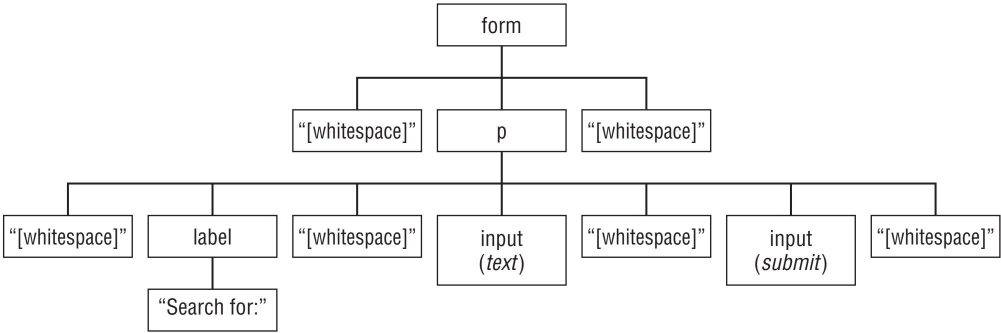


Figure 11-3 shows the DOM Level 0 tree for this same form. It includes only the input controls and omits the paragraph, the label, and the text nodes.

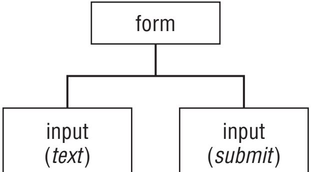
FIGURE 11-3

DOM Level 0 tree for the same form.



These two object trees are clearly useful for very different purposes. The DOM Level 2 tree can be used to read and write the entire document content with fine granularity. The DOM Level 0 tree makes it quick and easy to read and write the form controls only.

Please note that whether you're using DOM 0 or DOM 2 techniques in any given statement, the objects are the same. For example,

```
var oForm = document.getElementById('myForm');
var oControl = oForm.fritzy;
```

is perfectly valid JavaScript and will work fine if `fritzy` is the ID of an input control inside the form `myForm`.

In addition to a large collection of properties and methods it has in common with all HTML element objects, the form object features a number of items that are unique to this object. Almost all of these unique properties are scripted representations of the `form` element's attributes (`action`, `target`, and so on). Scriptable browsers allow scripts to change these properties under script control, which gives your scripts potentially significant power to direct the behavior of a form submission in response to user selections on the page.

Accessing form properties

Forms can be created from standard markup tags in the HTML page or by using DOM methods in JavaScript. Either way, you can set attributes such as `name`, `target`, `action`, `method`, and `enctype`. Each of these is a property of a form object, accessed by all lowercase versions of those words, as in:

```
var sURL = formObject.action;
```

To change any of these properties, simply assign new values to them:

```
formObject.action = "http://www.example.com/cgi/login.pl";
```

These last two JavaScript statements could be re-stated using compound object references:

```
var sURL = document.getElementById('formName').action;
document.forms[0].action = "http://www.example.com/cgi/login.pl";
```

However, combining multiple operations into a single expression doesn't allow the script to test for validity along the way. Separating steps and testing as we go is a more bulletproof way to code:

```
var oForm = document.getElementById ('formName');
   if (!oForm)
   {
      // do something if the named form isn't found
   }
var sURL = oForm.action;
```

form.elements[] property

The `elements[]` property is a collection of all the input controls within a form. This is another array with items listed in the order their HTML tags appear in the source code. It is generally more efficient to refer to a single element directly using its ID, but sometimes a script needs to look through all

of the elements in a form. For example, a form-validation routine might loop through every element checking to make sure that its value has been entered correctly by the user. A loop like that might not need to look at the text nodes and other elements that aren't form controls, and in fact it would have to perform a series of tests on each element it encountered to determine whether it were a control. In a case like this, using the `elements[]` collection is vastly more efficient.

The following code fragment shows the `form.elements[]` property at work in a `for` repeat loop that looks at every control element in a form to set the contents of text fields to an empty string. The script cannot simply barge through the form and set every element's content to an empty string because some elements may be types (for example, a button) whose `value` properties have different purposes.

```
var oForm = document.getElementById('registration-form');
   if (!oForm) return false;

for (var i = 0; i < oForm.elements.length; i++)
{
   if (oForm.elements[i].type == "text")
   {
      oForm.elements[i].value = "";
   }
}
```

In the first statement, we create the variable `oForm` that holds a reference to the desired form. We do this so that when we make many references to form elements later in the script, the typical length of each reference is much shorter (and marginally faster). We can use the `oForm` variable as a shortcut to building references to items more deeply nested in the form.

Next, we start looping through the items in the `elements` array for the form. Each form control element has a `type` property, which reveals what kind of form control it is: text, button, radio, checkbox, textarea, and so on. We're interested in finding elements whose type is `text`. For each of those, we set the `value` property to an empty string.

We're permitting compound expressions such as `oForm.elements[i].type` in this case because, having already tested to make sure the form exists, we can trust the DOM to deliver us a valid form control object with each iteration of the `elements[]` collection. Even if the form were empty of controls, the script wouldn't fail; if the `elements[]` collection were an empty array, the `for` loop above would simply terminate before its first iteration with no error because `oForm.elements.length` would be zero.

We'll return to forms later in this chapter to show you how to submit a form without a Submit button and how client-side form validation works.

Form Controls as Objects

Three kinds of HTML elements nested inside a `<form>` tag become scriptable objects in all browser DOMs. Most of the objects owe their existence to the `<input>` tag in the page's source code. Only the value assigned to the `type` attribute of an `<input>` tag determines whether the element is a text box, password entry field, hidden field, button, checkbox, or radio button. The other two kinds of form controls, `textarea` and `select`, have their own tags.

To reference a particular form control as an object, you can point directly to it using its `id` or `tagName` with DOM Level 2 methods, or, using DOM Level 0 syntax, build a reference as a hierarchy starting with the `document`, through the form, and then to the control. You've already seen how many ways you can reference merely the form part — all of which are valid for building form control references. But if you are using only the identifiers assigned to the form and form control elements (rather than the associated arrays of elements), the syntax is as follows:

```
document.getElementById(controlName)
```

or

```
document.formName.controlName
```

For example, consider the following simple form:

```
<form id="searchForm" action="cgi-bin/search.pl">
   <p>
      <input type="text" id="entry" name="entry">
      <input type="submit" id="sender" name="sender" value="Search">
   </p>
</form>
```

The following sample references to the text input control are all valid:

```
document.getElementById("entry")
document.searchForm.entry
document.searchForm.elements[0]
document.forms["searchForm"].elements["entry"]
document.forms["searchForm"].entry
```

Although form controls have several properties in common, some properties are unique to a particular control type or to related types. For example, only a `select` object offers a property that reveals which item in its list is currently selected. Checkboxes and radio buttons both have a property that indicates whether the control is currently set to on. Similarly, all text-oriented controls operate the same way for reading and modifying their content.

Having a good grasp of the scriptable features of form control objects is important to your success with JavaScript. In the next sections, you meet the most important form control objects and see how scripts interact with them.

Text-related input objects

Each of the four text-related HTML form elements — input elements of the `text`, `password`, and `hidden` types, plus the `textarea` element — is an element in the document object hierarchy. All but the hidden types are normally displayed on the page, enabling users to enter text and select options.

To make these form control objects scriptable in a page, you don't need to do anything special to their normal HTML tags — with the possible exception of assigning an `id` attribute. We strongly recommend assigning both unique IDs and names to every text-related form control element if your scripts will be getting or setting properties, or invoking their methods. IDs are handy for DOM manipulation and for associating labels with controls, and names are necessary for a form to function normally.

When a form is actually submitted to a server-side program, it is the control elements' `name` attributes that are sent to the server along with the elements' values.

For the visible objects in this category, event handlers are triggered from many user actions, such as giving a field focus (getting the text insertion pointer in the field) and changing text (entering new text and then leaving the field). Most of your text-field actions are triggered by the change of text (the `onchange` event handler). In current browsers, events fire in response to individual keystrokes as well.

Without a doubt, the single most-used property of a text-related element is the `value` property. This property represents the current contents of the text element. A script can retrieve and set its content at any time. Content of the `value` property is always a string. This may require conversion to numbers (see Chapter 8, "Programming Fundamentals, Part I") if text fields are used for entering values for math operations.

Text Object Behavior

Many scripters look to JavaScript to solve what are perceived as shortcomings or behavioral anomalies with text-related objects in forms. We want to single these out early in your scripting experience so that they do not confuse you later.

Most browser forms practice a behavior that was recommended long ago as an informal standard by web pioneers. When a form contains only one text `input` object, a press of the Enter/Return key while the text object has focus automatically submits the form. For two or more fields in browsers other than IE5/Mac and Safari, you need another way to submit the form (for example, a Submit button). This one-field submission scheme works well in many cases, such as the search page of most web search sites. But if you are experimenting with simple forms containing only one field, you can submit the form with a press of the Enter/Return key. Submitting a form that has no other action or target specified means the page performs an unconditional reload, wiping out any information entered into the form. You can, however, cancel the submission through an `onsubmit` event handler in the form, as shown later in this chapter. You can also script the press of the Enter/Return key in any text field to submit a form (see Chapter 32, ''Event Objects'').

To demonstrate how a text field's `value` property can be read and written, Listing 11-2 provides a complete HTML page with a single-entry field. When you enter text into the field and press Tab or Enter, the input text is made all uppercase.

LISTING 11-2

Getting and Setting a Text Object's value Property

HTML: jsb-11-02.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Text Object value Property</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-11-02.js"></script>
```

```
   </head>
   <body>
      <h1>Text Object value Property</h1>
      <form id="UCform" action="make-uppercase.php">
         <p>
            <input type="text" id="converter" name="converter" value="sample">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-11-02.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

var oInput;   // (global) input field to make uppercase

// apply behaviors when document has loaded
function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // apply event handler to the button
      oInput = document.getElementById('converter');
         if (oInput)
         {
            addEvent(oInput, 'change', upperMe);
         }

      // apply event handler to the form
      var oForm = document.getElementById('UCform');
         if (oForm)
         {
            addEvent(oForm, 'submit', upperMe);
         }
   }
}

// make the text UPPERCASE
function upperMe(evt)
{
      // consolidate event handling
      if (!evt) evt = window.event;

   // set input field value to the uppercase version of itself
   var sUpperCaseValue = oInput.value.toUpperCase();
   oInput.value = sUpperCaseValue;

   // cancel default behavior (esp. form submission)
      // W3C DOM method (hide from IE)
```

continued

LISTING 11-2 *(continued)*

```
        if (evt.preventDefault) evt.preventDefault();

    // IE method
    return false;
}
```

Here's how it works: When the page loads into the browser, the `initialize()` function applies event handlers to the form and to the input field it contains. The `onchange` event handler of both the form and the input field invokes the `upperMe()` function, which converts the text to uppercase.

Notice that the `oInput` variable, used to refer to the input field `converter`, is declared outside of all the functions and is therefore a global variable. This means that it's accessible from anywhere in the script. We've done this so that we can use it from two separate functions — `initialize()` and `upperMe()`. (In contrast to global variables, *local variables* are declared with `var` inside of a function and cannot be seen outside of the function in which they were declared.)

The core of the `upperMe()` function consists of two statements:

```
var sUpperCaseValue = oInput.value.toUpperCase();
oInput.value = sUpperCaseValue;
```

A lot goes on in the first statement of the function. The right side of the assignment statement performs a couple of key tasks. The reference to the `value` property of the object (`oInput.value`) evaluates to whatever content is in the text field at that instant. (Remember that `oInput` is that global variable that points to the input field `converter`.) Then that string is handed over to one of JavaScript's string functions, `toUpperCase()`, which converts the value to uppercase. The evaluated result of the right-side statement is then assigned to the second variable: `sUpperCaseValue`. Nothing has changed yet in the text box. That comes in the second statement, where the `value` property of the text box is assigned whatever the `sUpperCaseValue` variable holds. We've divided this logic into two statements for learning purposes so that you can see the process. In practice, you can combine the actions of steps 1 and 2 into one power-packed statement:

```
oInput.value = oInput.value.toUpperCase();
```

The `onchange` event for the input field is what makes the text uppercase when you press Tab to navigate away from that field. Because this is a one-input-field form, the Enter key acts to submit the form, so we've set the form's `onsubmit` event to run the `upperMe()` function as well. In addition to making the text uppercase, that function also cancels the normal submit behavior. (More on event capture later in this chapter.)

If JavaScript is disabled or not supported by the user agent rendering this page, the entered text is submitted to a server-side program called `make-uppercase.php`, which presumably performs the uppercasing of the text as well.

Note

The function to assign event handlers throughout the code in this chapter and much of the book is `addEvent()`**, a cross-browser event handler explained in detail in Chapter 32, "Event Objects."**

The `addEvent()` **function is located in the file** `jsb-global.js` **on the accompanying CD-ROM and is included in each HTML example with a** `script` **tag in the document** `head`**.** ■

The button input object

We use the button-type `input` element in many examples in this book. The button is one of the simplest objects to script. In the simplified object model of this tutorial, the button object has only a few properties that are rarely accessed or modified in day-to-day scripts. Like the text object, the visual aspects of the button are governed not by HTML or scripts but by the operating system and browser that the page visitor uses. By far the most useful event of the button object is the `click` event. It fires whenever the user clicks the button. Simple enough. No magic here.

The checkbox input object

A checkbox is also a simple element of the `form` object, but some of the properties may not be entirely intuitive. Unlike the `value` property of a plain button object (the text of the button label), the `value` property of a checkbox is any other text you want associated with the object. This text does not appear on the page in any fashion, but the property (initially set via the `value` attribute) might be important to a script that wants to know more about the purpose of the checkbox within the form.

For example, consider this:

```
<input type="checkbox" id="memory" name="remember-me" value="yup">
<label for="memory">Remember me on this computer</label>
```

If we check this checkbox and submit the form, the browser sends the server the name/value pair “remember-me” and “yup”; the label text “Remember me on this computer” appears on the screen but is not sent to the server.

The key property of a checkbox object is whether the box is checked. The `checked` property is a Boolean value: `true` if the box is checked, `false` if not. When you see that a property is a Boolean value, it’s a clue that the value will be easy to use in an `if` or `if...else` conditional expression. In Listing 11-3, the value of the `checked` property determines which alert box the user sees.

LISTING 11-3

The Checkbox Object’s checked Property

HTML: jsb-11-03.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Checkbox Inspector</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-11-03.js"></script>
   </head>
   <body>
      <h1>Checkbox Inspector</h1>
      <form action="">
         <p>
            <input type="checkbox" id="checkThis" name="checkThis">
```

continued

LISTING 11-3 *(continued)*

```
            <label for="checkThis">Check here</label>
            <input type="button" id="inspectIt" value="Inspect Box">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-11-03.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

var oCheckbox;   // checkbox object (global)

// apply behaviors when document has loaded
function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to crucial elements
      oCheckbox = document.getElementById('checkThis');
      var oButton = document.getElementById('inspectIt');

         // if they exist, apply event handler
         if (oCheckbox && oButton)
         {
            addEvent(oButton, 'click', inspectBox);
         }
   }
}

// report the checked state of the checkbox
function inspectBox()
{
   if (oCheckbox.checked)
   {
      alert("The box is checked.");
   }
   else
   {
      alert("The box is not checked at the moment.");
   }
}
```

Checkboxes are generally used as preference setters rather than as action inducers. Although a checkbox object has an `onclick` event handler, a click of a checkbox should never do anything drastic, such as navigate to another page.

The radio input object

Setting up a group of radio objects for scripting requires a bit more work. To let the browser manage the highlighting and unhighlighting of a related group of buttons, you must assign the same `name` attribute to each of the buttons in the group. You can have multiple radio groups within a form, but each member of the same group must have the same name.

Assigning the same name to a form element forces the browser to manage the elements differently than if they each had a unique name. Instead, the browser maintains an array list of objects with the same name. The name assigned to the group becomes the name of the array. Some properties apply to the group as a whole; other properties apply to individual buttons within the group and must be addressed via array index references. For example, you can find out how many buttons are in a radio group by reading the `length` property of the group:

```
formObject.groupName.length
```

If you want to find out whether a particular button is currently highlighted via the same `checked` property used for the checkbox, you can access the button element by its position in the collection of same-named input fields:

```
formObject.groupName[0].checked
```

Listing 11-4 demonstrates several aspects of the radio-button object, including how to look through a group of buttons to find out which one is checked, and how to use the `value` attribute and corresponding property for meaningful work.

The page includes three radio buttons and a plain button. Each radio button's `value` attribute contains the full name of one of the Three Stooges. When the user clicks the button, the `onclick` event handler invokes the `fullName()` function. In that function, the first statement creates a shortcut reference to the form. Next, a `for` repeat loop looks through all the buttons in the `stooges` radio-button group. An `if` construction looks at the `checked` property of each button. When a button is checked, the `break` statement bails out of the `for` loop, leaving the value of the `i` loop counter at the number where the loop broke ranks. Then the alert dialog box uses a reference to the `value` property of the `i`th button so that the full name can be displayed in the alert.

LISTING 11-4

Scripting a Group of Radio Objects

HTML: jsb-11-04.html

```
<!DOCTYPE html>
<html>

LISTING 11-4 *(continued)*

```
         <fieldset>
            <legend>Select your favorite Stooge:</legend>
            <p>
               <input type="radio" name="stooges" id="stooges-1"
               value="Moe Howard" checked>
               <label for="stooges-1">Moe</label>
            </p>
            <p>
               <input type="radio" name="stooges" id="stooges-2"
               value="Larry Fine">
               <label for="stooges-2">Larry</label>
            </p>
            <p>
               <input type="radio" name="stooges" id="stooges-3"
               value="Curly Howard">
               <label for="stooges-3">Curly</label>
            </p>
            <p>
               <input type="submit" id="Viewer" name="Viewer"
               value="View Full Name...">
            </p>
         </fieldset>
      </form>
   </body>
</html>
```

JavaScript: jsb-11-04.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

var aStooges;   // radio button array (global)

// apply behaviors when document has loaded
function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to crucial elements
      var oButton = document.getElementById('Viewer');
      var aForms = document.forms;
         if (aForms) aStooges = aForms[0].stooges;   // global variable

         // if they exist, apply event handler
         if (oButton && aStooges)
         {
            addEvent(oButton, 'click', showFullName);
         }
```

```
    }
}

// display the full name of the selected stooge
function showFullName()
{
    for (var i = 0; i < aStooges.length; i++)
    {
        if (aStooges[i].checked)
        {
            break;
        }
    }
    alert("You chose " + aStooges[i].value + ".");
}
```

The select object

The most complex form control to script is the `select` element object. As you can see from the DOM Level 0 form object hierarchy diagram (see Figure 11-1), the select object is really a compound object that contains an array of option objects. Moreover, you can establish this object in HTML to display itself as either a drop-down list or a scrolling list — the latter configurable to accept multiple selections by users. For the sake of simplicity at this stage, this lesson focuses on deploying it as a drop-down list that allows only single selections.

Some properties belong to the entire select object; others belong to individual options inside the select object. If your goal is to determine which item the user selects, and you want the code to work on the widest range of browsers, you must use properties of both the select and option objects.

The most important property of the select object itself is the `selectedIndex` property, accessed as follows:

```
formObject.selectName.selectedIndex
```

This value is the index number of the currently selected item. As with most index counting schemes in JavaScript, the first item (the one at the top of the list) has an index of zero. The `selectedIndex` value is critical for enabling you to access properties of the selected option. Two important properties of an option item are `text` and `value`, accessed as follows:

```
formObject.selectName.options[n].text
formObject.selectName.options[n].value
```

The `text` property is the string that appears onscreen in the select object's list. It is unusual for this information to be exposed as a form object property because the HTML that generates a select object defines the text as an `<option>` tag's nested text. But inside the `<option>` tag, you can set a `value` attribute, which, like the radio buttons shown earlier, enables you to associate some hidden string information with each visible entry in the list.

To read the `value` or `text` property of a selected option most efficiently for all browsers, you can use the select object's `selectedIndex` property as an index value to the option. References for this kind of operation get pretty long, so take the time to understand what's happening here. In the following function, the first statement creates a shortcut reference to the select object. Then the

selectedIndex property of the select object is substituted for the index value of the options array of that same object:

```
function inspect()
{
   var oList = document.getElementById('choices');
      if (oList)
      {
         var sChosenItemValue = oList.options[oList.selectedIndex].value;
      }
}
```

To bring a select object to life, use the onchange event handler. As soon as a user makes a new selection in the list, the script associated with the onchange event is run. Listing 11-5 shows a common application for a select object. Its text entries describe places to go in and out of a web site, and the value attributes hold the URLs for those locations. When a user makes a selection in the list, the onchange event handler triggers a script that extracts the value property of the selected option and assigns that value to the location.href object property to effect the navigation.

Of course, most of these new locations (web pages) won't already exist on your computer in the folder where the HTML page resides. When you select a location and your page attempts to relocate there, you'll see a "File not found" error page. Notice the intended page in the address bar, and then click the Back button to return to the sample form.

The form includes a submit button so that, when JavaScript is turned off or is non-existent in the user agent, the page still works by submitting the form to a server-side program to perform the redirection. Under JavaScript control, it can be argued that this kind of navigation doesn't need a separate Go button on the page, and in this example we've hidden the button from view using JavaScript to set its display style to "none." Note, however, that some people criticize the usability and accessibility of a select list that submits a form as soon as a selection is made. The argument is that since form submission isn't a normal function of a select list, adding that behavior with JavaScript will take some users by surprise and will switch them to a new page without their deliberate consent. Also, the list's behavior assumes that the user's first selection from the list is where they really want to go and doesn't allow for accidental selections, which anyone could make, but particularly those with motor-skill disabilities. Try this form with JavaScript turned off to see the difference for yourself.

LISTING 11-5

Navigating with a select Object

HTML: jsb-11-05.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Select Navigation</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-11-05.js"></script>
   </head>
   <body>
```

```
      <h1>Select Navigation</h1>
      <form action="redirect.php" method="get">
         <p>
            <label for="urlList">Choose a place to go:</label>
            <select id="urlList" name="urlList">
               <option selected value="index.html">Home Page</option>
               <option value="store.html">Shop Our Store</option>
               <option value="policies.html">Shipping Policies</option>
               <option value="http://www.google.com">Search the Web</option>
            </select>

            <input type="submit" id="submit-button" value="Go">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-11-05.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

var oList;   // select list (global)

// apply behaviors when document has loaded
function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to crucial elements
      oList = document.getElementById('urlList');
      oButton = document.getElementById('submit-button');

         // if they exist...
         if (oList && oButton)
         {
            // make the list dynamic
            addEvent(oList, 'change', goThere);

            // make the submit button disappear when JavaScript is running
            oButton.style.display = 'none';
         }
   }
}

// direct the browser to the selected URL
function goThere()
{
   location.href = oList.options[oList.selectedIndex].value;
}
```

Note
Recent browsers also expose the `value` property of the selected option item by way of the `value` property of the `select` object. This is certainly a logical and convenient shortcut, and you can use it safely if your target browsers include IE, Mozilla-based browsers, and Safari. ■

There is much more to the select object, including the ability to change the contents of a list in newer browsers. Chapter 37 covers the select object in depth.

Passing Elements to Functions with this

In all the examples so far in this lesson, when an event handler invokes a function that works with form elements, the form or form control is explicitly referenced by a global variable. But valuable shortcuts exist for transferring information about the form or form control directly to the function without having to declare global variables.

JavaScript features a keyword — `this` — that always refers to whatever object contains the script in which the keyword is used. For instance, if you attach a function to a button by its `click` event, then you click the button, the keyword `this` inside the function refers to the button itself. Using `this` is cool: it means having to use fewer global variables, lessening the chance that two independent scripts will someday use the same global variable name and mess up each other's logic, and it means that you can use the same generic function for multiple elements. Here's a simple example:

```
function identify()
{
   if (this.tagName)
   {
      alert('My tagName is ' + this.tagName);
   }
}
```

If you apply the `identify()` function to multiple elements on the page and then click them, each reports its `tagName`: `P`, `LABEL`, `INPUT`, `FORM`, `BODY`, etc.

Take a look at Listing 11-6. There are two functions that use the `this` keyword: `processData()`, which is attached to the submit button, and `verifySong()`, which is attached to the song name input field.

LISTING 11-6

Passing Elements to Functions with this

HTML: jsb-11-06.html

```
<!DOCTYPE html>
<html>
   <head>
     <meta http-equiv="content-type" content="text/html;charset=utf-8">
     <title>Beatle Picker</title>
     <script type="text/javascript" src="../jsb-global.js"></script>
```

```
    <script type="text/javascript" src="jsb-11-06.js"></script>
  </head>
  <body>
    <h1>Beatle Picker</h1>
    <form id="beatles-form" action="beatles.php" method="get">
      <p>
        <label>Choose your favorite Beatle:</label>
        <input type="radio" name="Beatles" id="radio1"
                     value="John Lennon" checked>
        <label for="radio1">John</label>
        <input type="radio" name="Beatles" id="radio2" value="Paul McCartney">
        <label for="radio2">Paul</label>
        <input type="radio" name="Beatles" id="radio3" value="George Harrison">
        <label for="radio3">George</label>
        <input type="radio" name="Beatles" id="radio4" value="Ringo Starr">
        <label for="radio4">Ringo</label>
      </p>
      <p>
        <label for="song">Enter the name of your favorite Beatles song:</label>
        <input type="text" id="song" name="song" value="Eleanor Rigby">
        <input type="submit" id="submit" value="Process Request...">
      </p>
    </form>
  </body>
</html>
```

JavaScript: jsb-11-06.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

// apply behaviors when document has loaded
function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to crucial elements
      var oForm = document.getElementById('beatles-form');
      var oSong = document.getElementById('song');
      var oButtonSubmit = document.getElementById('submit');

         // if they all exist...
         if (oForm && oSong && oButtonSubmit)
         {
            // apply behavior to input field & button
            addEvent(oSong, 'change', verifySong);
            addEvent(oButtonSubmit, 'click', processData);
         }
   }
}
```

continued

LISTING 11-6 *(continued)*

```
// verify all input & suppress form submission
function processData(evt)
{
      // consolidate event handling
      if (!evt) evt = window.event;

   // point to the activated control's form ancestor
   var oForm = this.form;

   // see which radio button was selected
   for (var i = 0; i < oForm.Beatles.length; i++)
   {
      if (oForm.Beatles[i].checked)
      {
         break;
      }
   }

   // assign values to variables for convenience
   var sBeatle = oForm.Beatles[i].value;
   var sSong = oForm.song.value;

   // this is where a data lookup would go...
   alert("Checking whether " + sSong + " features " + sBeatle + "...");

      // cancel form submission
      if (evt.preventDefault) evt.preventDefault();
   return false;
}

// verify the song name when it's changed
function verifySong()
{
   // get the input song
   // ('this' is the object whose event handler called this function)
   var sSong = this.value;

   // this is where a data lookup would go...
   alert("Checking whether " + sSong + " is a Beatles tune...");
}
```

The function `verifySong()` wants access to the value entered into the song input field, so it uses `this` in the statement:

```
var sSong = this.value;
```

In other words, get the value of the current object (the input field) and assign it to the variable `sSong`. We're using `this` as a shortcut replacement for

```
var oInput = document.getElementById('song');
var sSong = oInput.value;
```

The function `processData()` needs to refer to several form elements, so it first takes advantage of the fact that every form element points to the form it belongs to with the `form` property:

```
var oForm = this.form;
```

Regardless of which input control `this` refers to, `this.form` points to the parent form. Then it can proceed to use object references such as `oForm.Beatles` and `oForm.song` to point to various controls within the form by name.

If you're a bit puzzled by the behavior of this script when you run it in your browser, here's an explanation of the programming logic behind what you experience. When you enter a new song title in the text box and exit the input field by pressing Tab or clicking elsewhere, the `onchange` event handler calls the `verifySong()` function, which displays an alert saying that it's checking the song. (It doesn't actually validate it against a database in this example.)

When you click the Process Request button, its `onclick` event handler calls the function `processData()`, which announces that it's checking to see if the entered song features the Beatle selected in the radio buttons above.

Now let's throw it two balls at once. Type a new song name in the input field, and then immediately click the Process Request button. You see only one alert — the `verifySong()` message that it's checking the song. Why don't you see both alerts? Because the button `click` action is interrupted by the `onchange` event handler of the text box. In other words, the button doesn't really get clicked, because the `onchange` alert dialog box comes up first. That's why you have to click the button for what seems to be a second time to get the song/Beatle verification. If you don't change the text in the field, your click of the button occurs without interruption, and the `processData()` verification takes place.

Note

Discrepancies between the ways that IE and other browsers handle event assignments and event processing require explanations beyond the scope of this tutorial. You'll meet them soon enough, however, beginning in Chapter 25, "Document Object Model Essentials," and again in Chapter 32, "Event Objects." ■

Submitting and Prevalidating Forms

In an ordinary HTML document, we submit a form by clicking on a `submit` button; the browser then gathers up the values we entered or selected with the input controls and sends them to the specified URI. JavaScript lets us intercept that submit request, validate the input or do whatever else we need to do, and then either permit the form submission to proceed or cancel it so that we can guide the user to improve the input.

You can perform this sort of last-second validation of data or other scripting (for example, changing the form's `action` property based on user choices) in a function invoked by the form's `onsubmit` event handler. We'll go into substantial detail about validation routines in Chapter 46, "Data-Entry Validation," on the CD-ROM. For now, we just want to show you how the `onsubmit` event handler works.

To juggle the ways different browsers handle events, we need to use two techniques to cancel the event, corresponding exactly to the two techniques our `addEvent()` function uses to apply the event handlers in the first place:

```
// add an event to an element
function addEvent(elem, evtType, func)
{
   // first try the W3C DOM method
   if (elem.addEventListener)
   {
      elem.addEventListener(evtType, func, false);
   }
   // otherwise use the 'traditional' technique
   else
   {
      elem["on" + evtType] = func;
   }
}
```

Compare this to how the script in Listing 11-7 cancels the submit event:

```
function checkForm(evt)
{
      // consolidate event handling
      if (!evt) evt = window.event;
   ...
   // cancel form submission
      // W3C DOM method (hide from IE)
      if (evt.preventDefault) evt.preventDefault();
   // IE method
   return false;
   ...
}
```

For browsers compatible with the W3C DOM, the event is added with `addEventListener()`, and the form submission is cancelled with `preventDefault()`. Attempting to invoke a DOM method that the browser thinks doesn't exist causes a runtime error, so we protect the older and less capable browsers by testing first, to make sure the method exists for the event object.

For those less capable browsers, notably Internet Explorer, the event is added to the object by setting the event property (in this case, `onsubmit`), and form submission is cancelled simply by returning a `false` value from the function called by the event handler.

We'll get into all the whys and wherefores later in this book, but for now let's use this dual technique for handling events.

Listing 11-7 shows a page with a simple validation routine that ensures that all fields have something in them before allowing form submission to take place. The HTML marks up a form with four input fields and a submit button. Note that the `action` of the `form` element is the fictitious server-side program `validate.php`. If this page is delivered to a user agent not running JavaScript, the form will submit the input values to the server-side program for validation. Fundamental form validation

must always happen server-side; we're duplicating that validation in client-side JavaScript to give the user a more immediate response to their actions. (Incidentally, that's one indicator of whether there's a typo in the script: if you submit this form with any of the input fields blank and the browser window attempts to bring up `validate.php`, you'll know that you probably made a typo while entering the HTML or JavaScript code because the script isn't blocking form submission.)

After the page loads, the script attaches the `checkForm()` function to the `onsubmit` event of the form. Note that we're not applying `onclick` behavior to the `submit` button; instead, we're letting the button do its normal job and we're intercepting the submission process at the form object itself.

When `submit` is clicked, the next normal step is for the browser to submit the form, but first it honors the `onsubmit` event handler and calls our function `checkForm()`. This function's principal job is to loop through all the form controls, looking for a blank input field. If it finds one, it displays an error message and cancels form submission.

Inside the loop, the `if` statement performs two tests. The first test is to make sure that we're examining form controls whose `type` properties are text (so as not to bother with, say, buttons). Next, it checks to see whether the value of the text field is empty. The `&&` operator (called a Boolean `AND` operator) forces both sides to evaluate to `true` before the entire condition expression inside the parentheses evaluates to `true`. If either subtest fails, the whole condition fails.

LISTING 11-7

Last-Minute Checking Before Form Submission

         </p>
         <p>
            <input type="submit" id="submit">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-11-07.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

// apply behaviors when document has loaded
function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to the form
      var oForm = document.getElementById('theForm');

         // if it exists, apply the behavior
         if (oForm)
         {
            addEvent(oForm, 'submit', checkForm);
         }
   }
}

// when the form is submitted,
// check to make sure all input fields have been filled in
function checkForm(evt)
{
      // consolidate event handling
      if (!evt) evt = window.event;

   // 'this' is the current object, in this case the form
   for (var i = 0; i < this.elements.length; i++)
   {
      if (this.elements[i].type == "text" && this.elements[i].value == "")
      {
         alert("Fill out ALL fields.");

         // cancel form submission
            // W3C DOM method (hide from IE)
```

```
            if (evt.preventDefault) evt.preventDefault();
         // IE method
         return false;
      }
   }
   // allow form submission
   return true;
}
```

A word about submit()

The scripted equivalent of submitting a form is the form object's `submit()` method. All you need in the statement is a reference to the form and this method:

```
formObject.submit();
```

One quirky bit of behavior involving the `submit()` method and the `onsubmit` event handler needs explanation. Although you might think (and logically so, in our opinion) that the `submit()` method would be the exact scripted equivalent of the click of the real Submit button, it's not. The `submit()` method does not cause the form's `submit` event to fire at all. If you want to perform validation on a form submitted via the `submit()` method, invoke the validation in the script function that ultimately calls the `submit()` method.

So much for the basics of forms and form controls. In Chapter 12, you step away from HTML for a moment to look at more advanced JavaScript core language items: strings, math, and dates.

Exercises

1. Rework Listings 11-2, 11-3, 11-4, and 11-5 to use the `this` keyword instead of global variables.
2. For the following form (assume that it's the only form on the page), write at least 10 ways to reference the text input field as an object in all modern scriptable browsers.

```
<form name="subscription" action="cgi-bin/maillist.pl" method="post">
 <p>
   <input type="text" id="email" name="email">
   <input type="submit">
 </p>
</form>
```

3. Write a function that displays the value of an input field in an alert dialog box, plus the script that causes that function to be called when the input field is changed.
4. A document contains two forms, `specifications` and `accessories`. In the `accessories` form is a field named `acc1`. Write at least two different statements that set the contents of that field to `Leather Carrying Case`.
5. Create a page that includes a select object to change the background color of the current page. The property that you need to set is `document.body.style.backgroundColor`, and the three values you should offer as options are `red`, `yellow`, and `green`. In the `select` list, the colors should display as `Stop`, `Caution`, and `Go`.

CHAPTER 12

Strings, Math, and Dates

For most of the lessons in the tutorial so far, the objects at the center of attention belong to the document object model (DOM). But, as indicated in Chapter 2, "Developing a Scripting Strategy," a clear dividing line exists between the DOM and the JavaScript language. The language has some of its own objects that are independent of the DOM. These objects are defined such that if a vendor wished to implement JavaScript as the programming language for an entirely different kind of product, the language would still use these core facilities for handling text, advanced math (beyond simple arithmetic), and dates. You can find formal specifications of these objects in the ECMA-262 recommendation.

IN THIS CHAPTER

How to modify strings with common string methods

When and how to use the Math object

How to use the Date object

Core Language Objects

It is often difficult for newcomers to programming — or even experienced programmers who have not worked with object-oriented languages before — to think about objects, especially when objects are attributed to things that don't seem to have a physical presence. For example, it doesn't require lengthy study to grasp the notion that a button on a page is an object. It has several physical properties that make perfect sense. But what about a string of characters? As you learn in this chapter, in an object-based environment such as JavaScript, "everything that moves" is treated as an object — each piece of data from a Boolean value to a date. Each such object probably has one or more properties that help define the content; such an object may also have methods associated with it to define what the object can do or what you can do to the object.

JavaScript objects that are not part of the DOM are called *core language objects*. You can see the full complement of them in the Quick Reference in Appendix A. This chapter focuses on the `String`, `Math`, and `Date` objects.

String Objects

You have used `String` objects many times in earlier lessons. A *string* is any text inside a quote pair. A quote pair consists of either double quotes (`" "`) or single quotes (`' '`). That JavaScript includes two types of quotes makes it easy to nest one string inside another. In the following example, the `alert()` method requires a quoted string as a parameter:

```
alert('You cannot lose.');
```

If the quoted expression includes an apostrophe, it's easy enough to switch the outer quotes to double:

```
alert("You can't lose.");
```

When the solution isn't so simple, as when both apostrophe and quotation mark appear in the quoted string, *escape sequences* come to the rescue. More on them in Chapter 15, "The String Object."

JavaScript imposes no practical limit on the number of characters that a string can hold. However, most older browsers have a limit of 255 characters for a script statement. This limit is sometimes exceeded when a script includes a lengthy string that is to become scripted content in a page. You need to divide such lines into smaller chunks, using techniques described in a moment.

You have two ways to assign a string value to a variable. The simplest is a basic assignment statement:

```
var myString = "Howdy";
```

This works perfectly well except in some exceedingly rare instances. You can also create a string object using the more formal syntax that involves the `new` keyword and a constructor function (that is, it constructs a new object):

```
var myString = new String("Howdy");
```

Whichever way you initialize a variable with a string, the variable receiving the assignment can respond to all `String` object methods.

Joining strings

Bringing two strings together as a single string is called *concatenation*, a term you learned in Chapter 8, "Programming Fundamentals, Part I." String concatenation requires one of two JavaScript operators. Even in your first close look at script, in Chapter 3, "Selecting and Using Your Tools," you saw how the addition operator (+) combines multiple strings into one:

```
var today = new Date();
var msg = "This is JavaScript saying it's now " + today.
    toLocaleString();
```

As valuable as the + operator is, another related operator can be even more scripter-friendly: +=. This operator is helpful when you are assembling large strings in a single variable. The strings may be so long or cumbersome that you need to divide the building process into multiple statements. Or you might decide to split the concatenation into several statements to help it make more sense to the human reader. The pieces may be combinations of *string literals* (strings inside quotes) and variable values. The clumsy way to do it (perfectly doable in JavaScript) is to use the addition operator to append more text to the existing chunk:

```
var msg = "Four score";
msg = msg + " and seven";
msg = msg + " years ago,";
```

But the += operator, called the *add-by-value operator*, offers a handy shortcut. The symbol for the operator is a plus and equal sign together. This operator means *append the stuff on the right of me to the end of the stuff on the left of me*. Therefore, the preceding sequence is shortened as follows:

```
var msg = "Four score";
msg += " and seven";
msg += " years ago,";
```

You can also combine the operators if the need arises:

```
var msg = "Four score";
msg += " and seven" + " years ago";
```

String methods

Of all the core JavaScript objects, the `String` object has the most diverse collection of methods associated with it. Many methods are designed to help scripts extract segments of a string. Another group, rarely used and now obsolete in favor of Cascading Style Sheets (CSS), wraps a string with one of several style-oriented tags (a scripted equivalent of tags for font size, font style, and the like).

In a string method, the string being acted upon becomes part of the reference followed by the method name:

```
myString.methodName();
```

All methods return a value of some kind. Most of the time, the returned value is a converted version of the string object referred to in the method call — but the original string is still intact. To capture the modified version, you need to assign the results of the method to a variable:

```
var result = myString.methodName();
```

The following sections introduce you to several important string methods available to all browser brands and versions.

Changing string case

Two methods convert a string to all uppercase or all lowercase letters:

```
var result = string.toUpperCase();
var result = string.toLowerCase();
```

As always, you must strictly observe the case of each letter of the method names if you want them to work. These methods come in handy when your scripts need to compare strings that may not have the same case (for example, a string in a lookup table compared with a string typed by a user). Because the methods don't change the original strings attached to the expressions, you can simply compare the evaluated results of the methods:

```
var foundMatch = false;
   if (stringA.toUpperCase() == stringB.toUpperCase())
   {
      foundMatch = true;
   }
```

String searches

You can use the `string.indexOf()` method to determine whether one string is contained by another. For example, say you've built a contact form on a web site that sends visitors' messages to the public relations department, but you want to carbon copy the ombudsman any messages containing the word "complaint." That word could occur anywhere within the long message string. In this case, you probably don't need to know exactly where the word occurs, just whether it's there.

The `string.indexOf()` method returns a number indicating the index value (zero-based) of the character in the larger string where the smaller string begins. The key point about this method is that, if no match occurs, the returned value is `-1`. To find out whether the smaller string is inside, all you need to test is whether the returned value is something other than `-1`.

Two strings are involved with this method: the shorter one and the longer one. The longer string is the one that appears in the reference to the left of the method name; the shorter string is inserted as a parameter to the `indexOf()` method. To demonstrate the method in action, the following fragment looks to see whether the input message contains the word 'complaint':

```
var sMsg = '';
var oInput = document.getElementById('message');
   if (oInput)
   {
      sMsg = oInput.value;
   }
var isComplaint = false;
   if (sMsg.indexOf("complaint") != -1)
   {
      isComplaint = true;
   }
```

The operator in the `if` construction's condition (`!=`) is the inequality operator. You can read it as meaning *is not equal to.*

Extracting copies of characters and substrings

To extract a single character at a known position within a string, use the `charAt()` method. The parameter of the method is an index number (zero-based) of the character to extract. When we say *extract,* we don't mean delete, but grab a snapshot of the character. The original string is not modified in any way.

For example, consider a script in a main window that is capable of inspecting a variable, `stringA`, in another window that displays map images of different corporate buildings. When the window has a map of Building C in it, the `stringA` variable contains `"Building C"`. In English the building letter is always at the 10th character position of the string (or number 9 in a zero-based counting world), so the script can examine that one character to identify the map currently in that other window:

```
var stringA = "Building C";
var bldgLetter = stringA.charAt(9);
   // result: bldgLetter = "C"
```

There are two similar methods — `string.substr()` and `string.substring()` — that enable you to extract a contiguous sequence of characters, provided that you know the starting position of the substring you want to grab. The difference between the two methods is that `string.substr()`

wants to know the length of the substring, whereas `string.substring()` wants to know the ending position of the substring:

```
string.substr(startingPosition [, length])
string.substring(startingPosition [, endingPosition])
```

Either method will extract everything up to the end of the original string if the second parameter (length or ending position) is omitted. The original string from which the extraction is made appears to the left of the method name in the reference. The starting and ending position parameters are index values (zero-based).

```
var stringA = "banana daiquiri";

var excerpt = stringA.substr(2,4);     // result: "nana"
var excerpt = stringA.substr(2);       // result: "nana daiquiri"

var excerpt = stringA.substring(2,6);  // result: "nana"
var excerpt = stringA.substring(2);    // result: "nana daiquiri"
```

String manipulation in JavaScript is fairly cumbersome compared with that in some other scripting languages. Higher-level notions of words, sentences, or paragraphs are absent. Therefore, sometimes it takes a bit of scripting with string methods to accomplish what seems like a simple goal. Yet you can put your knowledge of expression evaluation to the test as you assemble expressions that utilize heavily nested constructions.

For example, let's say you want to grab everything from a multiword expression except the first word:

```
var stringA = "The Painted Bird";
var firstSpace = stringA.indexOf(" ");
var excerpt = stringA.substring(firstSpace + 1);
   // result: excerpt = "Painted Bird"
```

Assuming that the first word can be of any length, the second statement uses the `string.indexOf()` method to look for the first space character. We add 1 to that value to serve as the starting index value for the `string.substring()` method. We omit the second `length` parameter in order to extract everything up to the end of `stringA`.

Creating statements like this one is not something you are likely to enjoy over and over again, so in Chapter 23, "Function Objects and Custom Objects," we show you how to create your own library of string functions that you can reuse in all of your scripts that need their string-handling facilities. More powerful string-matching facilities are also built into today's browsers by way of *regular expressions* (see Chapter 15, "The String Object," and Chapter 45, "The Regular Expression and RegExp Objects").

The Math Object

JavaScript provides ample facilities for math — far more than most scripters who don't have a background in computer science and math will likely use. But every genuine programming language needs these powers to accommodate clever programmers who can make windows fly in circles onscreen.

The `Math` object contains all these powers. This object is unlike most of the other objects in JavaScript in that you don't generate copies of the object to use. Instead, your scripts use the properties and

methods of a single `Math` object. (Technically, one `Math` object actually occurs per window or frame, but this fact has no impact whatsoever on your scripts.) Programmers call this kind of fixed object a *static object*. That `Math` object (with an uppercase *M*) is part of the reference to the property or method. Properties of the `Math` object are constant values, such as pi and the square root of 2:

```
var piValue = Math.PI;
var rootOfTwo = Math.SQRT2;
```

`Math` object methods cover a wide range of trigonometric functions and other math functions that work on numeric values already defined in your script. For example, you can find which of two numbers is the larger:

```
var larger = Math.max(value1, value2);
```

Or you can raise one number to a power of 10:

```
var result = Math.pow(value1, 10);
```

More common, perhaps, is the method that rounds a value to the nearest integer value:

```
var result = Math.round(value1);
```

Another common request of the `Math` object is a random number. The `Math.random()` method returns a floating-point number between 0 and 1. If you design a script to act like a card game, you need random integers between 1 and 52; for dice, the range is 1 to 6 per die. To generate a random integer between 0 and any top value, use the following formula

```
Math.floor(Math.random() * (n + 1))
```

where `n` is the top number. (`Math.floor` returns the integer part — the digits to the left of the decimal point — of any floating-point number.) To generate random numbers between 1 and any higher number, use this formula

```
Math.floor(Math.random() * n) + 1
```

where `n` equals the top number of the range. For the dice game, the formula for each die is

```
newDieValue = Math.floor(Math.random() * 6) + 1;
```

To see this, enter the right part of the preceding statement in the top text box of The Evaluator Jr. and repeatedly click the Evaluate button.

The Date Object

Working with dates beyond simple tasks can be difficult business in JavaScript. A lot of the difficulty comes from the fact that dates and times are calculated internally according to *Greenwich Mean Time (GMT)* — provided that the visitor's own internal PC clock and control panel are set accurately. As a result of this complexity, better left for Chapter 17, "The Date Object," this section of the tutorial touches on only the basics of the JavaScript `Date` object.

A scriptable browser contains one global `Date` object (in truth, one `Date` object per window) that is always present, ready to be called upon at any moment. The `Date` object is another one of those static objects. When you wish to work with a date, such as displaying today's date, you need to invoke the `Date` object constructor function to obtain an instance of a `Date` object tied to a specific time and date. For example, when you invoke the constructor without any parameters, as in

```
var today = new Date();
```

the `Date` object takes a snapshot of the PC's internal clock and returns a Date object for that instant. Notice the distinction between the static `Date` object and a `Date` object instance, which contains an actual date value. The variable `today` contains not a ticking clock but a value that you can examine, tear apart, and reassemble as needed for your script.

Internally, the value of a `Date` object instance is the time, in milliseconds, from zero o'clock on January 1, 1970, in the GMT zone — the world standard reference point for all time conversions. That's how a `Date` object contains both date and time information.

You can also grab a snapshot of the `Date` object for a particular date and time in the past or future by specifying that information as parameters to the `Date` object constructor function:

```
var someDate = new Date("Month dd, yyyy hh:mm:ss");
var someDate = new Date("Month dd, yyyy");
var someDate = new Date(yyyy,mm,dd,hh,mm,ss);
var someDate = new Date(yyyy,mm,dd);
var someDate = new Date(GMT milliseconds from 1/1/1970);
```

If you attempt to view the contents of a raw `Date` object, JavaScript converts the value to the local time-zone string, as indicated by your PC's control panel setting. To see this in action, use The Evaluator Jr.'s top text box to enter the following:

```
new Date();
```

Your PC's clock supplies the current date and time as the clock calculates them (even though JavaScript still stores the date object's millisecond count in the GMT zone). You can, however, extract components of the `Date` object via a series of methods that you apply to a `Date` object instance. Table 12-1 shows an abbreviated listing of these properties and information about their values.

Caution

Be careful about values whose ranges start with zero, especially the months. The `getMonth()` and `setMonth()` method values are zero based, so the numbers are 1 less than the month numbers you are accustomed to working with (for example, January is 0 and December is 11). ■

You may notice one difference about the methods that set values of a `Date` object. Rather than returning some new value, these methods actually modify the value of the instance of the `Date` object referenced in the call to the method.

TABLE 12-1

Some Date Object Methods

Method	Value Range	Description
dateObj.getTime()	0-...	Milliseconds since 1/1/70 00:00:00 GMT
dateObj.getYear()	70-...	Specified year minus 1900; four-digit year for 2000+
dateObj.getFullYear()	1970-...	Four-digit year (Y2K-compliant); version 4+ browsers
dateObj.getMonth()	0-11	Month within the year (January = 0)
dateObj.getDate()	1-31	Date within the month
dateObj.getDay()	0-6	Day of week (Sunday = 0)
dateObj.getHours()	0-23	Hour of the day in 24-hour time
dateObj.getMinutes()	0-59	Minute of the specified hour
dateObj.getSeconds()	0-59	Second within the specified minute
dateObj.setTime(*val*)	0-...	Milliseconds since 1/1/70 00:00:00 GMT
dateObj.setYear(*val*)	70-...	Specified year minus 1900; four-digit year for 2000+
dateObj.setMonth(*val*)	0-11	Month within the year (January = 0)
dateObj.setDate(*val*)	1-31	Date within the month
dateObj.setDay(*val*)	0-6	Day of week (Sunday = 0)
dateObj.setHours(*val*)	0-23	Hour of the day in 24-hour time
dateObj.setMinutes(*val*)	0-59	Minute of the specified hour
dateObj.setSeconds(*val*)	0-59	Second within the specified minute

Date Calculations

Performing calculations with dates frequently requires working with the millisecond values of the Date objects. This is the surest way to compare, add, and subtract date values. To demonstrate a few Date object machinations, Listing 12-1 displays the current date and time and one way to calculate the date and time seven days from now.

LISTING 12-1

Date Object Calculations

HTML: jsb-12-01.html

```
<!DOCTYPE html>
<html>
   <head>
```

```
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Date Calculation</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-12-01.js"></script>
   </head>
   <body>
      <h1>Date Calculation</h1>
      <form id="date-form" action="date-calc.php">
         <p>
            <label for="today">Today is:</label>
            <input type="text" id="today" name="today" size="80">
         </p>
         <p>
            <label for="nextWeek">Next week will be:</label>
            <input type="text" id="nextWeek" name="nextWeek" size="80">
         </p>
         <p>
            <input type="submit" id="submit">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-12-01.js

```
// run script when the page has loaded
addEvent(window, 'load', calcDates);

// calculate dates and plug into document
function calcDates()
{
   var dTodaysDate = new Date();

   // plug in today
   var oToday = document.getElementById('today');
      if (oToday)
      {
         oToday.value = dTodaysDate;
      }

   // plug in next week
   var oNextWeek = document.getElementById('nextWeek');
      if (oNextWeek)
      {
         // today in milliseconds
         var msToday = dTodaysDate.getTime();

         // one week = 1000 milliseconds * 60 seconds * 60 minutes
         //            * 24 hours * 7 days
         var msOneWeek = 1000 * 60 * 60 * 24 * 7;
```

continued

LISTING 12-1 *(continued)*

```
          // next week in milliseconds
          var msNextWeek = msToday + msOneWeek;

          // next week as date object
          var dAWeekFromNow = new Date(msNextWeek);

          // plug in string value
          oNextWeek.value = dAWeekFromNow;
       }
}
```

The script first creates a new `Date` object and assigns it to the variable `dTodaysDate`. Then it displays the current date and time by setting the value of the input field `today` equal to `dTodaysDate`. Although you might expect that this would insert a copy of the `Date` object into the input field, what really happens is that it uses the `toString()` method of the `Date` object to output a string such as

```
Sun Dec 05 2010 16:47:20 GMT-0800 (Pacific Standard Time)
```

Next, we display the date and time one week from now. To work with milliseconds, we start by assigning the current date and time in milliseconds to variable `msToday`. To add one week to this, we need to know how many milliseconds there are in a week: 1000 ms. per second, 60 seconds per minute, 60 minutes per hour, 24 hours per day, and seven days per week. The product of all these we store in variable `msOneWeek`. We add that week of milliseconds to the current date and time, and then use the result to create a new `Date` object, which we store in variable `dAWeekFromNow`. Displaying the resultant date and time is done the same way as before — simply by assigning the new `Date` object to an input field's `value` attribute.

To add time intervals to or subtract time intervals from a `Date` object, you can use a shortcut that doesn't require the millisecond conversions. By combining the date object's `set` and `get` methods, you can let the `Date` object work out the details. For example, in Listing 12-1, you could replace the "next week" logic with:

```
dTodaysDate.setDate(dTodaysDate.getDate() + 7);
oNextWeek.value = dTodaysDate;
```

Because JavaScript tracks the date and time internally as milliseconds, the accurate date appears in the end, even if the new date is into the next month. JavaScript automatically takes care of figuring out how many days there are in a month, as well as in leap years.

Many other-quirks and complicated behavior await you if you script dates in your page. As later chapters demonstrate, however, the results may be worth the effort.

Exercises

1. Create a web page that has one form field for entering the user's email address, and a Submit button. In the accompanying JavaScript script, write a presubmission validation routine that verifies that the text field contains the @ symbol used in all email addresses before you allow submission of the form.
2. Given the string `"Internet Explorer"`, fill in the blanks of the `string.substring()` method parameters here that yield the results shown to the right of each method call.

```
var myString = "Internet Explorer";
myString.substring(___,___)     // result = "Int"
myString.substring(___,___)     // result = "plorer"
myString.substring(___,___)     // result = "net Exp"
```

3. Consider this logic for extracting the part of a string that comes after the first word:

```
var stringA = "The Painted Bird";
var firstSpace = stringA.indexOf(" ");
var excerpt = stringA.substring(firstSpace + 1);
```

What will happen in this logic if `stringA` does not contain a space? Work out what you think should occur, then run the script to see if you're right.

4. Fill in the rest of the function in the listing that follows so that it looks through every character of the entry field and counts how many times the letter *e* (either upper- or lowercase) appears in the field. (Hint: All that is missing is a `for` repeat loop.)

```
var inputString = 'Elephantine';
var count = 0;

MISSING CODE

var msg = "The number of e's in '" + this.mainstring.value + "'";
msg += " is " + count;
alert(msg);
```

5. Create a page that has two fields and one button. The button should trigger a function that generates two random numbers between 1 and 6, placing each number in one of the fields. (Think of using this page as a substitute for rolling a pair of dice in a board game.)
6. Create a script that displays the number of days between today and next Christmas.

CHAPTER

13

Scripting Frames and Multiple Windows

IN THIS CHAPTER

Relationships among frames in the browser window

How to access objects and values in other frames

How to control navigation of multiple frames

Communication skills between separate windows

One of the attractive aspects of JavaScript for some applications on the client is that it allows user actions in one frame or window to influence what happens in other frames and windows. In this section of the tutorial, you extend your existing knowledge of object references to the realm of multiple frames and windows.

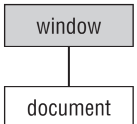
Frames: Parents and Children

You've seen in earlier top-level hierarchy illustrations (such as Figure 6-2) that the `window` object is at the top of the chart. The `window` object also has several synonyms, which stand in for the `window` object in special cases. For instance, in Chapter 10, "Window and Document Objects," you learned that `self` is synonymous with `window` when the reference applies to the same window that contains the script's document. In this lesson, you learn the roles of three other references that point to objects behaving as windows: `frame`, `top`, and `parent`.

Loading an ordinary HTML document into the browser creates a model in the browser that starts out with one `window` object and the document it contains. The top rungs of the hierarchy model are as simple as can be, as shown in Figure 13-1. This is where references begin with `window` or `self` (or with `document` because the current window is assumed).

FIGURE 13-1

Single-frame window and document hierarchy.



To frame or not to frame?

Frames and iFrames are valid HTML and their use might be seen as desirable for accomplishing some tasks. However, frame-based web sites pose serious usability and accessibility issues that can make them less than ideal for general web site development.

The fundamental problem with framesets is that any given combination of framed pages is not directly addressable. That is, if you navigate through a frameset to bring up a particular combination of content in the frames, the URL in the browser's address bar will remain that of the parent frameset document, not that of the actual content you're viewing. This lack of unique addressing of frame-paged content prevents search engines from indexing content and prevents other people from publishing links to the framed content, bookmarking them on their computers, or sharing them in email. Framesets can also be disorienting or completely inaccessible for the users of mobile devices and assistive technology such as magnifiers and screen-readers.

Web usability expert Jakob Nielsen wrote ''Why Frames Suck (Most of the Time)'' back in 1996. The situation hasn't improved in all the years since.

Alternatives to frames that avoid these problems include using server-side scripting to combine multiple source pages, and using the CSS properties `overflow: auto`, to create fields of scrolling content, and `position: fixed`, to establish sections that don't move when the rest of the page scrolls.

In this book, we assume that you've considered the pros and cons of using frames and may have a web development problem — or mere curiosity — that requires their use. We want you to know how to manipulate them with JavaScript if you have to, and they make for great exercise in navigating the DOM, but we don't recommend their use in most circumstances.

The instant a framesetting document loads into a browser, the browser starts building a slightly different hierarchy model. The precise structure of that model depends entirely on the structure of the frameset defined in that framesetting document. Consider the following skeletal frameset definition:

```
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.01 Frameset//EN"
        "http://www.w3.org/TR/html4/frameset.dtd">
<html>
   <head>
      <meta http-equiv="Content-Type" content="text/html; charset=utf-8">
      <title>Title of all pages in this frameset</title>
   </head>
   <frameset cols="50%,50%">
      <frame name="leftFrame" src="somedoc1.html" title="Frame 1">
      <frame name="rightFrame" src="somedoc2.html" title="Frame 2">
      <noframes>
```

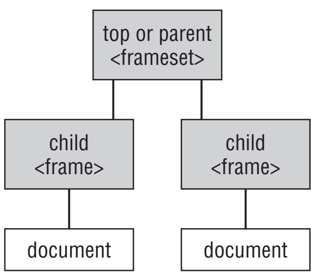
```
            ...
         </noframes>
      </frameset>
   </html>
```

This markup splits the browser window into two frames side by side, with a different document loaded into each frame. The model conveys both the structure (parent with children) and the layout (the relative sizes of the frames and whether they're set up in columns or rows). Because frames markup is not backward-compatible — it displays absolutely nothing in browsers that don't support frames — we also provide a no-frames alternative, which might be actual content or a hyperlink to a frameless page.

Framesets establish relationships among the frames in the collection. Borrowing terminology from the object-oriented programming world, the framesetting document loads into a *parent window*. Each of the frames defined in that parent window document is a *child frame*. Figure 13-2 shows the hierarchical model of a two-frame environment. This illustration reveals a lot of subtleties about the relationships among framesets and their frames.

FIGURE 13-2

Two-frame window and document hierarchy.



It is often difficult at first to visualize the frameset as a window object in the hierarchy. After all, with the exception of the URL showing in the browser's Location/Address field, you don't see anything about the frameset in the browser. But that window object exists in the object model. Notice, too, that in the diagram the framesetting parent window has no document object showing. This may also seem odd, because the window obviously requires an HTML file containing the specifications for the frameset. In truth, the parent window has a `document` object associated with it, but it is omitted from the diagram to better portray the relationships among parent and child windows. A frameset parent's document cannot itself contain most of the typical HTML objects such as forms and controls, so references to the parent's document are rarely, if ever, used.

If you add a script to the framesetting document that needs to access a property or method of that window object, references are like any single-frame situation. Think about the point of view of a script located in that window. Its immediate universe is the very same window.

Things get more interesting when you start looking at the child frames. Each of these frames contains a `document` object whose content you see in the browser window, and the structure is such that each frame's document is entirely independent of the other. It is as though each document lived in its own browser window. Indeed, that's why each child frame is also a window type of object. A frame has the same kinds of properties and methods as the `window` object that occupies the entire browser.

From the point of view of either child window in Figure 13-2, its immediate container is the `parent` window. When a `parent` window is at the top of the hierarchical model loaded in the browser, that window is also referred to as the `top` object.

References Among Family Members

Given the frame structure of Figure 13-2, it's time to look at how a script in any one of those windows can access objects, functions, or variables in the others. An important point to remember about this facility is that if a script has access to an object, function, or global variable in its own window, that same item can be reached by a script from another frame in the hierarchy (provided that both documents come from the same web server).

A script reference may need to take one of three possible routes in the two-generation hierarchy described so far: parent to child; child to parent; or child to child. Each of the paths between these windows requires a different reference style.

Parent-to-child references

Probably the least common direction taken by references is when a script in the parent document needs to access some element of one of its frames. Since the parent can contain one or more frames, the parent maintains an array of the child frame objects. You can address a frame by array syntax or by the name you assign to it with the `id` or `name` attribute inside the `<frame>` tag. In the following examples of reference syntax, we substitute a placeholder named `ObjFuncVarName` for whatever object, function, or global variable you intend to access in the distant window or frame. Remember that each visible frame contains a `document` object, which generally is the container of elements you script; be sure that references to the elements include `document`. With that in mind, a reference from a parent to one of its child frames can follow any one of these models:

```
[window.]frames[n].ObjFuncVarName
[window.]frames["frameName"].ObjFuncVarName
[window.]frameName.ObjFuncVarName
```

Numeric index values for frames are based on the order in which their `<frame>` tags appear in the framesetting document. You will make your life easier, however, if you assign recognizable names to each frame and use the frame's name in the reference.

Child-to-parent references

It is not uncommon to link scripts to the parent frameset document (in the `head` portion) that multiple child frames or multiple documents in a frame use as a common script library. Because they load in the frameset, these scripts load only once while the frameset is visible. If other documents from the same server load into the frames over time, they can take advantage of the parent's scripts without having to load their own copies into the browser.

From the child's point of view, the next level up the hierarchy is called the `parent`. Therefore, a reference from a child frame to items at the parent level is simply:

```
parent.ObjFuncVarName
```

If the item accessed in the parent is a function that returns a value, the returned value transcends the parent/child borders down to the child without hesitation.

```
var sValue = parent.FuncName();
```

When the parent window is also at the top of the object hierarchy currently loaded into the browser, you can optionally refer to it as the *top window,* as in:

```
top.ObjFuncVarName
```

Using the `top` reference can be hazardous if for some reason your web page gets displayed in some other web site's frameset. What if your top window is not the master frameset's top window? Therefore, we recommend using the `parent` reference whenever possible (unless you want your script to fail when nested inside an unwanted framer of your web site).

Child-to-child references

The browser needs a bit more assistance when it comes to getting a child window to communicate with one of its siblings. One of the properties of any window or frame is its `parent` (whose value is `null` for a single window). A reference must use the `parent` property to work its way out of the current frame to a point that both child frames have in common — the parent, in this case. When the reference is at the parent level, the rest of the reference can carry on as though it were starting at the parent. Thus, from one child to one of its siblings, you can use any of the following reference formats:

```
parent.frames[n].ObjFuncVarName
parent.frames["frameName"].ObjFuncVarName
parent.frameName.ObjFuncVarName
```

A reference from the other sibling back to the first looks the same, but the `frames[]` array index or `frameName` part of the reference differs. Of course, much more complex frame hierarchies exist in HTML. Even so, the object model and referencing scheme provide a solution for the most deeply nested and gnarled frame arrangement you can think of — following the same precepts you just learned.

Frame-Scripting Tips

One of the first mistakes that frame-scripting newcomers make is writing immediate script statements that call on other frames while the pages load. The problem here is that you cannot rely on the document loading sequence to follow the frameset source-code order. All you know for sure is that the parent document *begins* loading first. Regardless of the order of `<frame>` tags, child frames can begin loading in any sequence. Moreover, a frame's loading time depends on other elements in the document, such as images or Java applets.

Fortunately, you can use a certain technique to initiate a script when all the documents in the frameset are completely loaded. Just as the `load` event for a window fires when that window's document is fully loaded, a parent's `load` event fires after the `load` events in its child frames have fired. When you specify a `window.onload` event handler in a script linked to the frameset document, it's the equivalent of applying the event handler to the `frameset` element. That handler might invoke a function in the framesetting document that then has the freedom to tap the objects, functions, or variables of all frames throughout the object hierarchy.

Make special note that a reference to a frame as a type of window object is quite separate from a reference to the `frame` element object. An element object is one of those DOM element nodes in the document node tree (see Chapter 6, "Browser and Document Objects"). The properties and methods of this node differ from the properties and methods that accrue to a window-type object. It may be a difficult distinction to grasp, but it's an important one. The way you reference a frame — as a window object or element node — determines which set of properties and methods are available to your scripts.

Cross-Reference

See Chapter 26, "Generic HTML Element Objects," for a more detailed introduction to element node scripting. ■

If you start with a reference to the `frame` element object, you can still reach a reference to the `document` object loaded into that frame, but the syntax is different, depending on the browser. IE4+ and Safari let you use the same `document` reference as for a window; Mozilla-based browsers follow the W3C DOM standard more closely, using the `contentDocument` property of the frame element. To accommodate both syntaxes, you can build a reference as follows:

```
var docObj;
var frameObj = document.getElementById("myFrame");
   if (frameObj.contentDocument)
   {
      docObj = frameObj.contentDocument;
   }
   else
   {
      docObj = frameObj.document;
   }
```

About iframe Elements

The `iframe` element is supported as a scriptable object in IE4+, Mozilla-based browsers, and Safari (among other modern browsers). It is often used as a way to fetch and load HTML from a server without disturbing the current HTML page. It's not uncommon for an `iframe` to be hidden from view while scripts handle all the processing between it and the main document. (Today, the trick of asynchronously loading data from the server into an already-downloaded page is often accomplished using `XMLHttpRequest()` — see Chapter 39, "Ajax, E4X, and XML," on the CD.)

An `iframe` element becomes another member of the current window's `frames` collection, but you may also reference the `iframe` as an element object through W3C DOM `document.getElementById()` terminology. As with the distinction between the traditional frame-as-window object and DOM element object, a script reference to the `document` object within an `iframe` element object needs special handling. See Chapter 27, "Window and Frame Objects," for additional details.

Highlighting Footnotes: A Frameset Scripting Example

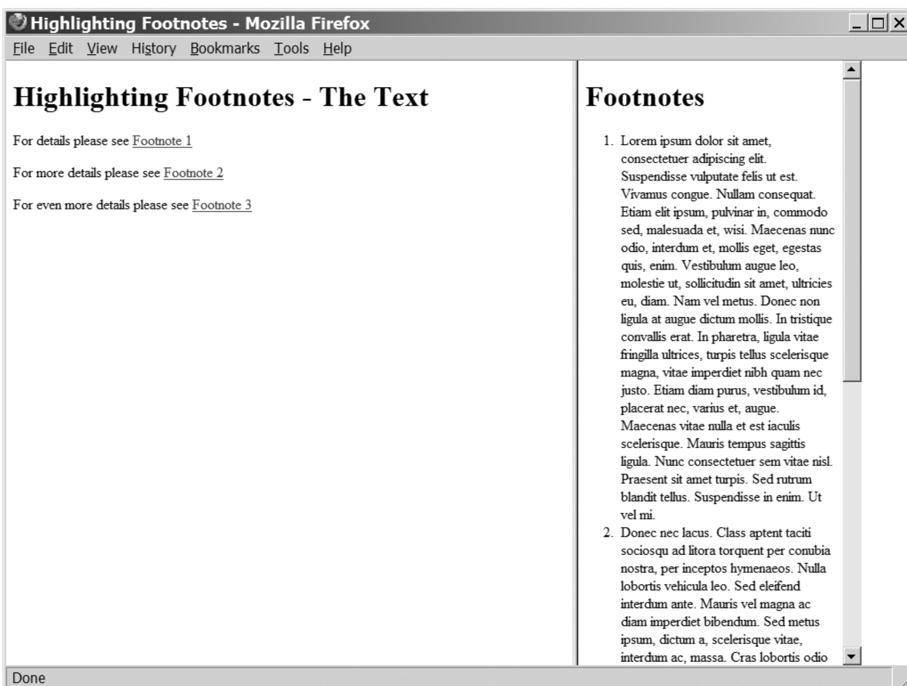
For a taste of inter-window scripting, consider a frameset that highlights a footnote in one frame when the corresponding link is clicked in the document text. Figure 13-3 shows what this frameset looks like, and Listing 13-1 provides the markup and scripting.

The three HTML files establish a frameset with two child frames, one for the main text and one for the footnotes. Clicking on a footnote link in the text brings the selected footnote to the top of the footnote frame. It does this by adding the element ID of the selected footnote to the 'hash' of the URL:

```
<a target="frameFootnotes" ↩
href="jsb-13-01-frame-footnotes.html#footnote-01">Footnote 1</a>
```

FIGURE 13-3

Highlighting Footnotes frameset.



The `target` attribute identifies the child frame while the `href` specifies which document will appear in that frame. The final part of the `href` URL `#footnote-01` matches up with the footnote markup:

```
<li id="footnote-01">Lorem ipsum dolor ...
```

It is basic browser functionality that, when the ID of an element is set as the hash of a URL, the page scrolls up (if it can) to position that element at the top of the window.

JavaScript and CSS work together to highlight the selected footnote: when the user clicks on a footnote link in the text window, JavaScript assigns a "selected" class to the footnote element. CSS styles that class with a background color.

```
/* style the selected footnote */
ol.footnotes li.selected
{
   background-color: aqua;
}
```

Let's walk through the JavaScript to see how the highlighting works. The script is linked to the `frame-text.html` document because it's the act of clicking the links in that document that triggers the highlighting event. The `addEvent()` function call tells JavaScript to run the `initialize()` function when the document has loaded. That function loops through all the anchor elements in the document. If it finds a `target` attribute set to `frameFootnotes`, it applies the `onclick` event to run the function `highlightFootnote()`.

When the user clicks on one of these links in the document text, the `highlightFootnote()` function gives the anchor element the `selected` class. To make it easy to restore a link to its previous class name later, the script stores the current anchor element pointer and its class attribute in global variables `oFootnote` and `sFootnoteClass`. So, the first thing it does when a link is clicked is to restore the previously-clicked link, if any.

To set the `class` attribute of the footnote in the other child frame, the script needs to determine the names of the frame and the footnote element. The frame name is exactly the same as the `target` attribute of the link that's clicked. The footnote element is whatever element in the footnote frame has the ID equal to the hash at the end of the link's URL.

If the named frame exists and the named element exists, the script can safely save the element's existing class (if any) and set the class to `selected`. Finally, the style sheet linked to the footnotes document applies a background color to any footnote with the `selected` class.

There are two important scripting principles illustrated with Listing 13-1. First, the fundamental operation of this page — bringing the selected footnote to the top of the footnote frame — is handled entirely by HTML without any help from JavaScript. This ensures that the page will be usable when viewed with user agents that don't support JavaScript, such as mobile devices, or with browsers in which the user has disabled JavaScript. This is an example of *progressive enhancement*, which stipulates that our scripting efforts should enhance already functional pages rather than supplying mission-critical functionality. We want to improve the experience for those who are running JavaScript and not break the page for those who aren't.

Second, we're using JavaScript to indicate that the footnotes are "selected" but not how they should be styled. We could have scripted:

```
oFootnote.style.backgroundColor = 'aqua';
```

Instead, the styling is left to CSS. This is an example of *separation of development layers*, whereby HTML structure and content are kept separate from JavaScript behavior and CSS presentation. This mode of development makes it quick and easy to create new code, tweak existing code, and apply old code to new projects. For example, when the web site designer changes the look of the site — and rest assured nearly every site *will* be changed either during development or afterward — cosmetic changes should be within the grasp of someone who knows CSS, without requiring the services of a JavaScript programmer.

References for Multiple Windows

In Chapter 10 you saw how to create a new window and communicate with it by way of the `window` object reference returned from the `window.open()` method. In this section, we show you how one of those subwindows can communicate with objects, functions, and variables in the window or frame that creates the subwindow.

Every `window` object has a property called `opener`. This property contains a reference to the window or frame that held the script whose `window.open()` statement generated the subwindow. For the main browser window and frames therein, this value is `null`. Because the `opener` property is a valid window reference (when its value is not `null`), you can use it to begin the reference to items in the original window — just like a script in a child frame uses `parent` to access items in the parent document. (The `parent` keyword isn't used for a subwindow's opener, however.)

Listing 13-2 contains two documents that work together in separate windows. `jsb-13-02-main.html` displays a button that opens a smaller window and loads `jsb-13-02-sub.html` into it, and another button that closes the subwindow. The main window document also contains a text field that gets filled in when you enter text in a corresponding field in the subwindow.

Note

You may have to turn off pop-up blocking temporarily to experiment with these examples.

Because so many people have set their browsers to block pop-up windows, and because pop-ups can be so disorienting to folks using assistive technology such as screen readers, and simply irritating to everyone else, we don't recommend that you create subwindows with JavaScript in real-world applications — and especially not for any critical function. Instead, use other techniques, such as CSS pop-ups, that gracefully degrade to simple HTML navigation in the absence of styling and scripting. ■

In the main window's script, the `openSubWindow()` function generates the new window. Because the `closeSubWindow()` function needs to know which window to close, we store the pointer to the new window in a global variable.

// apply behaviors when document has loaded
function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to button
      var oButton = document.getElementById('open-sub-window');

         // if it exists, apply behavior
         if (oButton)
         {
            addEvent(oButton, 'click', openSubWindow);
         }

      // point to button
      oButton = document.getElementById('close-sub-window');

         // if it exists, apply behavior
         if (oButton)
         {
            addEvent(oButton, 'click', closeSubWindow);
         }
   }
}

// open (create) sub window
function openSubWindow()
{
   // store sub-window pointer in global variable
   oSubWindow = window.open("jsb-13-02-sub.html", "sub", "height=200,width=300");
}

// close (destroy) sub window
function closeSubWindow()
{
      // if the sub-window has been opened, close it
      if (oSubWindow)
      {
         oSubWindow.close();
      }
}
```

HTML: jsb-13-02-sub.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Sub-Document</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
```

```
      <script type="text/javascript" src="jsb-13-02-sub.js"></script>
   </head>
   <body>
      <h1>Sub-Document</h1>
      <form id="sendForm" action="">
         <p>
            <label for="input">Enter text to be copied to the main window:</label>
            <input type="text" id="input">
         </p>
         <p>
            <input type="button" value="Send Text to Opener" id="send-text">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-13-02- sub.js

```
// run script when the page has loaded
addEvent(window, 'load', initialize);

// apply behaviors when document has loaded
function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to button
      var oButton = document.getElementById('send-text');

         // if it exists, apply behavior
         if (oButton)
         {
            addEvent(oButton, 'click', copyToOpener);
         }
   }
}

// copy input text to output in parent
function copyToOpener()
{
   // find the input field in the current window
   var oInput = document.getElementById('input');

   // find the output field in the parent window
   var oOutput = opener.document.getElementById('output');

      // if they both exist, copy input text
      if (oInput && oOutput)
      {
         oOutput.value = oInput.value;
      }
}
```

All the action in the subwindow document stems from the `onclick` event handler assigned to the Send Text button. It triggers the `copyToOpener()` function, which assigns the subwindow input field's value to the value of the output field in the opener window's document. Remember, the contents of each window and frame belong to a document. Even after your reference targets a specific window or frame, the reference must continue helping the browser find the ultimate destination, which generally is some element of the document.

Just one more lesson to go before we let you explore all the details elsewhere in the book. We'll use the final tutorial chapter to show you some fun things you can do with your web pages, such as changing images when the user rolls the mouse over a picture.

Exercises

Before answering the first three questions, study the structure of the following frameset for a web site that lists college courses:

```
<html>
   <head>
      ...
   </head>
   <frameset rows="85%,15%">
      <frameset cols="20%,80%">
         <frame name="mechanics" src="history101M.html">
         <frame name="description" src="history101D.html">
      </frameset>
      <frameset cols="100%">
         <frame name="navigation" src="navigator.html">
      </frameset>
   </frameset>
   <noframes>
      ...
   </noframes>
</html>
```

1. Each document that loads into the description frame links to a JavaScript script that uses the `onload` event handler to store a course identifier value in the framesetting document's global variable `currCourse`. Write the function that sets this value to `history101`.
2. Draw a block diagram that describes the hierarchy of the windows and frames represented in the frameset definition.
3. Write the HTML markup and JavaScript statements located in the navigation frame that together perform two actions: load the file `french201M.html` into the mechanics frame, and load the file `french201D.html` into the description frame.
4. While a frameset is still loading, a JavaScript error message suddenly appears, saying, "window.document.navigation.form.selector is undefined." What do you think is happening in the application's scripts, and how can you solve the problem?
5. A script in a child frame of the main window uses `window.open()` to generate a second window. How can a script in the second window access the `location` object (URL) of the top (framesetting) window in the main browser window?

CHAPTER

14

Images and Dynamic HTML

The previous eight lessons have been intensive, covering a lot of ground for both programming concepts and JavaScript. Now it's time to apply those fundamentals to learning more advanced techniques. We cover two areas here. First, we show you how to implement the ever-popular *mouse rollover,* in which images swap when the user rolls the cursor around the screen. Then we introduce you to techniques for modifying a page's style and content after the page has loaded.

Although image swapping on mouse rollover can be accomplished more easily using Cascading Style Sheets (CSS), we'll demonstrate how to do it with JavaScript because you'll probably see a lot of it in legacy scripts, and because it's a handy way to illustrate how to manipulate image objects.

IN THIS CHAPTER

How to pre-cache images

How to swap images for mouse rollovers

Changing style sheet settings

Modifying body content dynamically

The Image Object

One of the objects contained by the document is the Image object — supported in all scriptable browsers since the days of NN3 and IE4. Image object references for a document are stored in the object model as an array belonging to the `document` object. Therefore, you can reference an image by array index or image name. Moreover, the array index can be a string version of the image's name. All the following are valid references to an image object:

```
document.getElementById("imageName")
document.getElementsByTagName("img")[n]
document.images[n]
document.images["imageName"]
document.imageName
```

(The last reference will work only if `imageName` doesn't include any valid HTML ID characters that aren't permitted in JavaScript names, such as a hyphen or period.)

We are no longer constrained by ancient scriptable browser limitations that required an image be encased within an `a` element to receive mouse events. You

may still want to do so if a click is intended to navigate to a new URL, but to use a visitor's mouse click to trigger local JavaScript execution, it's better to let the `img` element's event handlers do all the work.

Interchangeable images

The advantage of having a scriptable image object is that a script can change the image occupying the rectangular space already occupied by an image. In current browsers, the images can even change size, with surrounding content automatically reflowing around the resized image.

The script behind this kind of image change is simple enough. All it entails is assigning a new URL to the `img` element object's `src` property. The size of the image on the page is governed by the `height` and `width` attributes set in the `<img>` tag, and the `height` and `width` properties set in the style sheet. The most common image rollovers use the same size of image for each of the rollover states.

Pre-caching images

Images take extra time to download from a web server until they are stored in the browser's cache. If you design your page so that an image changes in response to user action, you usually want the same fast response that users are accustomed to in other programs. Making the user wait seconds for an image to change can detract from enjoyment of the page.

JavaScript comes to the rescue by enabling scripts to load images into the browser's memory cache without displaying the image, a technique called *pre-caching images*. The tactic that works best is to preload the image into the browser's image cache while the page initially loads. Users are less impatient for those few extra seconds when the main page loads, than they are waiting for an image to download in response to some mouse action. However, keep in mind that there is a balance. Today's audience tends to give a page less than 10 seconds to load before moving on. Although pre-caching images means a fast response to a mouse action, if you pre-cache too many images, you risk losing web site visitors before they can see your amazing image swapping in response to mouse actions.

Pre-caching an image requires constructing an image object in memory. An image object created in memory differs in some respects from the document `img` element object that you create with the `<img>` tag. Memory-only objects are created by script, and you don't see them on the page at all. But their presence in the document code forces the browser to load the images as the page loads. The object model provides an `Image` object constructor function to create the memory type of image object as follows:

```
var myImage = new Image(width, height);
```

Parameters to the constructor function are the pixel `width` and `height` of the image. These dimensions should match the `width` and `height` attributes of the `<img>` tag. Once the image object exists in memory, you can then assign a filename or URL to the `src` property of that image object:

```
myImage.src = "someArt.gif";
```

When the browser encounters a statement assigning a URL to an image object's `src` property, the browser fetches and loads that image into the image cache. All the user sees is some extra loading information in the status bar, as though another image were in the page. By the time the entire page loads, all images generated in this manner are tucked away in the image cache. You can then assign your cached image's `src` property, or the actual image URL, to the `src` property of the document image created with the `<img>` tag:

```
document.images[0].src = myImage.src;
```

or

```
document.getElementById("myImg").src = myImage.src ;
```

The change to the image in the document is instantaneous.

Listing 14-1 demonstrates a page that has one <img> tag and a select list that enables you to replace the image in the document with any of four pre-cached images (including the original image specified for the tag). If you type this listing, you can obtain copies of the four image files from the companion CD-ROM in the Chapter 14 directory of listings. (You still must type the HTML and code, however.)

LISTING 14-1

Pre-Caching Images

HTML: jsb-14-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Image Object</title>
      <style type="text/css">
         img
         {
            height:90px; width:120px;
         }
      </style>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-14-01.js"></script>
   </head>
   <body >
      <h2>Image Object</h2>
      <img src="desk1.gif" id="thumbnail">
      <form>
         <select id="imageChooser">
            <option value="image1">Bands</option>
            <option value="image2">Clips</option>
            <option value="image3">Lamp</option>
            <option value="image4">Erasers</option>
         </select>
      </form>
   </body>
</html>
```

JavaScript: jsb-14-01.js

```
// initialize when the page has loaded
var oImageChooser;
addEvent(window, "load", initialize);
```

continued

LISTING 14-1 *(continued)*

```
function initialize()
{
   // get W3C DOM or IE4+ reference for an ID
   // imageChooser is the select element
   if (document.getElementById)
   {
      oImageChooser = document.getElementById("imageChooser");
   }
   else
   {
      oImageChooser = document.imageChooser;
   }

   addEvent(oImageChooser, 'change', loadCached);

}

// initialize empty array
var imageLibrary = new Array();
// pre-cache four images
imageLibrary["image1"] = new Image(120,90);
imageLibrary["image1"].src = "desk1.gif";
imageLibrary["image2"] = new Image(120,90);
imageLibrary["image2"].src = "desk2.gif";
imageLibrary["image3"] = new Image(120,90);
imageLibrary["image3"].src = "desk3.gif";
imageLibrary["image4"] = new Image(120,90);
imageLibrary["image4"].src = "desk4.gif";

// load an image chosen from select list
function loadCached()
{
   var imgChoice = oImageChooser.options[oImageChooser.selectedIndex].value;
   document.getElementById("thumbnail").src = imageLibrary[imgChoice].src;
}
```

As the page loads, it executes several statements immediately. These statements create an array that is populated with four new memory image objects. Each image object has a filename assigned to its `src` property. These images are loaded into the image cache as the page loads. Down in the `body` portion of the document, an `<img>` tag stakes its turf on the page and loads one of the images as a starting image.

A `select` element lists user-friendly names for the pictures while housing (in the option values) the names of image objects already pre-cached in memory. When the user makes a selection from the list, the `loadCached()` function extracts the selected item's value — which is a string index of the image within the `imageLibrary` array. The `src` property of the chosen image object is assigned to the `src` property of the visible `img` element object on the page, and the pre-cached image appears instantaneously.

Creating image rollovers

A favorite technique to add some pseudo-excitement to a page is to swap button images as the user rolls the cursor over them. The degree of change to the image is largely a matter of taste. The effect can be subtle (a slight highlight or glow around the edge of the original image) or drastic (a radical change of color). Whatever your approach, the scripting is the same.

When several of these graphical buttons occur in a group, we tend to organize the memory image objects as arrays, and create naming and numbering schemes that facilitate working with the arrays. Listing 14-2 shows such an arrangement for four buttons that control a slide show. The code in the listing is confined to the image-swapping portion of the application. This is the most complex and lengthiest listing of the tutorial, so it requires a bit of explanation as it goes along. It begins with a style sheet rule for each of the `img` elements located in a `controller` container.

LISTING 14-2

Image Rollovers

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Slide Show/Image Rollovers</title>
      <style type="text/css">
         div#controller img {
            height: 70px; width: 136px; padding: 5px;
            }
      </style>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript">
```

Only browsers capable of handling image objects should execute statements that pre-cache images. Therefore, the entire sequence is nested inside an `if` construction that tests for the presence of the `document.images` array. In older browsers, the condition evaluates to *undefined,* which an `if` condition treats as `false`:

```
if (document.images)
{
```

Image pre-caching starts by building two arrays of image objects. One array stores information about the images depicting the graphical buttons' off position; the other is for images depicting their on position. These arrays use strings (instead of integers) as index values. The string names correspond to the names given to the visible `img` element objects whose tags come later in the source code. The code is clearer to read (for example, you know that the `offImgArray["first"]` entry has to do with the First button image). Also, as you see later in this listing, rollover images don't conflict with other visible images on the page (a possibility if you rely exclusively on numeric index values when referring to the visible images for the swapping).

After creating the array and assigning new blank image objects to the first four elements of the array, we go through the array again, this time assigning file pathnames to the `src` property of each object

stored in the array. These lines of code execute as the page loads, forcing the images to load into the image cache along the way:

```
// pre-cache all 'off' button images
var offImgArray = new Array();
offImgArray["first"] = new Image(136,70);
offImgArray["prev"] = new Image(136,70);
offImgArray["next"] = new Image(136,70);
offImgArray["last"] = new Image(136,70);

// off image array -- set 'off' image path for each button
offImgArray["first"].src = "firstoff.png";
offImgArray["prev"].src = "prevoff.png";
offImgArray["next"].src = "nextoff.png";
offImgArray["last"].src = "lastoff.png";

// pre-cache all 'on' button images
var onImgArray = new Array();
onImgArray["first"] = new Image(136,70);
onImgArray["prev"] = new Image(136,70);
onImgArray["next"] = new Image(136,70);
onImgArray["last"] = new Image(136,70);

// on image array -- set 'on' image path for each button
onImgArray["first"].src = "firston.png";
onImgArray["prev"].src = "prevon.png";
onImgArray["next"].src = "nexton.png";
onImgArray["last"].src = "laston.png";
```

Do you see the repeating pattern in the statements above? Instead of those statements, here's a way you could take advantage of the repeating pattern:

```
var offImgArray = new Array();
var onImgArray = new Array();
var ButtonArray = ["first", "prev", "next", "last"];

for (var i=0; i < ButtonArray.length; i++)
{
   var Button = ButtonArray[i];

   // pre-cache 'off' button image
   offImgArray[Button] = new Image(136,70);
   offImgArray[Button].src = Button + "off.png";

   // pre-cache 'on' button image
   onImgArray[Button] = new Image(136,70);
   onImgArray[Button].src = Button + "on.png";
}
```

As you can see in the following code, when the user rolls the mouse atop any of the visible document image objects, the `onmouseover` event handler invokes the `imageOn()` function,

passing the name of the particular image. The `imageOn()` function uses that name to synchronize the `document.images` array entry (the visible image) with the entry of the in-memory array of on images from the `onImgArray` array. The `src` property of the array entry is assigned to the corresponding document image `src` property. At the same time, the cursor changes to look like it does over active links.

```
}
// functions that swap images & status bar
function imageOn(imgName)
{
   if (document.images)
   {
      document.images[imgName].style.cursor = "pointer";
      document.images[imgName].src = onImgArray[imgName].src;
   }
}
```

The same goes for the `onmouseout` event handler, which needs to turn the image off by invoking the `imageOff()` function with the same index value.

```
function imageOff(imgName)
{
   if (document.images)
   {
      document.images[imgName].style.cursor = "default";
      document.images[imgName].src = offImgArray[imgName].src;
   }
}
```

Both the `onmouseover` and `onmouseout` event handlers set the status bar text to a friendly descriptor — at least in those browsers that still support displaying custom text in the status bar. The `onmouseout` event handler sets the status bar message to an empty string.

```
function setMsg(msg)
{
   window.status = msg;
   return true;
}
```

For this demonstration, we disable the functions that control the slide show. But we leave the empty function definitions here so they catch the calls made by the clicks of the links associated with the images.

```
// controller functions (disabled)
function goFirst()
{
}
function goPrev()
{
}
function goNext()
{
}
```

```
function goLast()
{
}
// event handler assignments
function init()
{
   if (document.getElementById)
   {
      oImageFirst = document.getElementById("first");
      oImagePrev = document.getElementById("prev");
      oImageNext = document.getElementById("next");
      oImageLast = document.getElementById("last");
   }
   else
   {
      oImageFirst = document.first;
      oImagePrev = document.prev;
      oImageNext = document.next;
      oImageLast = document.last;
   }

   addEvent(oImageFirst, 'click', goFirst);
   addEvent(oImageFirst, 'mouseover', function()
      {
         imageOn("first");
         return setMsg("Go to first picture");
      });
   addEvent(oImageFirst, 'mouseout', function()
      {
         imageOff("first");
         return setMsg("");
      });
   addEvent(oImagePrev, 'click', goPrev);
   addEvent(oImagePrev, 'mouseover', function()
      {
         imageOn("prev");
         return setMsg("Go to previous picture");
      });
   addEvent(oImagePrev, 'mouseout', function()
      {
         imageOff("prev");
         return setMsg("");
      });
   addEvent(oImageNext, 'click', goNext);
   addEvent(oImageNext, 'mouseover', function()
      {
         imageOn("next");
         return setMsg("Go to next picture");
      });
```

```
            addEvent(oImageNext, 'mouseout', function()
               {
                  imageOff("next");
                  return setMsg("");
               });
            addEvent(oImageLast, 'click', goLast);
            addEvent(oImageLast, 'mouseover', function()
               {
                  imageOn("last");
                  return setMsg("Go to last picture");
               });
            addEvent(oImageLast, 'mouseout', function()
               {
                  imageOff("last");
                  return setMsg("");
               });
         }

         // initialize when the page has loaded
         addEvent(window, "load", init);
      </script>
   </head>

   <body>
      <h1>Slide Show Controls</h1>
```

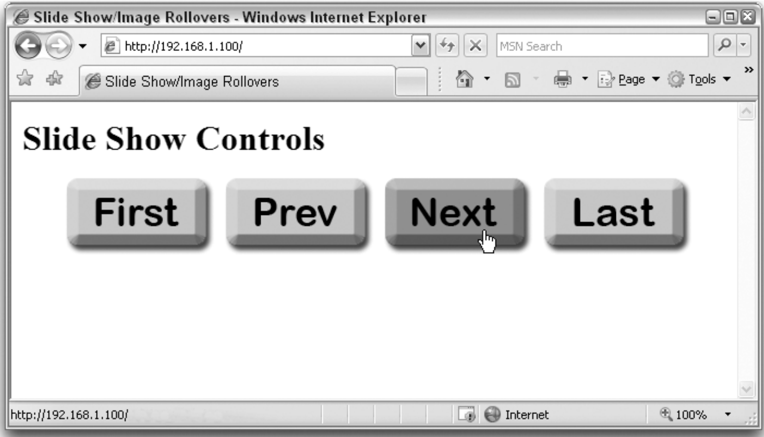
We elected to place the controller images inside a `div` element so that the images could be positioned or styled as a group. Each `img` element's `onmouseover` event handler (defined above) calls the `imageOn()` function, passing the name of the image to be swapped. Because both the `onmouseover` and `onmouseout` event handlers require a `return true` statement to work in older browsers, we combine the second function call (`to setMsg()`) with the `return true` requirement. The `setMsg()` function always returns `true` and is combined with the `return` keyword before the call to the `setMsg()` function. It's just a trick to reduce the amount of code in these event handlers.

```
      <div id="controller">
         <img src="images/firstoff.png" name="first" id="first" >
         <img src="images/prevoff.png" name="prev" id="prev" >
         <img src="images/nextoff.png" name="next" id="next" >
         <img src="images/lastoff.png" name="last" id="last" >
      </div>
   </body>
</html>
```

You can see the results of this lengthy script in Figure 14-1. As the user rolls the mouse atop one of the images, it changes from a light to dark color by swapping the entire image. You can access the image files on the CD-ROM, and we encourage you to enter this lengthy listing and see the magic for yourself.

FIGURE 14-1

Typical mouse rollover image swapping.



Rollovers Without Scripts

As cool as the rollover effect is, thanks to CSS technology, you don't always need JavaScript to accomplish rollover dynamism. You can blend CSS with JavaScript to achieve the same effect. Listing 14-3 demonstrates a version of Listing 14-2, but using CSS for the rollover effect, while JavaScript still handles the control of the slide show.

The HTML for the buttons consists of `li` elements that are sized and assigned background images of the off versions of the buttons. The text of each `li` element is surrounded by an `a` element so that CSS `:hover` pseudo-elements can be assigned. (Internet Explorer through version 7 requires this, whereas W3C DOM browsers recognize `:hover` for all elements.) When the cursor hovers atop an `a` element, the background image changes to the on version. The `onclick` event handler assignments remain in the script portion of the page, where they are performed after the page loads (to make sure the elements exist).

LISTING 14-3

CSS Image Rollovers

HTML: jsb-14-03.html

    left: 292px;
    }
#last {
    left: 438px;
    }

#first a {
    background-image: url("firstoff.png");
    }
#first a:hover {
    background-image: url("firston.png");
    }
#prev a {
    background-image: url("prevoff.png");
    }
#prev a:hover {
    background-image: url("prevon.png");
    }
```

continued

LISTING 14-3 *(continued)*

```
#next a {
   background-image: url("nextoff.png");
   }
#next a:hover {
   background-image: url("nexton.png");
   }
#last a {
   background-image: url("lastoff.png");
   }
#last a:hover {
   background-image: url("laston.png");
   }
```

JavaScript: jsb-14-03.js

```
// controller functions (disabled)
function goFirst()
{
   alert("in gofirst");
}
function goPrev()
{
   alert("in goprev");
}
function goNext()
{
   alert("in gonext");
}
function goLast()
{
   alert("in golast");
}

// event handler assignments
function init()
{
   if (document.getElementById)
   {
      oImageFirst = document.getElementById("first");
      oImagePrev = document.getElementById("prev");
      oImageNext = document.getElementById("next");
      oImageLast = document.getElementById("last");
   }
   else
   {
      oImageFirst = document.first;
      oImagePrev = document.prev;
      oImageNext = document.next;
      oImageLast = document.last;
   }
```

```
    addEvent(oImageFirst, 'click', goFirst);
    addEvent(oImagePrev, 'click', goPrev);
    addEvent(oImageNext, 'click', goNext);
    addEvent(oImageLast, 'click', goLast);
}

// initialize when the page has loaded
addEvent(window, "load", init);
```

The need to wrap the `li` element text for Internet Explorer (which the CSS shifts completely off-screen, because we don't need the text) forces scripters to address further considerations. In this application, a click of an `li` element is intended to run a local script, not to load an external URL. But the `a` element's default behavior is to load another URL. The # placeholder shown in Listing 14-3 causes the current page to reload, which will wipe away any activity of the `onclick` event handler function. It is necessary, therefore, to equip each of the slide-show navigation functions with some extra code lines that prevent the `a` element from executing its default behavior. You'll learn how to do that in Chapter 32, "Event Objects." (It requires different syntax for the incompatible W3C DOM and IE event models.)

One other note about the CSS approach in Listing 14-3 is that there is no image pre-caching taking place. You could add the pre-caching code for the "on" images from Listing 14-2 to get the alternative background images ready for the browser to swap. That's a case of CSS and JavaScript really working together.

The javascript: Pseudo-URL

You have seen instances in previous chapters of applying what is called the `javascript:` pseudo-URL to the `href` attributes of `<a>` and `<area>` tags. This technique should not be used for public web sites that may be accessed by browsers with scripting turned off (for which the links will be inactive).

The technique was implemented to supplement the `onclick` event handler of objects that act as hyperlinks. Especially in the early scripting days, when elements such as images had no event handlers of their own, hyperlinked elements surrounding those inactive elements allowed users to appear to interact directly with elements such as images. When the intended action was to invoke a script function (rather than navigate to another URL, as is usually the case with a hyperlink), the language designers invented the `javascript:` protocol for use in assignments to the `href` attributes of hyperlink elements (instead of leaving the required attribute empty).

When a scriptable browser encounters an `href` attribute pointing to a `javascript:` pseudo-URL, the browser executes the script content after the colon when the user clicks the element. For example, the `a` elements of Listing 14-3 could have been written to point to `javascript:` pseudo-URLs that invoke script functions on the page, such as:

```
<a href="javascript:goFirst()">
```

Note that the `javascript:` protocol is not a published standard, despite its wide adoption by browser makers. In a public web site that may be accessed by visitors with accessibility concerns (and potentially by browsers having little or no JavaScript capability), a link should point to a server

URL that performs an action (for example, through a server program), which in turn replicates what client-side JavaScript does (faster) for visitors with scriptable browsers.

Popular Dynamic HTML Techniques

Because today's scriptable browsers uniformly permit scripts to access each element of the document and automatically reflow the page's content when anything changes, a high degree of dynamism is possible in your applications. Dynamic HTML (DHTML) is a very deep subject, with lots of browser-specific peculiarities. In this section of the tutorial, you will learn techniques that work in Internet Explorer and W3C DOM-compatible browsers. We'll focus on two of the most common tasks for which DHTML is used: changing element styles and modifying document content.

Changing style sheet settings

Each element that renders on the page (and even some elements that don't) has a property called `style`. This property provides script access to all CSS properties supported for that element by the current browser. Property values are the same as those used for CSS specifications — frequently, a different syntax from similar settings that used to be made by HTML tag attributes. For example, if you want to set the text color of a `blockquote` element whose ID is `FranklinQuote`, the syntax is

```
document.getElementById("FranklinQuote").style.color = "rgb(255, 255, 0)";
```

Because the CSS `color` property accepts other ways of specifying colors (such as the traditional hexadecimal triplet — `#ffff00`), you may use those as well.

Some CSS property names, however, do not conform to JavaScript naming conventions. Several CSS property names contain hyphens. When that occurs, the scripted equivalent of the property compresses the words and capitalizes the start of each word. For example, the CSS property `font-weight` would be set in script as follows:

```
document.getElementById("highlight").style.fontWeight = "bold";
```

A related technique properly gives responsibility for the document design to CSS. For example, if you define CSS rules for two different classes, you can simply switch the class definition being applied to the element by way of the element object's `className` property. Let's say you define two CSS class definitions with different background colors:

```
.normal {background-color: #ffffff};
.highlighted {background-color: #ff0000};
```

In the HTML page, the element first receives its default class assignment as follows:

```
<p id="news" class="normal">...</p>
```

A script statement can then change the class of that element object so that the highlighted style applies to it:

```
document.getElementById("news").className = "highlighted";
```

Restoring the original class name also restores its look and feel. This approach is also a quick way to change multiple style properties of an element with a single statement.

Dynamic content via W3C DOM nodes

In Chapter 10, "Window and Document Objects," you saw the `document.createElement()` and `document.createTextNode()` methods in action. These methods create new document object model (DOM) objects out of thin air, which you may then modify by setting properties (attributes) prior to plugging the new stuff into the document tree for all to see.

As an introduction to this technique, we'll demonstrate the steps you would go through to add an element and its text to a placeholding `span` element on the page. In this example, a paragraph element belonging to a class called `centered` will be appended to a `span` whose `id` is `placeholder`. Some of the text for the content of the paragraph comes from a text field in a form (the visitor's first name). Here is the complete sequence:

```
var newElem = document.createElement("p");
newElem.className = "centered";
var newText = document.createTextNode("Thanks for visiting, " +
   document.forms[0].firstName.value);
// insert text node into new paragraph
newElem.appendChild(newText);
// insert completed paragraph into placeholder
document.getElementById("placeholder").appendChild(newElem);
```

After the element and text nodes are created, the text node must be inserted into the element node. Because the new element node is empty when it is created, the DOM `appendChild()` method plugs the text node into the element (between its start and end tags, if you could see the tags). When the paragraph element is assembled, it is inserted at the end of the initially empty `span` element. Additional W3C DOM methods (described in Chapter 26, "Generic HTML Element Objects," and Chapter 27, "Window and Frame Objects") provide more ways to insert, remove, and replace nodes.

Dynamic content through the innerHTML property

Prior to the W3C DOM specification, Microsoft invented a property of all element objects: `innerHTML`. This property first appeared in Internet Explorer 4, and it became popular due to its practicality. The property's value is a string containing HTML tags and other content, just as it would appear in an HTML document inside the current element's tags. Even though the W3C DOM working group did not implement this property for the published standard, the property proved to be too practical and popular for modern browser makers to ignore. You can find it implemented as a de facto standard in Mozilla-based browsers and Safari, among others.

To illustrate the difference in the approach, the following code example shows the same content creation and insertion as shown in the previous W3C DOM section, but this time with the `innerHTML` property:

```
// accumulate HTML as a string
var newHTML = "<p class='centered'>Thanks for visiting, ";
newHTML += document.forms[0].firstName.value;
newHTML += "</p>";
// blast into placeholder element's content
document.getElementById("placeholder").innerHTML = newHTML;
```

Although the `innerHTML` version seems more straightforward — and makes it easier for HTML coders to visualize what's being added — the DOM node approach is more efficient when the document modification task entails lots of content. Extensive JavaScript string concatenation operations can slow browser script processing. Sometimes, the shortest script is not necessarily the fastest.

And so ends the final lesson of the *JavaScript Bible* tutorial. If you have gone through every lesson and tried your hand at the exercises, you are ready to dive into the rest of the book to learn the fine details and many more features of both the DOM and the JavaScript language. You can work sequentially through the chapters of Part III, "JavaScript Core Language Reference," and Part IV, "Document Objects Reference," but before too long, you should also take a peek at Chapter 48, "Debugging Scripts," to learn some important debugging techniques.

Exercises

1. Explain the difference between a document `img` element object and the memory type of an image object.
2. Write the JavaScript statements needed to pre-cache an image file named `jane.jpg` that later will be used to replace the document image defined by the following HTML:

```
<img name="people" src="john.jpg" height="120" width="100" alt="people">
```

3. With the help of the code you wrote for question 2, write the JavaScript statement that replaces the document image with the memory image.
4. Backward-compatible `img` element objects do not have event handlers for mouse events. How do you trigger scripts needed to swap images for mouse rollovers?
5. Assume that a `table` element contains an empty table cell (`td`) element whose ID is `forwardLink`. Using W3C DOM node creation techniques, write the sequence of script statements that create and insert the following hyperlink into the table cell:

```
<a href="page4.html">Next Page</a>
```

The String Object

IN THIS CHAPTER

How to parse and work with text

Performing search-and-replace operations

Scripted alternatives to text formatting

The tutorial in Chapter 8, "Programming Fundamentals, Part I," introduced you to the concepts of values and the types of values that JavaScript works with — features such as strings, numbers, and Boolean values. Chapter 12, "Strings, Math, and Dates," described several characteristics and methods of strings. In this chapter, you look more closely at the very important String data type, as well as its relationship to the Number data type. Along the way, you encounter the many ways in which JavaScript enables scripters to manipulate strings.

Note

Much of the syntax that you see in this chapter is identical to that of the Java programming language. Because the scope of JavaScript activity is much narrower than that of Java, you don't have nearly as much to learn for JavaScript as you do for Java. ■

String and Number Data Types

Although JavaScript is what is known as a "loosely typed" language, you still need to be aware of several data types, because of their impact on the way you work with the information in those forms. In this section, we focus on strings and two types of numbers.

Simple strings

A *string* consists of one or more standard text characters placed between matching quote marks. JavaScript is forgiving in one regard: You can use single or double quotes, as long as you match two single quotes or two double quotes around a string. A major benefit of this scheme becomes apparent when you try to include quoted text inside a string. For example, say that you're assembling a line of HTML code in a variable that you will eventually write to a new

window that is completely controlled by JavaScript. The line of text that you want to assign to a variable is the following:

```
<input type="checkbox" name="candy" />Chocolate
```

To assign this entire line of text to a variable, you have to surround the line in quotes. But because quotes appear inside the string, JavaScript (or any language) has problems deciphering where the string begins or ends. By carefully placing the other kind of quote pairs, however, you can make the assignment work. Here are two equally valid ways:

```
result = '<input type="checkbox" name="candy" />Chocolate';
result = "<input type='checkbox' name='candy' />Chocolate";
```

Notice that in both cases, the same unique pair of quotes surrounds the entire string. Inside the string, two quoted strings appear that are treated as such by JavaScript. It is helpful stylistically to settle on one form or the other, and then use that form consistently throughout your scripts.

If the expression you're quoting contains both apostrophes and double quotes, you need to *escape* one or the other within the string, with a backslash:

```
Pat's favorite word is "syzygy."
result = "Pat's favorite word is \"syzygy.\""
result = 'Pat\'s favorite word is "syzygy."'
```

Because escaped characters aren't as easy to read and proofread, you might want to choose a quote character that doesn't appear in the expression you're quoting, if possible.

Building long string variables

The act of joining strings together — concatenation — enables you to assemble long strings out of several little pieces. This feature is very important for some scripting — for example, when you need to build an HTML page's specifications entirely within a variable before writing the page to another frame, with one statement. It is often unwieldy and impractical to include such lengthy information in a single string on one line of code, which is why you may want to build the large string out of substrings.

One tactic keeps the length of each statement in this building process short enough so that it's easily readable in your text editor. This method uses the add-by-value assignment operator (+=) that appends the right-hand side of the equation to the left-hand side. Here is a simple example, which begins by initializing a variable, `newDocument`, as an empty string:

```
var newDocument = "";
newDocument += "<!DOCTYPE html>";
newDocument += "<html>" ;
newDocument += "<head>";
newDocument += '<meta http-equiv="content-type"';
newDocument += ' content="text/html;charset=utf-8">';
newDocument += "<title>Prodigal Summer</title>";
newDocument += "</head>";
newDocument += "<body>";
newDocument += "<h1>Prodigal Summer</h1>";
newDocument += '<p class="byline">by Barbara Kingsolver</p>';
```

Starting with the second line, each statement adds more data to the string being stored in `newDocument`. You can continue appending string data until the entire page's specification is contained in the `newDocument` variable.

Note

Excessive use of the add-by-value operator involving large quantities of text can become inefficient. If you are experiencing slow performance when accumulating large strings, try pushing your string segments into items of an array (see Chapter 18, "The Array Object"). Then use the array's `join()` method to generate the resulting large string value. ■

Joining string literals and variables

In some cases, you need to create a string out of literal strings (characters with quote marks around them) and string variable values. The methodology for concatenating these types of strings is no different from that of multiple string literals. The plus-sign operator does the job. Therefore, in the following example, a variable contains a name. That variable value is made a part of a larger string whose other parts are string literals:

```
teamName = prompt("Please enter your favorite team:","");
var msg = "The " + teamName + " are victorious!";
alert(msg);
```

Some common problems that you may encounter while attempting this kind of concatenation include the following:

- Accidentally omitting one of the quotes around a literal string
- Failing to insert blank spaces in the string literals to accommodate word spacing
- Forgetting to concatenate punctuation after a variable value

Also, don't forget that what we show here as variable values can be any expression that evaluates to a string, including property references and the results of some methods. For example:

```
var msg = "The name of this document is " + document.title + ".";
alert(msg);
```

Special inline characters

The way string literals are created in JavaScript makes adding certain characters to strings difficult — primarily quotes, carriage returns, apostrophes, and tab characters. Fortunately, JavaScript provides a mechanism for entering such characters into string literals. A backslash symbol, followed by the character that you want to appear as inline, makes that task happen. For the "invisible" characters, a special set of letters following the backslash tells JavaScript what to do.

The most common backslash pairs are as follows:

- `\"` Double quote
- `\'` Single quote (apostrophe)
- `\\` Backslash
- `\b` Backspace
- `\t` Tab

- \n New line
- \r Carriage return
- \f Form feed

Use these *inline characters* (also known as *escaped characters*, but this terminology has a different connotation for Internet strings) inside quoted string literals to make JavaScript recognize them. When assembling a block of text that needs a new paragraph, insert the \n character pair. Here are some examples of syntax using these special characters:

```
msg = "I say \"trunk\" and you say \"boot.\"";
msg = 'You\'re doing fine.';
msg = "This is the first line.\nThis is the second line.";
msg = document.title + "\n" + document.links.length + " links present.";
```

Technically speaking, a complete carriage return, as it was known in the days of the typewriter, is both a line feed (advance the line by one) and a carriage return (move the carriage all the way to the left margin). Although JavaScript strings treat a line feed (\n new line) as a full carriage return, you may have to construct \r\n breaks when assembling strings that go back to a cgi script on a server. The format that you use depends on the string-parsing capabilities of the cgi program. (Also see the special requirements for the textarea object in Chapter 36, "Text-Related Form Objects," on the CD.)

It's easy to confuse the strings assembled for display in textarea objects or alert boxes with strings to be written as HTML. In most cases, browsers ignore carriage returns or render them like spaces. For HTML strings, make sure that you use standard HTML tags, such as paragraphs (<p>...</p>) and line-breaks (<br>), rather than, or in addition to, the inline return or line feed symbols.

String Object

Properties	Methods

†Member of the static `String` object

Syntax

Creating a string object:

```
var myString = new String("characters");
```

Creating a string value:

```
var myString = "characters";
```

Accessing static `String` object properties and methods:

```
String.property | method([parameters])
```

Accessing string object properties and methods:

```
string.property | method([parameters])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

About this object

JavaScript draws a fine line between a string value and a string object. Both let you use the same methods on their contents, so that by and large, you do not have to create a string object (with the `new String()` constructor) every time you want to assign a string value to a variable. A simple assignment operation (`var myString = "fred"`) is all you need to create a string value that behaves on the surface very much like a full-fledged string object.

Where the difference comes into play is when you want to exploit the "object-ness" of a genuine string object, which is explained further in the discussion of the `string.prototype` property, later in this chapter. You may also encounter the need to use a full-fledged string object when passing string data to Java applets. If you find that your applet doesn't receive a string value as a Java `String` data type, then create a new string object via the JavaScript constructor function before passing the value to the applet.

With string data often comes the need to massage string text in scripts. In addition to concatenating strings, at times you need to extract segments of strings, delete parts of strings, and replace one part of a string with some other text. Unlike many plain-language scripting languages, JavaScript is fairly low-level in its built-in facilities for string manipulation. This characteristic means that unless you can take advantage of the regular expression powers of IE4+/Moz1+ or advanced array techniques, you must fashion your own string handling routines out of the very elemental powers built into JavaScript. Later in this chapter, we provide several functions that you can use in your own scripts for common string handling in a manner fully compatible with older browsers.

As you work with string values, visualize every string value as an object, with properties and methods, like other JavaScript objects. JavaScript defines a few properties and a slew of methods for any string value (and one extra property for the static `String` object that is always present in the context of the browser window). The syntax is the same for string methods as it is for any other object method:

```
stringObject.method()
```

What may seem odd at first is that the *`stringObject`* part of this reference can be any expression that evaluates to a string, including string literals, variables containing strings, methods or functions that return strings, or other object properties. Therefore, the following examples of calling the `toUpperCase()` method are all valid:

```
"blah blah blah".toUpperCase()
yourName.toUpperCase() // yourName is a variable containing a string
window.prompt("Enter your name","").toUpperCase()
document.forms[0].entry.value.toUpperCase() // entry is text field object
```

A very important (and often misunderstood) concept to remember is that invoking a string method does not change the string object that is part of the reference. Rather, the method returns a string value, which can be used as a parameter to another method or function call, or assigned to a variable.

Therefore, to change the contents of a string variable to the results of a method, you must use an assignment operator, as in:

```
yourName = yourName.toUpperCase(); // variable is now all uppercase
```

Properties

constructor

Value: Function reference Read/Write

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `constructor` property is a reference to the function that was invoked to create the current string. For a native JavaScript string object, the constructor function is the built-in `String()` constructor.

When you use the `new String()` constructor to create a string object, the type of the value returned by the constructor is `object` (meaning that the `typeof` operator returns `object`). Therefore, you can use the `constructor` property on an object value to see if it is a string object:

```
if (typeof someValue == "object" )
{
   if (someValue.constructor == String)
   {
      // statements to deal with string object
   }
}
```

Although the property is read/write, and you can assign a different constructor to the `String.prototype`, the native behavior of a `String` object persists through the new constructor.

Example

Use The Evaluator (see Chapter 4) to test the value of the `constructor` property. One line at a time, enter and evaluate the following statements into the top text box:

```
a = new String("abcd")
a.constructor == String
a.constructor == Number
```

Related Items: `prototype` property

length

Value: Integer Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The most frequently used property of a string is `length`. To derive the length of a string, read its property as you would read the `length` property of any object:

```
string.length
```

The `length` value represents an integer count of the number of characters within the string. Spaces and punctuation symbols count as characters. Any backslash special characters embedded in a string count as one character, including such characters as newline and tab. Here are some examples:

```
"Lincoln".length // result = 7
"Four score".length // result = 10
"One\ntwo".length // result = 7
"".length // result = 0
```

The `length` property is commonly summoned when dealing with detailed string manipulation in repeat loops. For example, if you want to iterate through every character in a string, and somehow examine or modify each character, you would use the string's length as the basis for the loop counter.

prototype

Value: String object Read/Write

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

`String` objects defined with the `new String("`*`stringValue`*`")` constructor are robust objects compared to run-of-the-mill variables that are assigned string values. You certainly don't have to create this kind of string object for every string in your scripts, but these objects do come in handy if you find that strings in variables go awry. This happens occasionally while trying to preserve string information as script variables in other frames or windows. By using the `String` object constructor, you can be relatively assured that the string value will be available in the distant frame when needed.

Another benefit to using true `String` objects is that you can assign prototype properties and methods to all string objects in the document. A *prototype* is a collection of properties and methods that become part of every new object created after the prototype items are added. As an example, you may want to define a new method for transforming a string that isn't already defined by the JavaScript `String` object. Listing 15-1 shows how to create and use such a prototype.

Note

The property assignment event-handling technique employed throughout the code in this chapter, and much of the book, is `addEvent()`, a cross-browser event handler explained in detail in Chapter 32, "Event Object."

The `addEvent()` function is part of the script file `jsb-global.js`, located on the accompanying CD-ROM in the `Content/` folder, where it is accessible to all chapters' scripts. ■

LISTING 15-1

Using the String Object Prototype

HTML: jsb-15-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Using the String Object Prototype</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-15-01.js"></script>
   </head>
```

```
   <body>
      <h1>Using the String Object Prototype</h1>
      <form action="initialCap.php">
         <p>
            <label for="entry">Enter one or more words to be Initial Capped:</label>
         </p>
         <p>
            <input type="text" id="entry" name="entry" value="">
            <input type="button" id="do-it" value="Initial Caps">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-15-01.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to critical elements
      var oButton = document.getElementById('do-it');
      var oEntry = document.getElementById('entry');

         // if they all exist...
         if (oButton && oEntry)
         {
            // apply behavior to button
            addEvent(oButton, 'click', doIt);
         }
   }
}

// try out the new String method
function doIt()
{
   // point to input field
   var oEntry = document.getElementById('entry');

   // use the new method to update the input text
   oEntry.value = oEntry.value.initialCaps();
}

// add a new method to the String prototype
// to capitalize the first letter of each word

String.prototype.initialCaps = function()
```

continued

LISTING 15-1 *(continued)*

```
{
   // get the input text
   var sText = this.toString();

   // separate individual words
   var aWords = sText.split(' ');

   // capitalize each word
   for (var i = 0; i < aWords.length; i++)
   {
      var sInitial = aWords[i].charAt(0);
      var sRemainder = aWords[i].substr(1);
      aWords[i] = sInitial.toUpperCase() + sRemainder.toLowerCase();
   }

   // reassemble the array of words back into a string
   return aWords.join(' ');
}
```

Note

Many of the HTML example pages in this book include a form action to post input to a server-side PHP program — as a reminder that it's important to make sure that our pages can function even when JavaScript is not running. The server-side scripts themselves do not exist and are outside the scope of this book. If written, they would perform essentially the same operations as the JavaScript logic does. ■

The core of the JavaScript in Listing 15-1 is the last block, where we add the `initialCaps()` method to the `String` object prototype, and spell out what that method does. Similar to most object methods, this new one doesn't modify the original string itself, but rather returns a value we can use for any purpose we want. Here, we grab the contents of the input field `entry`, transform it with `initialCaps()`, and use that new value to reset the input field contents.

Modifying object prototypes is a powerful way to add new features to the JavaScript language on-the-fly.

In the next sections, we divide `String` object methods into two distinct categories. The first, parsing methods, focuses on string analysis and character manipulation within strings. The second group, formatting methods, is devoted entirely to assembling strings in HTML syntax for those scripts that assemble the text to be written into new documents or other frames.

Parsing methods

string.charAt(*index*)

Returns: One-character string

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Use the *string*.charAt() method to read a single character from a string when you know the position of that character. For this method, you specify an index value in the string as a parameter to the method. The index value of the first character of the string is 0. To grab the last character of a string, mix string methods:

```
myString.charAt(myString.length - 1)
```

If your script needs to get a range of characters, use the *string*.substring() method. Using *string*.substring() to extract a character from inside a string is a common mistake — the *string*.charAt() method is more efficient.

Example

Enter each of the following statements into the top text box of The Evaluator:

```
a = "banana daiquiri"
a.charAt(0)      // result = 'b'
a.charAt(5)      // result = 'a' (the third 'a')
a.charAt(6)      // result = ' ' (space)
a.charAt(20)     // result = '' (empty string)
```

Related Items: *string*.lastIndexOf(), *string*.indexOf(), *string*.substring() methods

string.charCodeAt([*index*])
string.fromCharCode(*num1* [, *num2* [, ... *numn*]])

Returns: Integer code number for a character; concatenated string value of code numbers supplied as parameters

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Conversions from plain language characters to their numeric equivalents have a long tradition in computer programming. For many years, the most common numbering scheme was the ASCII standard, which covers the basic English alphanumeric characters and punctuation within 128 values (numbered 0 through 127). An extended version with a total of 256 characters, with some variations, depending on the operating system, accounts for other roman characters in other languages, particularly accented vowels. To support all languages, including pictographic languages, and other non-Roman writing systems, a world standard called Unicode provides space for thousands of characters. All modern browsers work with the Unicode system.

In JavaScript, character conversions are handled by string methods. The two methods that perform character conversions work in very different ways syntactically. The first, *string*.charCodeAt(), converts a single string character to its numeric equivalent. The string being converted is the one to the left of the method name — and the string may be a literal string or any other expression that evaluates to a string value. If no parameter is passed, the character being converted is by default the first character of the string. However, you can also specify a different character as an index value into the string (first character is 0), as demonstrated here:

```
"abc".charCodeAt()  // result = 97
"abc".charCodeAt(0)  // result = 97
"abc".charCodeAt(1)  // result = 98
```

If the string value is an empty string, or the index value is beyond the last character, the result is `NaN`.

To convert numeric values to their characters, use the `String.fromCharCode()` method. Notice that the object beginning the method call is the static `String` object, not a string value. Then, as parameters, you can include one or more integers, separated by commas. In the conversion process, the method combines the characters for all of the parameters into one string, an example of which is shown here:

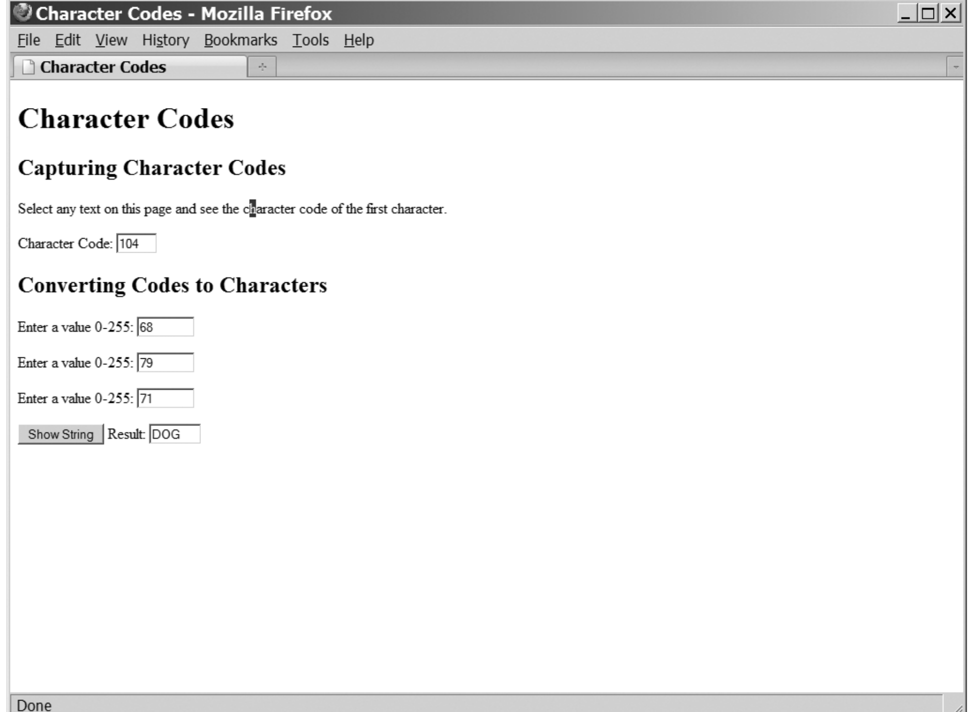
```
String.fromCharCode(97, 98, 99)  // result "abc"
```

Note

Although most modern browsers support character values across the entire Unicode range, the browser won't properly render characters above 255 unless the computer is equipped with language and font support for the designated language. To assist with Unicode character display, all our HTML documents begin with declarations of UTF-8 character encoding. ■

FIGURE 15-1

Conversions from text characters to ASCII values and vice versa.



Example

Listing 15-2 provides examples of both methods on one page. Moreover, because one of the demonstrations relies on the automatic capture of selected text on the page, the scripts include code to accommodate the different handling of selection events, and the capture of the selected text in a variety of browsers.

After you load the page, select part of the body text anywhere on the page. If you start the selection with the lowercase letter "a," the character code displays as 97.

Try entering numeric values in the three fields at the bottom of the page. Values below 32 are ASCII control characters that most fonts represent as blanks or hollow squares. But try other values to see what you get. Notice that the script passes all three values as a group to the `String.fromCharCode()` method, and the result is a combined string. Thus, Figure 15-1 shows what happens when you enter the uppercase ASCII values for a three-letter animal name.

      }
      else if (document.getSelection)
      {
         theText = document.getSelection();
      }
      else if (document.selection && document.selection.createRange)
      {
         theText = document.selection.createRange().text;
      }

      // display the result if any
      if (theText)
      {
         oDisplay.value = theText.charCodeAt();
      }
      else
      {
         oDisplay.value = " ";
      }
}
```

string.concat(*string2*)

Returns: Combined string

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

JavaScript's add-by-value operator (+=) provides a convenient way to concatenate strings. Most browsers, however, include a string object method that performs the same task. The base string to which more text is appended is the object or value to the left of the period. The string to be appended is the parameter of the method, as the following example demonstrates:

```
"abc".concat("def")  // result: "abcdef"
```

As with the add-by-value operator, the `concat()` method doesn't know about word spacing. You are responsible for including the necessary space between words if the two strings require a space between them in the result.

Related Items: Add-by-value (+=) operator

string.indexOf(*searchString* [, *startIndex*])

Returns: Index value of the character within *string* where *searchString* begins

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Like some programming languages' offset string function, JavaScript's `indexOf()` method enables your script to obtain the position in the main string where a search string begins. Optionally, you can specify where in the main string the search should begin — but the returned value is always relative to the very first character of the main string. Like all string object methods, index values start their count with `0`. If no match occurs within the main string, the returned value is `-1`. Thus, this method is also a convenient way to determine whether one string contains another, regardless of position.

Example

Enter each of the following statements (up to but not including the "//" comment symbols) into the top text box of The Evaluator (you can simply replace the parameters of the `indexOf()` method for each statement after the first one). Compare your results with the results shown below.

```
a = "bananas"
a.indexOf("b")      // result = 0 (index of 1st letter is zero)
a.indexOf("a")      // result = 1
a.indexOf("a",1)    // result = 1 (start from 2nd letter)
a.indexOf("a",2)    // result = 3 (start from 3rd letter)
a.indexOf("a",4)    // result = 5 (start from 5th letter)
a.indexOf("nan")    // result = 2
a.indexOf("nas")    // result = 4
a.indexOf("s")      // result = 6
a.indexOf("z")      // result = -1 (no "z" in string)
```

Related Items: *string*.`lastIndexOf()`, *string*.`charAt()`, *string*.`substring()` methods

string.lastIndexOf(*searchString*[, *startIndex*])

Returns: Index value of the last character within the *string* where *searchString* begins

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The *string*.`lastIndexOf()` method is closely related to the method *string*.`indexOf()`. The only difference is that this method starts its search for a match from the end of the string (*string*.`length - 1`) and works its way backward through the string. All index values are still counted, starting with 0, from the front of the string. The examples that follow use the same values as in the examples for *string*.`indexOf()` so that you can compare the results. In cases where only one instance of the search string is found, the results are the same; but when multiple instances of the search string exist, the results can vary widely — hence the need for this method.

Example

Enter each of the following statements (up to, but not including the "//" comment symbols) into the top text box of The Evaluator (you can simply replace the parameters of the `lastIndexOf()` method for each statement after the first one). Compare your results with the results shown below.

```
a = "bananas"
a.lastIndexOf("b")    // result = 0 (index of 1st letter is zero)
a.lastIndexOf("a")    // result = 5
a.lastIndexOf("a",1)  // result = 1 (from 2nd letter toward the front)
a.lastIndexOf("a",2)  // result = 1 (start from 3rd letter working
```

```
                                        toward front)
a.lastIndexOf("a",4)  // result = 3 (start from 5th letter)
a.lastIndexOf("nan")  // result = 2 [except for -1 Nav 2.0 bug]
a.lastIndexOf("nas")  // result = 4
a.lastIndexOf("s")    // result = 6
a.lastIndexOf("z")    // result = -1 (no "z" in string)
```

Related Items: *string*.lastIndexOf(), *string*.charAt(), *string*.substring() methods

string.localeCompare(*string2*)

Returns: Integer

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The localeCompare() method lets a script compare the cumulative Unicode values of two strings, taking into account the language system for the browser. This method is necessitated by only a few human languages (Turkish is said to be one). If the two strings, adjusted for the language system, are equal, the value returned is zero. If the string value on which the method is invoked (meaning the string to the left of the period) sorts ahead of the parameter string, the value returned is a negative integer; otherwise the returned value is a positive integer.

The ECMA standard for this method leaves the precise positive or negative values up to the browser designer. NN6+ calculates the cumulative Unicode values for both strings and subtracts the string parameter's sum from the string value's sum. IE5.5+ and FF1+, on the other hand, return -1 or 1 if the strings are not colloquially equal.

Related Items: *string*.toLocaleLowerCase(), *string*.toLocaleUpperCase() methods

string.match(*regExpression*)

Returns: Array of matching substrings

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The *string*.match() method relies on the RegExp (regular expression) object to carry out a match within a string. The string value under scrutiny is to the left of the dot, whereas the regular expression to be used by the method is passed as a parameter. The parameter must be a regular expression object, created according to the two ways these objects can be generated.

This method returns an array value when at least one match turns up; otherwise the returned value is null. Each entry in the array is a copy of the string segment that matches the specifications of the regular expression. You can use this method to uncover how many times a substring or sequence of characters appears in a larger string. Finding the offset locations of the matches requires other string parsing.

Example

To help you understand the *string*.match() method, Listing 15-3 provides you with a regular expression workshop. Three input controls let you set up a test: the first is for the long string, to be examined by the method; the second is for a regular expression; and the third is a checkbox that lets you specify whether the search through the string for matches should be case-sensitive. Some default values are provided, in case you're not yet familiar with the syntax of regular expressions (see Chapter 45 on the CD-ROM). After you click the "Execute match()" button, the script creates a regular expression object out of your input, performs the *string*.match() method on the big string, and

reports two kinds of results to the page. The primary result is a string version of the array returned by the method; the other is a count of items returned.

   var sFlags = 'g';   // g = find all
      if (!oCaseSensitivity.checked) sFlags += 'i';   // i = case-insensitive

   // create regular expression object
   var oRegExp = new RegExp(oPattern.value, sFlags);

   // perform match
   var aResult = sString.match(oRegExp);

   // display results
   var oResult = document.getElementById('result');
   var oCount = document.getElementById('count');

      // got matches?
      if (aResult)
      {
         oResult.value = aResult.toString();
         oCount.value = aResult.length;
      }
      else
      {
         oResult.value = "<no matches>";
         oCount.value = "";
      }
}
```

The default value for the main string has unusual capitalization intentionally. The capitalization lets you see more clearly where some of the matches come from. For example, the default regular expression looks for any three-character string that has the letter "a" in the middle. Six string segments match that expression. With the help of capitalization, you can see where each of the four strings containing "man" is extracted from the main string. The following table lists some other regular expressions to try with the default main string.

RegExp	Description
`man`	Both case-sensitive and not
`man\b`	Where "man" is at the end of a word
`\bman`	Where "man" is at the start of a word
`me*an`	Where zero or more "e" letters occur between "m" and "a"
`.a.`	Where "a" is surrounded by any one character (including space)
`\sa\s`	Where "a" is surrounded by a space on both sides
`z`	Where a "z" occurs (none in the default string)

In the scripts for Listing 15-3, if the *`string`*`.match()` method returns `null`, you are informed politely, and the count field is emptied.

Related Items: `RegExp` object (see Chapter 45 on the CD-ROM)

string.replace(*regExpression*, *replaceString*)

Returns: Changed string

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Regular expressions are commonly used to perform search-and-replace operations. In conjunction with the *`string`*`.search()` method, JavaScript's *`string`*`.replace()` method provides a simple framework in which to perform this kind of operation on any string.

A replace operation using RegExp requires three components. The first is the main string that is the target of the operation. Second is the regular expression pattern to search for. And third is the string to replace each instance of the text found by the operation.

```
stringToSearch.replace(pattern, replacementString);
```

For the *`string`*`.replace()` method, the main string is the string value, or object referenced, to the left of the period. This string can also be a literal string (that is, text surrounded by quotes). The regular expression to search for is the first parameter, whereas the replacement string is the second parameter.

The regular expression definition determines whether the replacement is of just the first match encountered in the main string, or all matches in the string. If you add the `g` flag to the end of the regular expression, then one invocation of the `replace()` method performs a global search-and-replace throughout the entire main string.

As long as you know how to generate a regular expression, you can easily use the *`string`*`.replace()` method to perform simple replacement operations. But using regular expressions can make the operation more powerful. Consider these soliloquy lines by Hamlet:

```
To be, or not to be: that is the question:
Whether 'tis nobler in the mind to suffer
```

If you wanted to replace both instances of "be" with "exist," you can do it in this case by specifying

```
var regexp = /be/g;
soliloquy.replace(regexp, "exist");
```

But you can't always be assured that the letters "b" and "e" will be standing alone as a word. What happens if the main string contains the word "being" or "saber"? The above example would replace the "be" letters in them as well.

Rescue comes from special characters that better define what to search for. In the example here, the search is for the word "be." Therefore, the regular expression surrounds the search text with word boundaries (the `\b` special character), as in

```
var regexp = /\bbe\b/g;
soliloquy.replace(regexp, "exist");
```

This syntax also takes care of the fact that the first two "be" words are followed by punctuation, rather than a space, as you may expect for a freestanding word. For more about regular expression syntax, see Chapter 45 on the CD-ROM.

Example

The page created by Listing 15-4 lets you practice with the *`string`*`.replace()` and *`string`*`.search()` methods, and regular expressions, in a friendly environment. The source text is a five-line excerpt from *Hamlet*. You can enter the regular expression to search on, and the replacement text as well. Note that the script completes the job of creating the regular expression object, so that you can focus on the other special characters used to define the matching string. All replacement activities act globally because the `g` flag is automatically appended to any expression you enter.

Default values in the fields replace the contraction 'tis with "it is" after you click the "Execute replace()" button (see Figure 15-2). Notice that the backslash character in front of the apostrophe of 'tis (in the string assembled in `mainString`) makes the apostrophe a non-word boundary, and thus allows the `\B't` regular expression to find a match there. As described in the section on the *`string`*`.search()` method, the button connected to that method returns the offset character number of the matching string (or `-1` if no match occurs).

}
```

Related Items: *string*.match() method; RegExp object

string.search(*regExpression*)

Returns: Offset integer

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The results of the *string*.search() method may remind you of the *string*.indexOf() method. In both cases, the returned value is the character number where the matching string first appears in the main string, or -1 if no match occurs. The big difference, of course, is that the matching string for *string*.search() is a regular expression.

Example

Listing 15-4, which illustrates the string.replace() method, also provides a laboratory to experiment with the *string*.search() method.

Related Items: *string*.match() method; RegExp object

string.slice(*startIndex* [, *endIndex*])

Returns: String

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The *string*.slice() method resembles the method *string*.substring(), in that both let you extract a portion of one string and create a new string as a result (without modifying the original string). A helpful improvement in *string*.slice(), however, is that specifying an ending index value relative to the end of the main string is easier.

Using *string*.substring() to extract a substring that ends before the end of the string requires machinations such as the following:

```
string.substring(4, (string.length-2))
```

Instead, you can assign a negative number to the second parameter of *string*.slice() to indicate an offset from the end of the string:

```
string.slice(4, -2)
```

The second parameter is optional. If you omit the second parameter, the returned value is a string from the starting offset to the end of the main string.

Example

With Listing 15-5, you can try several combinations of parameters with the `string.slice()` method (see Figure 15-3). A base string is provided (along with character measurements). Select from the different choices available for parameters, and study the outcome of the slice.

FIGURE 15-3

JavaScript: jsb-15-05.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // check for critical elements
      var oSource = document.getElementById('source');
      var oParameter1 = document.getElementById('parameter1');
      var oParameter2 = document.getElementById('parameter2');
      var oResult = document.getElementById('result');

         // if they all exist...
         if (oSource && oParameter1 && oParameter2 && oResult)
         {
            // apply behaviors
            addEvent(oParameter1, 'change', showResults);
            addEvent(oParameter2, 'change', showResults);
         }
         else
         {
            alert('Critical element not found');
         }
   }
}

// execute the method and display the result
function showResults()
{
   // get source text
   var oSource = document.getElementById('source');
   var sSource = oSource.firstChild.nodeValue;

   // get paramaters
   var oParameter1 = document.getElementById('parameter1');
   var iParameter1 = parseInt(oParameter1.options[oParameter1.selectedIndex].value);

   var oParameter2 = document.getElementById('parameter2');
   var iParameter2 = parseInt(oParameter2.options[oParameter2.selectedIndex].value);

   // generate result & display it
   var oResult = document.getElementById('result');

      if (!iParameter2)
      {
```

```
      oResult.value = sSource.slice(iParameter1);
   }
   else
   {
      oResult.value = sSource.slice(iParameter1, iParameter2);
   }
}
```

Related Items: *string*.substr(), *string*.substring() methods

string.split("*delimiterCharacter*" [, *limitInteger*])

Returns: Array of delimited items

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The split() method is the functional opposite of the array.join() method (see Chapter 18, “The Array Object”). From the string object point of view, JavaScript splits a long string into pieces delimited by a specific character, and then creates a dense array with those pieces. You do not need to initialize the array via the new Array() constructor. Given the powers of array object methods, such as array.sort(), you may want to convert a series of string items to an array to take advantage of those powers. Also, if your goal is to divide a string into an array of single characters, you can still use the split() method, but specify an empty string as a parameter. For some older browsers, such as NN3 and IE4, only the first parameter is observed.

In modern browsers, you can use a regular expression object for the first parameter, enhancing your power to find delimiters in strings. For example, consider the following string:

```
var nameList = "Fred - 123-4567,Jane - 234-5678,Steve - 345-6789";
```

To convert that string into an array of only the names takes a lot of parsing without regular expressions before you can even use *string*.split(). However, with a regular expression as a parameter,

```
var regexp = / - [\d-]+,?\b/;
var newArray = nameList.split(regexp);
    // result = an array "Fred", "Jane", "Steve", ""
```

the new array entries hold only the names, and not the phone numbers or punctuation.

A second optional parameter, an integer value, allows you to specify a limit to the number of array elements generated by the method.

Example

Use The Evaluator (Chapter 4) to see how the string.split() method works. Begin by assigning a comma-delimited string to a variable:

```
a = "Anderson,Smith,Johnson,Washington"
```

Now split the string at comma positions so that the string pieces become items in an array, saved as `b`:

```
b = a.split(",")
```

To prove that the array contains four items, inspect the array's `length` property:

```
b.length    // result: 4
```

Related Items: `array.join()` method

string.substr(*start* [, *length*])

Returns: String

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The *string*.`substr()` method offers a variation of the *string*.`substring()` method that has been in the JavaScript language since the beginning. The distinction is that the *string*.`substr()` method's parameters specify the starting index and a number of characters to be included from that start point. In contrast, the `string.substring()` method parameters specify index points for the start and end characters within the main string.

As with all string methods requiring an index value, the *string*.`substr()` first parameter is zero-based. If you do not specify a second parameter, the returned substring starts at the indexed point and extends to the end of the string. A second parameter value that exceeds the end point of the string means that the method returns a substring to the end of the string.

Even though this method is newer than its partner, it is not part of the latest (Fifth) edition of the ECMA standard for the language. But because the method is so widely used, the standard does acknowledge it as an annex, so that other scripting contexts can implement the method, consistent with browser practice.

Example

Listing 15-6 lets you experiment with a variety of values to see how the *string*.`substr()` method works.

}
```

Related Items: *string*.substring() method

string.substring(*indexA[, indexB]*)

Returns: String of characters between index values *indexA* and *indexB*

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The *string*.substring() method enables your scripts to extract a copy of a contiguous range of characters from any string. The parameters to this method are the starting and ending index values (the first character of the string object is index value 0) of the main string from which the excerpt should be taken. An important item to note is that the excerpt goes up to, but does not include, the character pointed to by the higher index value.

It makes no difference which index value in the parameters is larger than the other: The method starts the excerpt from the lowest value and continues to (but does not include) the highest value. If both index values are the same, the method returns an empty string; and if you omit the second parameter, the end of the string is assumed to be the endpoint.

Example

Listing 15-7 lets you experiment with a variety of values to see how the *string*.substring() method works.

         oResult.value = sSource.substring(iParameter1, iParameter2);
      }
}
```

Related Items: *string*.substr(), *string*.slice() methods

string.toLocaleLowerCase()
string.toLocaleUpperCase()

Returns: String

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari-, Opera+, Chrome+

These two methods are variations on the standard methods for changing the case of a string. They take into account some language systems whose cases for a particular character don't necessarily map to the Latin alphabet character mappings.

Related Items: *string*.toLowerCase(), *string*.toUpperCase() methods

string.toLowerCase()
string.toUpperCase()

Returns: The string in all lower- or uppercase, depending on which method you invoke

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

A great deal of what takes place on the Internet (and in JavaScript) is case-sensitive. URLs on some servers, for instance, are case-sensitive for directory names and filenames.

These two methods, the simplest of the string methods, return a copy of a string converted to either all lowercase or all uppercase. Any mixed-case strings get converted to a uniform case. If you want to compare user input from a field against some coded string without worrying about matching case, you can convert copies of both strings to the same case for the comparison.

Example

You can use the toLowerCase() and toUpperCase() methods on literal strings, as follows:

```
var newString = "HTTP://www.Mozilla.ORG".toLowerCase();
    // result = "http://www.mozilla.org"
```

The methods are also helpful in comparing strings when case is not important, as follows:

```
if (guess.toUpperCase() == answer.toUpperCase()) {...}
    // comparing strings without case sensitivity
```

Note that these methods do not change the case of the strings themselves, but rather output modified copies, leaving the originals intact.

Related Items: *string*.toLocaleLowerCase(), *string*.toLocaleUpperCase() methods

string.toString()
string.valueOf()

Returns: String value

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Both of these methods return string values (as opposed to full-fledged string objects). If you have created a string object via the `new String()` constructor, the type of that item is `object`. Therefore, if you want to examine more precisely what kind of value is held by the object, you can use the `valueOf()` method to get the value and then examine it via the `typeof` operator. The `toString()` method is present for this object primarily because a string object inherits the method from the root object of JavaScript.

Example

Use The Evaluator (Chapter 4) to test the `valueOf()` method. Enter the following statements into the top text box and examine the values that appear in the Results field:

```
a = new String("hello")
typeof a
b = a.valueOf()
typeof b
```

Because all other JavaScript core objects also have the `valueOf()` method, you can build generic functions that receive a variety of object types as parameters, and the script can branch its code based on the type of value that is stored in the object.

Related Items: `typeof` operator (Chapter 22)

String Utility Functions

Figuring out how to apply the various string object methods to a string manipulation challenge is not always an easy task. The situation is only made worse if you need to support legacy or mobile browsers with limited JavaScript support. It's also difficult to anticipate every possible way you may need to massage strings in your scripts. But to help you get started, Listing 15-8 contains a fully backward-compatible library of string functions for inserting, deleting, and replacing chunks of text in a string. If your audience uses browsers capable of including external `.js` library files, that would be an excellent way to make these functions available to your scripts.

LISTING 15-8

Utility String Handlers

JavaScript: jsb-15-08.js

```
// extract front part of string prior to searchString
function getFront(sMain, sSearch)
{
   iOffset = sMain.indexOf(sSearch);

      if (iOffset == -1)
      {
         return null;
      }
      else
```

continued

LISTING 15-8 *(continued)*

```
      {
         return sMain.substring(0, iOffset);
      }
}

// extract back end of string after searchString
function getEnd(sMain, sSearch)
{
   iOffset = sMain.indexOf(sSearch);

      if (iOffset == -1)
      {
         return null;
      }
      else
      {
         return sMain.substring(iOffset + sSearch.length, sMain.length);
      }
}

// insert insertString immediately before searchString
function insertString(sMain, sSearch, sInsert)
{
   var sFront = getFront(sMain, sSearch);
   var sEnd = getEnd(sMain, sSearch);

      if (sFront == null || sEnd == null)
      {
         return null;
      }
      else
      {
         return sFront + sInsert + sSearch + sEnd;
      }
}

// remove sDelete from sMain
function deleteString(sMain, sDelete)
{
   return replaceString(sMain, sDelete, "");
}

// replace sSearch with sReplace
function replaceString(sMain, sSearch, sReplace)
{
```

```
   var sFront = getFront(sMain, sSearch);
   var sEnd = getEnd(sMain, sSearch);

      if (sFront == null || sEnd == null)
      {
         return null;
      }
      else
      {
         return sFront + sReplace + sEnd;
      }
}
```

The first two functions extract the front or end components of strings, as needed, for some of the other functions in this suite. The final three functions are the core of these string-handling functions. If you plan to use these functions in your scripts, be sure to notice the dependence that some functions have on others. Including all five functions as a group ensures that they work as designed.

A modern alternative to Listing 15-8 utilizes a combination of string and array methods to perform a global replace operation in a one-statement function:

```
function replaceString(sMain, sSearch, sReplace)
{
   return sMain.split(sSearch).join(sReplace);
}
```

Going one step further, you can create a custom method to use with all string values or objects in your scripts. Simply let the following statement execute as the page loads:

```
String.prototype.replaceString = function replaceString(sMain,
      sSearch, sReplace)
{
   return sMain.split(sSearch).join(sReplace);
}
```

Then, invoke this method on any string value in other scripts on the page, as in:

```
myString = myString.replaceString(" CD ", " MP3 ");
```

(Note that global search and replace can also be accomplished using regular expressions; see Chapter 45.)

HTML markup methods

Now we come to the other group of string object methods that effectively enclose text in HTML elements. None of these methods are part of the ECMAScript Fifth Edition standard; their persistence in JavaScript implementations is clearly in support of ancient scripts. Modern web pages use stylesheets to apply cosmetic formatting to elements, and DOM methods to insert new nodes.

string.anchor("*anchorName*")	*string*.link(*locationOrURL*)
string.blink()	*string*.big()
string.bold()	*string*.small()
string.fixed()	*string*.strike()
string.fontcolor(*colorValue*)	*string*.sub()
string.fontsize(*integer1to7*)	*string*.sup()
string.italics()	

First examine the methods that don't require any parameters. You probably see a pattern: All of these methods are font-style attributes that have settings of on or off. To turn on these attributes in an HTML document, you surround the text in the appropriate tag pairs, such as `<b> ... </b>` for boldface text. These methods take the string object, attach those tags, and return the resulting text, which is ready to be put into any HTML that your scripts are building. Therefore, the expression

```
"Good morning!".bold()
```

evaluates to

```
<b>Good morning!</b>
```

Listing 15-9 shows an example of applying these string methods to text on the page. (Internet Explorer, Chrome, and Safari do not support the `<blink>` element, so while they execute the *string*.blink() method, there is no resulting blink in the display.)

LISTING 15-9

Using Simple String Methods

HTML: jsb-15-09.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>HTML by JavaScript</title>

      sId = aElements[i].id;
```

continued

LISTING 15-9 *(continued)*

```
         //var sText = aElements[i].firstChild.nodeValue;
         var sText = aElements[i].innerHTML;

         switch (sId)
         {
            case 'anchor':   sText = sText.anchor('anchor-name');   break;
            case 'big':   sText = sText.big();   break;
            case 'blink':   sText = sText.blink();   break;
            case 'bold':   sText = sText.bold();   break;
            case 'fixed':   sText = sText.fixed();   break;
            case 'fontcolor':   sText = sText.fontcolor('red');   break;
            case 'fontsize':   sText = sText.fontsize(7);   break;
            case 'italics':   sText = sText.italics();   break;
            case 'link':   sText = sText.link('http://example.com/');   break;
            case 'small':   sText = sText.small();   break;
            case 'strike':   sText = sText.strike();   break;
            case 'sub':   sText = sText.sub();   break;
            case 'sup':   sText = sText.sup();   break;
            default: continue;
         }

         // replace the element's contents with the marked-up text
         aElements[i].innerHTML = sText;
      }
      alert('Here is the modified markup:\n' + oList.innerHTML);

      // cancel form submission
         // W3C DOM method (hide from IE)
         if (evt.preventDefault) evt.preventDefault();
      // IE method
      return false;
   }
```

string.fontsize() and *string*.fontcolor() affect the font characteristics of strings displayed in the HTML page. The parameters for these items are pretty straightforward — an integer between 1 and 7, corresponding to the seven browser font sizes, and a color value (as either a hexadecimal triplet or color constant name) for the designated text.

The final two string methods let you create an anchor and a link out of a string. The *string*.anchor() method uses its parameter to create a name for the anchor. Thus, the following expression

```
"Table of Contents".anchor("toc")
```

evaluates to

```
<a name="toc">Table of Contents</a>
```

In a similar fashion, the *string*.`link()` method expects a valid location or URL as its parameter, creating a genuine HTML link out of the string:

```
"Back to Home".link("index.html")
```

This evaluates to the following:

```
<a href="index.html">Back to Home</a>
```

The primary reason that we rarely, if ever, use these methods in contemporary web site scripting is that we endeavor to separate development layers — in this case, HTML structure from CSS presentation and from JavaScript behavior. The more we keep these layers apart, the more modular and efficient development, debugging, and modification will be. For example, if all the font size and color details are specified in the style sheet, and not hard-coded in to HTML or JavaScript, then the appearance of the text on a page can be changed independently of the page's markup and behavior, and by different personnel with different skill sets. Similarly, it makes sense to keep markup in the HTML document and to enable JavaScript to operate on that markup, but not to stipulate it unless absolutely necessary.

Changing the cosmetic appearance of a page by changing its markup is a very "90s" thing to do. It relies on the default styling of the browser for a given tag, instead of taking responsibility for styling in one's own stylesheet. A modern script will change the appearance of an element by assigning an `id` or `className`, and letting the stylesheet determine how that will be presented.

URL String Encoding and Decoding

When browsers and servers communicate, some non-alphanumeric characters that we take for granted (such as spaces) cannot make the journey in their native form. Only a narrower set of letters, numbers, and punctuation is allowed. To accommodate the rest, the characters must be encoded with a special symbol (%) and their hexadecimal ASCII values. For example, the space character is hex 20 (ASCII decimal 32). When encoded, it looks like `%20`. You may have seen this symbol in browser history lists or URLs.

JavaScript includes two functions, `encodeURIComponent()` and `decodeURIComponent()`, that offer instant conversion of whole strings. To convert a plain string to one with these escape codes, use the escape function, as in

```
encodeURIComponent("Howdy Pardner"); // result = "Howdy%20Pardner"
```

The `decodeURIComponent()` function converts the escape codes into human-readable form.

Cross-Reference

Both of these functions are covered in Chapter 24, "Global Functions and Statements." ■

CHAPTER 16

The Math, Number, and Boolean Objects

IN THIS CHAPTER

Advanced math operations

Number base conversions

Working with integers and floating-point numbers

The introduction to data types and values in Chapter 8's tutorial scratched the surface of JavaScript's numeric and Boolean powers. In this chapter, you look more closely at JavaScript's way of working with numbers and Boolean data.

Math often frightens away budding programmers. As you've seen so far in this book, however, you don't really have to be a math genius to program in JavaScript. The powers described in this chapter are here when you need them — if you need them. So if math is not your strong suit, don't freak out over the terminology here.

An important point to remember about the objects described in this chapter is that (like string values and string objects) numbers and Booleans are both values and objects. Fortunately for script writers, the differentiation is rarely, if ever, a factor, unless you get into some very sophisticated programming. To those who actually write the JavaScript interpreters inside the browsers we use, the distinctions are vital.

For most scripters, the information about numeric data types and conversions, as well as the `Math` object, are important to know.

Numbers in JavaScript

More powerful programming languages have many different kinds of numbers, each related to the amount of memory the number occupies in the computer. Managing all these different types may be fun for some, but it gets in the way of quick scripting. A JavaScript number has only two possibilities. It can be an integer or a floating-point value. An *integer* is any whole number within a humongous range that does not have any fractional part. Integers never contain a decimal point in their representation. *Floating-point numbers* in JavaScript spread across the same range, but they are represented with a decimal point and some fractional value. If you are an experienced programmer, refer to the discussion about the `Number`

object later in this chapter to see how the JavaScript number type lines up with the numeric data types you use in other programming environments.

Integers and floating-point numbers

Deep inside a computer, the microprocessor has an easier time performing math on integer values compared to any number with a decimal value tacked onto it. The microprocessor must go through extra work to add even two such floating-point numbers. We, as scripters, are unfortunately saddled with this historical baggage and must be conscious of the type of number used in certain calculations.

Most internal values generated by JavaScript, such as index values and `length` properties, consist of integers. Floating-point numbers usually come into play as the result of the division of numeric values, special values such as pi, and human-entered values such as dollars and cents. Fortunately, JavaScript is forgiving if you try to perform math operations on mixed numeric data types. Notice how the following examples resolve to the appropriate data type:

```
3 + 4 = 7 // integer result
3 + 4.1 = 7.1 // floating-point result
3.9 + 4.1 = 8 // integer result
```

Of the three examples, perhaps only the last result is unexpected. When two floating-point numbers yield a whole number, the result is rendered as an integer.

When dealing with floating-point numbers, be aware that not all browser versions return the precise same value down to the last digit to the right of the decimal. For example, the following table shows the result of 8/9 as calculated by various scriptable browsers, and converted for string display:

NN3 & NN4	.8888888888888888
NN6+/Moz+/Safari+/Opera+/Chrome+	0.8888888888888888
WinIE3	0.888888888888889
WinIE4+	0.8888888888888888

Clearly, from this display, you don't want to use floating-point math in JavaScript browsers to plan space flight trajectories or other highly accurate mission-critical calculations. Even for everyday math, however, you need to be cognizant of floating-point errors that accrue in PC arithmetic.

In Navigator, JavaScript relies on the operating system's floating-point math for its own math. Operating systems that offer accuracy to as many places to the right of the decimal as JavaScript displays are exceedingly rare. As you can detect from the preceding table, modern browsers agree about how many digits to display and how to perform internal rounding for this display. That's good for the math, but not particularly helpful when you need to display numbers in a specific format.

Until you get to IE5.5, Mozilla-based browsers, and other W3C-compatible browsers, JavaScript does not offer built-in facilities for formatting the results of floating-point arithmetic. (For modern browsers, see the `Number` object later in this chapter for formatting methods.) Listing 16-1 demonstrates a generic formatting routine for positive values, plus a specific call that turns a value into a dollar value. Remove the comments, and the routine is fairly compact.

Cross-Reference

The function to assign event handlers throughout the code in this chapter, and much of the book, is `addEvent()`**, a cross-browser event handler explained in detail in Chapter 32, "Event Objects."** ■

LISTING 16-1

A Generic Number-Formatting Routine

HTML: jsb-16-01.html

```
<!DOCTYPE html>
<html>
   <head>
     <meta http-equiv="content-type" content="text/html;charset=utf-8">
     <title>Number Formatting</title>
     <script type="text/javascript" src="../jsb-global.js"></script>
     <script type="text/javascript" src="jsb-16-01.js"></script>
  </head>
  <body>
     <h1>How to Make Money</h1>
     <form>
        <p>
          <label for="entry">Enter a positive floating point value or arithmetic
          expression to be converted to a currency format:</label>
        </p>
        <p>
          <input type="text" id="entry" name="entry" value="1/3">
          <input type="button" id="dollars" value="&gt; Dollars and Cents &gt;">
          <input type="text" id="result" name="result">
        </p>
     </form>
   </body>
</html>
```

JavaScript: jsb-16-01.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to critical elements
      var oButton = document.getElementById('dollars');
      var oEntry = document.getElementById('entry');
      var oResult = document.getElementById('result');

         // if they all exist...
         if (oButton && oEntry && oResult)
```

continued

LISTING 16-1 *(continued)*

```
        {
           // apply behavior to button
           oButton.onclick =
              function() { oResult.value = dollarize(oEntry.value); }
        }
    }
}
// turn incoming expression into a dollar value
function dollarize(expr)
{
   return "$" + format(expr,2);
}

// generic positive number decimal formatting function
function format(expr, decplaces)
{
   // evaluate the incoming expression
   var val = eval(expr);

   // raise the value by power of 10 times the number of decimal places;
   // round to an integer; convert to string
   var str = "" + Math.round(val * Math.pow(10, decplaces));

   // pad small value strings with zeros to the left of rounded number
   while (str.length <= decplaces)
   {
      str = "0" + str;
   }

   // establish location of decimal point
   var decpoint = str.length - decplaces;

   // assemble final result from:
   // (a) the string up to the position of the decimal point;
   // (b) the decimal point; and
   // (c) the balance of the string. Return finished product.
   return str.substring(0,decpoint) + "." + str.substring(decpoint, str.length);
}
```

This routine may seem like a great deal of work, but it's essential if your application relies on floating-point values and specific formatting for all browsers.

Note

The global `eval()` method used in this example is not a terrific choice for production work. Because `eval()` faithfully interprets all JavaScript expressions, it lays bare all the details of the script, its object and variable values, and the DOM, for the savvy visitor to peruse and act upon. The JavaScript language has deliberately been constrained to prevent security breaches on the client computer, but `XMLHttpRequest` gives access to the server. It's not appropriate to give strangers an open and unfiltered `eval()` input. ■

You can also enter floating-point numbers with exponents. An exponent is signified by the letter *e* (upper- or lowercase), followed by a sign (+ or −) and the exponent value. Here are examples of floating-point values expressed as exponents:

```
1e6 // 1,000,000 (the "+" symbol is optional on positive exponents)
1e-4 // 0.0001 (plus some error further to the right of the decimal)
-4e-3 // -0.004
```

For values between 1e-5 and 1e15, JavaScript renders numbers without exponents (although you can force a number to display in exponential notation in modern browsers). All other values outside these boundaries return with exponential notation in all browsers.

Hexadecimal and octal integers

JavaScript enables you to work with values in decimal (base-10), hexadecimal (base-16), and octal (base-8) formats. You have only a few rules to follow when dealing with any of these values.

Decimal values cannot begin with a leading 0. Therefore, if your page asks users to enter decimal values that begin with a 0, your script must strip those zeros from the input string, or use the number parsing global functions (described in the next section), before performing any math on the values.

Hexadecimal integer values are expressed with a leading `0x` or `0X`. (That's a zero, not the letter *o*.) The A through F values can appear in upper- or lowercase, as you prefer. Here are some hex values:

```
0X2B
0X1a
0xcc
```

Don't confuse the hex values used in arithmetic with the hexadecimal values used in color property specifications for web documents. Those values are expressed in a special *hexadecimal triplet* format, which begins with a crosshatch symbol followed by the three hex values bunched together (such as `#c0c0c0`).

Octal values are represented by a leading 0 followed by any digits between 0 and 7. Octal values consist only of integers.

You are free to mix and match base values in arithmetic expressions, but JavaScript renders all results in decimal form. For conversions to other number bases, you have to employ a user-defined function in your script. Listing 16-2, for example, is a function that converts any decimal value from 0 to 255 into a JavaScript hexadecimal value.

LISTING 16-2

Decimal-to-Hexadecimal Converter Function

```
function toHex(dec)
{
   hexChars = "0123456789ABCDEF";
   if (dec > 255)
   {
```

continued

LISTING 16-2 *(continued)*

```
      return null;
   }
   var i = dec % 16;
   var j = (dec - i) / 16;
   result = "0X";
   result += hexChars.charAt(j);
   result += hexChars.charAt(i);
   return result;
}
```

The `toHex()` conversion function assumes that the value passed to the function is a decimal integer. If you simply need a hexadecimal representation of a number in string format, see the `toString()` method in Chapter 15, "The String Object."

Converting strings to numbers

What is missing so far from this discussion is a way to convert a number represented as a string to a number with which the JavaScript arithmetic operators can work. Before you get too concerned about this, be aware that most JavaScript operators and math methods gladly accept string representations of numbers and handle them without complaint. You will run into data type incompatibilities most frequently when trying to accomplish addition with the + operator (which is also the string concatenation operator). Also know that if you perform math operations on values retrieved from form text boxes, those object `value` properties are strings. Therefore, in many cases, you need to convert those string values to a number type for math operations.

Conversion to numbers requires one of two JavaScript functions:

```
parseInt(string [,radix])
parseFloat(string  [,radix])
```

These functions are inspired by the Java language. The term *parsing* has many implied meanings in programming. One meaning is the same as *extracting*. The `parseInt()` function returns whatever integer value it can extract from the string passed to it; the `parseFloat()` function returns the floating-point number that can be extracted from the string. Here are some examples and their resulting values:

```
parseInt("42")         // result = 42
parseInt("42.33")      // result = 42
parseFloat("42.33")    // result = 42.33
parseFloat("42")       // result = 42
parseFloat("fred")     // result = NaN (Not a Number)
```

Because the `parseFloat()` function can also work with an integer and return an integer value, you may prefer using this function in scripts that have to deal with either kind of number, depending on the string entered into a text field by a user.

An optional second parameter to both functions enables you to specify the base of the number represented by the string. This comes in handy particularly when you need a decimal number from a string that starts with one or more zeros. Normally, the leading zero indicates an

octal value. But if you force the conversion to recognize the string value as a decimal, it is converted the way you expect:

```
parseInt("010")       // result = 8
parseInt("010",10)    // result = 10
parseInt("F2")        // result = NaN
parseInt("F2", 16)    // result = 242
```

Use these functions wherever you need the integer or floating-point value. For example:

```
var result = 3 + parseInt("3");    // result = 6
var ageVal = parseInt(document.forms[0].age.value);
```

The latter technique ensures that the string value of this property is converted to a number, although you should do more data validation — see Chapter 46, "Data-Entry Validation" (on the CD-ROM) — before trying any math on a user-entered value.

Both the `parseInt()` and `parseFloat()` methods start working on the first character of a string and continue until there are no more numbers or decimal characters. That's why you can use them on strings — such as the one returned by the `navigator.appVersion` property (for example, `6.0 (Windows; en-US)`) — to obtain just the leading, numeric part of the string. If the string does not begin with an acceptable character, the methods return `NaN` (not a number).

Converting numbers to strings

If you attempt to pass a numeric data type value to many of the string methods discussed in Chapter 15, JavaScript complains. Therefore, you should convert any number to a string before, for example, you find out how many digits make up a number.

Several ways exist to force conversion from any numeric value to a string. The old-fashioned way is to precede the number with an empty string and the concatenation operator. For example, assume that a variable named `dollars` contains the integer value of `2500`. To use the string object's `length` property (discussed later in this chapter) to find out how many digits the number has, use this construction:

```
("" + dollars).length    // result = 4
```

The parentheses force JavaScript to evaluate the concatenation before attempting to extract the `length` property.

A more elegant way is to use the `toString()` method. Construct such statements as you would to invoke any object's method. For example, to convert the `dollars` variable value to a string, use this statement:

```
dollars.toString()    // result = "2500"
```

This method has one added power in modern browsers: You can specify a number base for the string representation of the number. Called the *radix,* the base number is added as a parameter to the method name. Here is an example of creating a numeric value for conversion to its hexadecimal equivalent as a string:

```
var x = 30;
var y = x.toString(16);    // result = "1e"
```

Use a parameter of `2` for binary results and `8` for octal. The default is base `10`. Be careful not to confuse these conversions with true numeric conversions. You cannot use results from the `toString()` method as numeric operands in other statements.

Finally, in IE5.5+, Mozilla-based browsers, and other W3C browsers, three additional methods of the `Number` object — `toExponential()`, `toFixed()`, and `toPrecision()` — return string versions of numbers formatted according to the rules and parameters passed to the methods. We describe these in detail later in this chapter.

When a number isn't a number

In a couple of examples in the previous section, you probably noticed that the result of some operations was a value named `NaN`. That value is not a string, but rather a special value that stands for Not a Number. For example, if you try to convert the string `"joe"` to an integer with `parseFloat()`, the function cannot possibly complete the operation. It reports back that the source string, when converted, is not a number.

When you design an application that requests user input or retrieves data from a server-side database, you cannot be guaranteed that a value you need to be numeric is, or can be converted to, a number. If that's the case, you need to see if the value is a number before performing a math operation on it. JavaScript provides a special global function, `isNaN()`, that enables you to test the "numberness" of a value. The function returns `true` if the value is not a number and `false` if it is a number. For example, you can examine a form field that should be a number:

```
var ageEntry = parseInt(document.forms[0].age.value);
   if (isNaN(ageEntry))
   {
      alert("Try entering your age again.");
   }
```

Math Object

Whenever you need to perform math that is more demanding than simple arithmetic, look through the list of `Math` object methods for the solution.

Syntax

Accessing `Math` object properties and methods:

```
Math.property
Math.method(value [, value])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

About this object

In addition to the typical arithmetic operations (covered in detail in Chapter 22, "JavaScript Operators"), JavaScript includes more advanced mathematical powers that you can access in a way that may seem odd to you if you have not programmed in true object-oriented environments before. Although most arithmetic takes place on the fly (such as `var result = 2 + 2`), the rest requires use of the

JavaScript internal `Math` object (with a capital "M"). The `Math` object brings with it several properties (which behave like some other languages' constants) and many methods (which behave like some other languages' math functions).

The way you use the `Math` object in statements is the same way you use any JavaScript object: You create a reference beginning with the `Math` object's name, a period, and the name of the property or method you need:

```
Math.property | method([parameter]. . . [,parameter])
```

Property references return built-in values, such as pi. Method references require one or more values to be sent as parameters of the method. Every method returns a result.

Properties

JavaScript `Math` object properties represent a number of valuable constant values in math. Table 16-1 shows you those methods and their values, as displayed to 16 decimal places.

Because these property expressions return their constant values, you use them in your regular arithmetic expressions. For example, to obtain the circumference of a circle whose diameter is in variable `d`, employ this statement:

```
circumference = d * Math.PI;
```

Perhaps the most common mistakes scripters make with these properties are failing to capitalize the `Math` object name and observing the case-sensitivity of property names.

TABLE 16-1

JavaScript Math Properties

Property	Value	Description
`Math.E`	`2.718281828459045091`	Euler's constant
`Math.LN2`	`0.6931471805599452862`	Natural log of 2
`Math.LN10`	`2.302585092994045901`	Natural log of 10
`Math.LOG2E`	`1.442695040888963387`	Log base-2 of E
`Math.LOG10E`	`0.4342944819032518167`	Log base-10 of E
`Math.PI`	`3.141592653589793116`	π
`Math.SQRT1_2`	`0.7071067811865475727`	Square root of 0.5
`Math.SQRT2`	`1.414213562373095145`	Square root of 2

Methods

Methods make up the balance of JavaScript `Math` object powers. With the exception of the `Math.random()` method, all `Math` object methods take one or more values as parameters. Typical

trigonometric methods operate on the single values passed as parameters; others determine which of the numbers passed along are the highest or lowest of the group. The `Math.random()` method takes no parameters, but returns a randomized, floating-point value between `0` and `1`. Table 16-2 lists all the `Math` object methods with their syntax, and descriptions of the values they return.

TABLE 16-2

Math Object Methods

Method Syntax	Returns
`Math.abs(val)`	Absolute value of *val*
`Math.acos(val)`	Arc cosine (in radians) of *val*
`Math.asin(val)`	Arc sine (in radians) of *val*
`Math.atan(val)`	Arc tangent (in radians) of *val*
`Math.atan2(val1, val2)`	Angle of polar coordinates *x* and *y*
`Math.ceil(val)`	Next integer greater than or equal to *val*
`Math.cos(val)`	Cosine of *val*
`Math.exp(val)`	Euler's constant to the power of *val*
`Math.floor(val)`	Next integer less than or equal to *val*
`Math.log(val)`	Natural logarithm (base e) of *val*
`Math.max(val1, val2)`	The greater of *val1* or *val2*
`Math.min(val1, val2)`	The lesser of *val1* or *val2*
`Math.pow(val1, val2)`	*Val1* to the power of *val2*
`Math.random()`	Random number between 0 and 1
`Math.round(val)`	N+1 when *val* >= n.5; otherwise N
`Math.sin(val)`	Sine (in radians) of *val*
`Math.sqrt(val)`	Square root of *val*
`Math.tan(val)`	Tangent (in radians) of *val*

Although HTML may not exactly be a graphic artist's dream environment, it is possible to use JavaScript trig functions to obtain a series of values for HTML-generated charting. Since the advent of positionable elements, scripters have been able to apply their knowledge of using these functions to define fancy trajectories for flying elements. For scripters who are not trained in programming, math is often a major stumbling block. But as you've seen so far, you can accomplish a great deal with JavaScript by using simple arithmetic and a little bit of logic — leaving the heavy-duty math for those who love it.

Creating random numbers

One of the handiest methods in the Math object is Math.random(), which returns a random floating-point value between 0 and 1. If you design a script to act like a card game, you need random integers between 1 and 52; for dice, the range is 1 to 6 per die. To generate a random integer between zero and any top value (n), use the following formula (where n is the top number):

```
Math.floor(Math.random() * n)
```

This produces integers between 0 and n-1. To produce the spread between 1 and n, either add 1 or change floor() to ceil():

```
Math.floor(Math.random() * n) + 1
Math.ceil(Math.random() * n)
```

To generate random numbers within a range that starts somewhere other than zero, use this formula:

```
Math.floor(Math.random() * (n - m + 1)) + m
```

Here, m is the lowest possible integer value of the range, and n equals the top number of the range. For the dice game, the formula for each die is

```
newDieValue = Math.floor(Math.random() * 6) + 1;
```

Math object shortcut

In Chapter 21, "Control Structures and Exception Handling," you see details about a JavaScript construction that enables you to simplify the way you address multiple Math object properties and methods in statements. The trick is to use the with statement.

In a nutshell, the with statement tells JavaScript that the next group of statements (inside the braces) refers to a particular object. In the case of the Math object, the basic construction looks like this:

```
with (Math)
{
   //statements
}
```

For all intervening statements, you can omit the specific references to the Math object. Compare the long reference way of calculating the area of a circle (with a radius of six units)

```
result = Math.pow(6,2) * Math.PI;
```

to the shortcut reference way:

```
with (Math)
{
   result = pow(6,2) * PI;
}
```

Though the latter occupies more lines of code, the object references are shorter and more natural to read. For a longer series of calculations involving Math object properties and methods, the with

construction saves keystrokes and reduces the likelihood of a case-sensitive mistake with the object name in a reference. You can also include other full-object references within the `with` construction; JavaScript attempts to attach the object name only to those references lacking an object name. On the downside, the `with` construction is not particularly efficient in JavaScript because it must perform a lot of internal tracking in order to work. So, it's best not to use it in loops that iterate a large number of times.

Number Object

Properties	Methods
constructor	toExponential()
MAX_VALUE	toFixed()
MIN_VALUE	toLocaleString()
NaN	toString()
NEGATIVE_INFINITY	toPrecision()
POSITIVE_INFINITY	valueOf()
prototype	

Syntax

Creating a `Number` object:

```
var val = new Number(number);
```

Accessing number and `Number` object properties and methods:

```
number.property | method([parameters])
Number.property | method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

The `Number` object is rarely used because (for the most part) JavaScript satisfies day-to-day numeric needs with a plain number value. But the `Number` object contains some information and power of value to serious programmers.

First on the docket are properties that define the ranges for numbers in the language. The largest number is 1.79E+308; the smallest number is 2.22E-308. Any number larger than the maximum is `POSITIVE_INFINITY`; any number smaller than the minimum is `NEGATIVE_INFINITY`. Rarely will you accidentally encounter these values.

More to the point of a JavaScript object, however, is the `prototype` property. Chapter 15 shows how to add a method to a `string` object's prototype, such that every newly created object contains that method. The same goes for the `Number.prototype` property. If you have a need to add common functionality to every number object, this is where to do it. This prototype facility is unique to full-fledged number objects and does not apply to plain number values. For experienced programmers who care about such matters, JavaScript number objects and values are defined internally as IEEE double-precision 64-bit values.

Properties

constructor

(See `string.constructor` in Chapter 15)

MAX_VALUE
MIN_VALUE
NEGATIVE_INFINITY
POSITIVE_INFINITY

Value: Number Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The `Number.MAX_VALUE` and `Number.MIN_VALUE` properties belong to the static `Number` object. They represent constants for the largest and smallest possible positive numbers that JavaScript (and ECMAScript) can work with. Their actual values are $1.7976931348623157 \infty 10^{308}$, and $5 \infty 10^{-324}$, respectively. A number that falls outside the range of allowable numbers is equal to the constant `Number.POSITIVE_INFINITY` or `Number.NEGATIVE_INFINITY`.

Example

Enter each of the four `Number` object expressions into the top text field of The Evaluator (Chapter 4, "Javascript Essentials") to see how the browser reports each value.

```
Number.MAX_VALUE
Number.MIN_VALUE
Number.NEGATIVE_INFINITY
Number.POSITIVE_INFINITY
```

Related Items: `NaN` property; `isNaN()` global function

NaN

Value: NaN Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The `NaN` property is a constant that JavaScript uses to report when a number-related function or method attempts to work on a value other than a number, or when the result is something other than a number. You encounter the `NaN` value, most commonly as the result of the `parseInt()` and `parseFloat()` functions, whenever a string undergoing conversion to a number lacks a numeral as the first character. Use the `isNaN()` global function to see if a value is an `NaN` value.

Example

See the discussion of the `isNaN()` function in Chapter 24.

Related Items: `isNaN()` global function

`prototype`

(See `String.prototype` in Chapter 15)

Methods

`number.toExponential(`*`fractionDigits`*`)`
`number.toFixed(`*`fractionDigits`*`)`
`number.toPrecision(`*`precisionDigits`*`)`

Returns: String

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

These three methods let scripts control the formatting of numbers for display as string text. Each method has a unique purpose, but they all return strings. You should perform all math operations as unformatted number objects because the values have the most precision. Only after you are ready to display the results should you use one of these methods to convert the number to a string for display as body text or assignment to a text field.

The `toExponential()` method forces a number to display in exponential notation, even if the number is in the range in which JavaScript normally uses standard notation. The parameter is an integer specifying how many digits to the right of the decimal should be returned. All digits that far to the right of the decimal are returned, even if they are zero. For example, if a variable contains the numeric value `345`, applying `toExponential(3)` to that value yields `3.450e+2`, which is JavaScript's exponential notation for $3.45 \infty 10^2$.

Use the `toFixed()` method when you want to format a number with a specific number of digits to the right of the decimal. This is the method you use, for instance, to display the results of a financial calculation in units and hundredths of units (for example, dollars and cents). The parameter to the method is an integer indicating the number of digits to be displayed to the right of the decimal. If the number being formatted has more numbers to the right of the decimal than the number of digits specified by the parameter, the method rounds the rightmost visible digit — but only with respect to the unrounded value of the next digit. For example, the value `123.455` fixed to two digits to the right of the decimal is rounded up to `123.46`. But if the starting value is `123.4549`, the method ignores the 9 and sees that the 4 to the right of the 5 should be rounded down; therefore, the result is `123.45`. Do not consider the `toFixed()` method to be an accurate rounder of numbers; however, it does a satisfactory job in most cases.

The final method is `toPrecision()`, which enables you to define how many total digits of a number (including digits to the left and right of the decimal) to display. In other words, you define the precision of a number. The following list demonstrates the results of several parameter values signifying a variety of precisions:

```
var num = 123.45
num.toPrecision(1)    // result = 1e+2
num.toPrecision(2)    // result = 1.2e+2
```

```
num.toPrecision(3)    // result = 123
num.toPrecision(4)    // result = 123.5
num.toPrecision(5)    // result = 123.45
num.toPrecision(6)    // result = 123.450
```

Notice that the same kind of rounding can occur with `toPrecision()` as it does for `toFixed()`.

Example

You can use The Evaluator (see Chapter 4) to experiment with all three of these methods, with a variety of parameter values. Before invoking any method, be sure to assign a numeric value to one of the built-in global variables in The Evaluator (`a` through `z`).

```
a = 10/3
a.toFixed(4)
"$" + a.toFixed(2)
```

None of these methods works with number literals (for example, `123.toExponential(2)` does not work).

Related Items: `Math` object

number.toLocaleString()

Returns: String

Compatibility: WinIE5.5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `number.toLocaleString()` method returns a string value version of the current number in a format that may vary according to a browser's locale settings. According to the ECMA Edition 5 standard, browsers have some leeway in determining exactly how the `toLocaleString()` method should return a string value that conforms with the language standard of the client system or browser.

Related Items: `number.toFixed()`, `number.toString()` methods

number.toString([*radix*])

Returns: String

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `number.toString()` method returns a string value version of the current number. The default radix parameter (`10`) converts the value to base-10 notation if the original number isn't already of that type. Or, you can specify other number bases (for example, `2` for binary, `16` for hexadecimal) to convert the original number to the other base — as a string, not a number — for further calculation.

Example

Use The Evaluator (Chapter 4) to experiment with the `toString()` method. Assign the number `12` to the variable `a` and see how the number is converted to strings in a variety of number bases:

```
a = 12
a.toString()    // base 10
a.toString(2)
a.toString(16)
```

Related Items: `toLocaleString()` method

number.valueOf()

(See `string.valueOf()` in Chapter 15)

Boolean Object

Properties	Methods
`constructor`	`toString()`
`prototype`	`valueOf()`

Syntax

Creating a `Boolean` object:

```
var val = new Boolean(BooleanValue);
```

Accessing `Boolean` object properties:

```
BooleanObject.property | method
```

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

You work with Boolean values a lot in JavaScript — especially as the result of conditional tests. Just as string values benefit from association with string objects, and their properties and methods, so, too, do Boolean values receive aid from the `Boolean` object. For example, when you display a Boolean value in a text box, the `"true"` or `"false"` string is provided by the `Boolean` object's `toString()` method, so you don't have to invoke it directly.

The only time you need to even think about a `Boolean` object is if you wish to attach some property or method to `Boolean` objects that you create with the new `Boolean()` constructor. Parameter values for the constructor include the string versions of the values, numbers (0 for `false`; any other integer for `true`), and expressions that evaluate to a Boolean value. Any such new `Boolean` object is imbued with the new properties or methods you add to the `prototype` property of the core `Boolean` object.

For details about the properties and methods of the `Boolean` object, see the corresponding listings for the `String` object in Chapter 15.

CHAPTER

17

The Date Object

IN THIS CHAPTER

Working with date and time values in JavaScript

Performing date calculations

Validating date entry form fields

Perhaps the most untapped power of JavaScript is its date and time handling. Scripters passed over the `Date` object with good cause in the early days of JavaScript, because in earlier versions of scriptable browsers, significant bugs and platform-specific anomalies made date and time programming hazardous without significant testing. Even with the improved bug situation, working with dates requires a working knowledge of the world's time zones and their relationships with the standard reference point, known as Greenwich Mean Time (GMT) or Coordinated Universal Time (abbreviated UTC).

Now that date- and time-handling has stabilized in modern browsers, I hope more scripters look into incorporating these kinds of calculations into their pages. In Chapter 57, "Application: Intelligent 'Updated' Flags," on the CD-ROM, for example, I show you an application that lets your web site highlight the areas that have been updated since each visitor's last surf ride through your pages — an application that relies heavily on date arithmetic and time-zone conversion.

Before getting to the JavaScript part of date discussions, however, the chapter summarizes key facts about time zones and their impact on scripting date and time on a browser. If you're not sure what GMT and UTC mean, the following section is for you.

Time Zones and GMT

By international agreement, the world is divided into distinct time zones that allow the inhabitants of each zone to say with confidence that when the Sun appears directly overhead, it is roughly noon, squarely in the middle of the day. The current time in the zone is what we set our clocks to — the local time.

That's fine when your entire existence and scope of life go no further than the width of your own time zone. But with instant communication among all parts of the world, your scope reaches well beyond local time. Periodically you must

be aware of the local time in other zones. After all, if you live in New York, you don't want to wake up someone in Los Angeles before dawn with a phone call from your office.

Note

For the rest of this section, we speak of the Sun ''moving'' as if Earth were the center of the solar system. We do so for the convenience of our daily perception of the Sun arcing across what appears to us as a stationary sky. In point of fact, we believe Copernicus's theories, so please delete that email you were about to send us. ■

From the point of view of the time zone over which the Sun is positioned at any given instant, all time zones to the east have already had their noon, so it is later in the day for them — one hour later per time zone (except for those few time zones offset by fractions of an hour). That's why when U.S. television networks broadcast simultaneously to the eastern and central time zones, the announced schedule for a program is "10 eastern, 9 central."

Many international businesses must coordinate time schedules of far-flung events. Doing so and taking into account the numerous time zone differences (not to mention seasonal national variations, such as daylight saving time) would be a nightmare. To help everyone out, a standard reference point was devised: the time zone running through the celestial observatory at Greenwich (pronounced GREN-itch), England. This time zone is called Greenwich Mean Time, or GMT for short. The "mean" part comes from the fact that on the exact opposite side of the globe (through the Pacific Ocean) is the international date line, another world standard that decrees where the first instance of the next calendar day appears on the planet. Thus, GMT is located at the middle, or mean, of the full circuit of the day. Not that many years ago, GMT was given another abbreviation that is not based on any one language of the planet. The abbreviation is UTC (pronounced as its letters: yu-tee-see), and the English version is Coordinated Universal Time. Whenever you see UTC, it is for all practical purposes the same as GMT.

If your personal computer's system clock is set correctly, the machine ticks away in GMT time. But because you set your local time zone in the appropriate control panel, all file time stamps and clock displays are in your local time. The machine knows what the offset time is between your local time and GMT. For daylight savings time, you may have to check a preference setting so that the offset is adjusted accordingly; in Windows-based operating systems, the system knows when the changeover occurs and prompts you if changing the offset is okay. In any case, if you travel across time zones with a laptop, you should change the computer's time zone setting, not its clock.

JavaScript's inner handling of date and time works a lot like the PC clock (on which your programs rely). Date values that you generate in a script are stored internally in GMT time; however, almost all the displays and extracted values are in the local time of the visitor (not the web site server). And remember that the date values are created on the visitor's machine by virtue of your script's generating that value — you don't send "living" date objects to the client from the server. This concept is perhaps the most difficult to grasp as you work with JavaScript date and time.

Whenever you program time and date in JavaScript for a public web page, you must take the world-view. This view requires knowing that the visitor's computer settings determine the accuracy of the conversion between GMT and local time. You'll also have to do some testing by changing your PC's clock to times in other parts of the world and making believe you are temporarily in those remote locations, which isn't always easy to do. It reminds me (Danny) of the time I was visiting Sydney, Australia. I was turning in for the night and switched on the television in the hotel. This hotel received a live satellite relay of a long-running U.S. television program, *Today*. The program broadcast from New York was for the morning of the same day I was just finishing in Sydney. Yes, this time zone stuff can make your head hurt.

The Date Object

Like a handful of other objects in JavaScript and the document object models, there is a distinction between the single, static `Date` object that exists in every window (or frame) and a date object that contains a specific date and time. The static `Date` object (uppercase *D*) is used in only a few cases: Primarily to create a new instance of a date and to invoke a couple of methods that the `Date` object offers for the sake of some generic conversions.

Most of your date and time work, however, is with instances of the `Date` object. These instances are referred to generically as date objects (lowercase *d*). Each date object is a snapshot of an exact millisecond in time, whether it be for the instant at which you generate the object or for a specific time in the past or future you need for calculations. If you need to have a live clock ticking away, your scripts will repeatedly create new date objects to grab up-to-the-millisecond snapshots of your computer's clock. To show the time on the page, extract the hours, minutes, and seconds from the snapshot date object, and then display the values as you like (for example, a digital readout, a graphical bar chart, and so on). By and large, it is the methods of a date object instance that your scripts invoke to read or modify individual components of a date object (for example, the month or hour).

Despite its name, every date object contains information about date and time. Therefore, even if you're concerned only about the date part of an object's data, time data is standing by as well. As you learn in a bit, the time element can catch you off-guard for some operations.

Creating a date object

The statement that asks JavaScript to make an object for your script uses the special object construction keyword `new`. The basic syntax for generating a new date object is as follows:

```
var dateObjectName = new Date([parameters]);
```

The date object evaluates to an object data type rather than to some string or numeric value.

With the date object's reference safely tucked away in the variable name, you access all date-oriented methods in the dot-syntax fashion with which you're already familiar:

```
var result = dateObjectName.method();
```

With variables, such as `result`, your scripts perform calculations or displays of the date object's data (some methods extract pieces of the date and time data from the object). If you then want to put some new value into the date object (such as adding a year to the date object), you assign the new value to the object by way of the method that lets you set the value:

```
dateObjectName.method(newValue);
```

This example doesn't look like the typical JavaScript assignment statement, which has an equals sign operator. But this statement is the way in which methods that set date object data work.

You cannot get very far into scripting dates without digging into time zone arithmetic. Although JavaScript may render the string equivalent of a date object in your local time zone, the internal storage is strictly GMT.

Even though you haven't yet seen details of a date object's methods, here is how you use two of them to add one year to today's date:

```
var oneDate = new Date();          // creates object with current GMT date
var theYear = oneDate.getYear();   // stores the current four-digit year
```

```
theYear = theYear + 1;            // theYear now is next year
oneDate.setYear(theYear);         // the new year value now in the object
```

At the end of this sequence, the `oneDate` object automatically adjusts all the other date components for the next year's date. The day of the week, for example, will be different, and JavaScript takes care of that for you, should you need to extract that data. With next year's data in the `oneDate` object, you may now want to extract that new date as a string value for display in a field on the page or submit it quietly to a CGI program on the server.

The issue of parameters for creating a new date object is a bit complex, mostly because of the flexibility that JavaScript offers the scripter. Recall that the job of the `new Date()` statement is to create a place in memory for all data that a date needs to store. What is missing from that task is the data — what date and time to enter into that memory spot. That's where the parameters come in.

If you leave the parameters empty, JavaScript takes that to mean you want today's date and the current time to be assigned to that new date object. JavaScript isn't any smarter, of course, than the setting of the internal clock of your page visitor's personal computer. If the clock isn't correct, JavaScript won't do any better of a job identifying the date and time.

Note

Remember that when you create a new date object, it contains the current time as well. The fact that the current date may include a time of 16:03:19 (in 24-hour time) may throw off things, such as days-between-dates calculations. Be careful. ■

To create a date object for a specific date or time, you have five ways to send values as a parameter to the `new Date()` constructor function:

```
new Date("Month dd, yyyy hh:mm:ss")
new Date("Month dd, yyyy")
new Date(yy,mm,dd,hh,mm,ss)
new Date(yy,mm,dd)
new Date(milliseconds)
```

The first four variations break down into two styles — a long string versus a comma-delimited list of data — each with optional time settings. If you omit time settings, they are set to 0 (midnight) in the date object for whatever date you entered. You cannot omit date values from the parameters — every date object must have a real date attached to it, whether you need it or not.

In the long string versions, the month is spelled out in full in English. No abbreviations are allowed. The rest of the data is filled with numbers representing the date, year, hours, minutes, and seconds, even if the order is different from your local way of indicating dates. For single-digit values, you can use either a one- or two-digit version (such as 4:05:00). Colons separate hours, minutes, and seconds.

The short versions contain a non-quoted list of integer values in the order indicated. JavaScript cannot know that a 30 means the day if you accidentally place it in the month slot.

You use the last version only when you have the millisecond value of a date and time available. This generally occurs after some math arithmetic (described later in this chapter), leaving you with a date and time in millisecond format. To convert that numeric value to a date object, use the `new Date()` constructor. From the new date object created, you can retrieve more convenient values about the date and time.

Native object properties and methods

Like the String and Array objects, the Date object features a small handful of properties and methods that all native JavaScript objects have in common. On the property side, the Date object has a prototype property, which enables you to apply new properties and methods to every date object created in the current page. You can see examples of how this works in discussions of the prototype property for String and Array objects (Chapters 15 and 18, respectively). At the same time, every instance of a date object in modern browsers has a constructor property that references the constructor function that generated the object.

A date object has numerous methods that convert date object types to strings, most of which are more specific than the generic toString() one. The valueOf() method returns the millisecond integer that is stored for a particular date.

Date methods

The bulk of a date object's methods are for reading parts of the date and time information and for changing the date and time stored in the object. These two categories of methods are easily identifiable because they all begin with the word "get" or "set."

Table 17-1 lists all of the methods of both the static Date object and, by inheritance, date object instances. The list is impressive — some would say frightening — but there are patterns you should readily observe. Most methods deal with a single component of a date and time value: year, month, date, and so forth. Each block of "get" and "set" methods also has two sets of methods: one for the local date and time conversion of the date stored in the object; one for the actual UTC date stored in the object. After you see the patterns, the list should be more manageable. Unless otherwise noted, a method has been part of the Date object since the first generation of scriptable browsers, and is therefore also supported in newer browsers.

Deciding between using the UTC or local versions of the methods depends on several factors. If the browsers you must support go back to the beginning, you will be stuck with the local versions in any case. But even for newer browsers, activities, such as calculating the number of days between dates or creating a countdown timer for a quiz, won't care which set you use, but you must use the same set for all calculations. If you start mixing local and UTC versions of date methods, you'll be destined to get wrong answers. The UTC versions come in most handy when your date calculations must take into account the time zone of the client machine compared to some absolute in another time zone — calculating the time remaining to the chiming of Big Ben signifying the start of the New Year in London.

JavaScript maintains its date information in the form of a count of milliseconds (thousandths of a second) starting from January 1, 1970, in the GMT (UTC) time zone. Dates before that starting point are stored as negative values (but see the section on bugs and gremlins later in this chapter). Regardless of the country you are in or the date and time formats specified for your computer, the millisecond is the JavaScript universal measure of time. Any calculations that involve adding or subtracting times and dates should be performed in the millisecond values to ensure accuracy. Therefore, though you may never display the milliseconds value in a field or dialog box, your scripts will probably work with them from time to time in variables. To derive the millisecond equivalent for any date and time stored in a date object, use the dateObj.getTime() method, as in

```
var startDate = new Date();
var started = startDate.getTime();
```

TABLE 17-1

Date Object Methods

Method	Value Range	Description
`dateObj.getFullYear()`	1970–...	Specified year (NN4+, Moz1+, IE3+)
`dateObj.getYear()`	70–...	(See text of chapter)
`dateObj.getMonth()`	0–11	Month within the year (January = 0)
`dateObj.getDate()`	1–31	Date within the month
`dateObj.getDay()`	0–6	Day of week (Sunday = 0)
`dateObj.getHours()`	0–23	Hour of the day in 24-hour time
`dateObj.getMinutes()`	0–59	Minute of the specified hour
`dateObj.getSeconds()`	0–59	Second within the specified minute
`dateObj.getTime()`	0–...	Milliseconds since 1/1/70 00:00:00 GMT
`dateObj.getMilliseconds()`	0-999	Milliseconds since the previous full second (NN4+, Moz1+, IE3+)
`dateObj.getUTCFullYear()`	1970–...	Specified UTC year (NN4+, Moz1+, IE3+)
`dateObj.getUTCMonth()`	0–11	UTC month within the year (January = 0) (NN4+, Moz1+, IE3+)
`dateObj.getUTCDate()`	1–31	UTC date within the month (NN4+, Moz1+, IE3+)
`dateObj.getUTCDay()`	0–6	UTC day of week (Sunday = 0) (NN4+, Moz1+, IE3+)
`dateObj.getUTCHours()`	0–23	UTC hour of the day in 24-hour time (NN4+, Moz1+, IE3+)
`dateObj.getUTCMinutes()`	0–59	UTC minute of the specified hour (NN4+, Moz1+, IE3+)
`dateObj.getUTCSeconds()`	0–59	UTC second within the specified minute (NN4+, Moz1+, IE3+)
`dateObj.getUTCMilliseconds()`	0-999	UTC milliseconds since the previous full second (NN4+, Moz1+, IE3+)
`dateObj.setYear(`*`val`*`)`	1970–...	Be safe: always specify a four-digit year
`dateObj.setFullYear(`*`val`*`)`	1970–...	Specified year (NN4+, Moz1+, IE3+)
`dateObj.setMonth(`*`val`*`)`	0–11	Month within the year (January = 0)
`dateObj.setDate(`*`val`*`)`	1–31	Date within the month

Method	Value Range	Description
`dateObj.setDay(val)`	0–6	Day of week (Sunday = 0)
`dateObj.setHours(val)`	0–23	Hour of the day in 24-hour time
`dateObj.setMinutes(val)`	0–59	Minute of the specified hour
`dateObj.setSeconds(val)`	0–59	Second within the specified minute
`dateObj.setMilliseconds(val)`	0-999	Milliseconds since the previous full second (NN4+, Moz1+, IE3+)
`dateObj.setTime(val)`	0–...	Milliseconds since 1/1/70 00:00:00 GMT
`dateObj.setUTCFullYear(val)`	1970–...	Specified UTC year (NN4+, Moz1+, IE3+)
`dateObj.setUTCMonth(val)`	0–11	UTC month within the year (January = 0) (NN4+, Moz1+, IE3+)
`dateObj.setUTCDate(val)`	1–31	UTC date within the month (NN4+, Moz1+, IE3+)
`dateObj.setUTCDay(val)`	0–6	UTC day of week (Sunday = 0) (NN4+, Moz1+, IE3+)
`dateObj.setUTCHours(val)`	0–23	UTC hour of the day in 24-hour time (NN4+, Moz1+, IE3+)
`dateObj.setUTCMinutes(val)`	0–59	UTC minute of the specified hour (NN4+, Moz1+, IE3+)
`dateObj.setUTCSeconds(val)`	0–59	UTC second within the specified minute (NN4+, Moz1+, IE3+)
`dateObj.setUTCMilliseconds(val)`	0-999	UTC milliseconds since the previous full second (NN4+, Moz1+, IE3+)
`dateObj.getTimezoneOffset()`	0–...	Minutes offset from GMT/UTC
`dateObj.toDateString()`		Date-only string in a format determined by browser (WinIE5.5+)
`dateObj.toGMTString()`		Date/time string in universal format
`dateObj.toLocaleDateString()`		Date-only string in your system's localized format (NN6+, Moz1+, WinIE5.5+)
`dateObj.toLocaleString()`		Date/time string in your system's localized format
`dateObj.toLocaleTimeString()`		Time-only string in your system's localized format (NN6+, Moz1+, WinIE5.5+)

continued

TABLE 17-1 *(continued)*

Method	Value Range	Description
`dateObj.toString()`		Date/time string in a format determined by browser
`dateObj.toTimeString()`		Time-only string in a format determined by browser (WinIE5.5+)
`dateObj.toUTCString()`		Date/time string in universal format (NN4+, Moz1+, IE3+)
`Date.parse("`*`dateString`*`")`		Converts string date to milliseconds integer
`Date.UTC(`*`date values`*`)`		Converts GMT string date to milliseconds integer

Although the method has the word "time" in its name, the fact that the value is the total number of milliseconds from January 1, 1970, means the value also conveys a date.

Other date object get methods read a specific component of the date or time. You have to exercise some care here, because some values begin counting with 0 when you may not expect it. For example, January is month 0 in JavaScript's scheme; December is month 11. Hours, minutes, and seconds all begin with 0, which, in the end, is logical. Calendar dates, however, use the actual number that would show up on the wall calendar: the first day of the month is date value 1. For the twentieth-century years, the year value is whatever the actual year number is, minus 1900. For 1996, that means the year value is 96. But for years before 1900 and after 1999, JavaScript uses a different formula, showing the full year value. This means you have to check whether a year value is less than 100 and add 1900 to it before displaying that year.

```
var today = new Date();
var thisYear = today.getYear();
   if (thisYear < 100)
   {
      thisYear += 1900;
   }
```

This assumes, of course, you won't be working with years before A.D. 100. If you can assume that your audience is using a modern browser, which is quite likely, use only the `getFullYear()` method. This method returns the complete set of year digits from all ranges.

To adjust any one of the elements of a date value, use the corresponding set method in an assignment statement. If the new value forces the adjustment of other elements, JavaScript takes care of that. For example, consider the following sequence and how some values are changed for us:

```
myBirthday = new Date("July 4, 1776");
result = myBirthday.getDay(); // result = 4, a Thursday
myBirthday.setYear(1777);     // bump up to next year
result = myBirthday.getDay(); // result = 5, a Friday
```

Because the same date in the following year is on a different day, JavaScript tracks that for you.

Accommodating time zones

Understanding the `dateObj.getTimezoneOffset()` method involves both your operating system's time control panel setting and an internationally recognized (in computerdom, anyway) format for representing dates and times. If you have ignored the control panel stuff about setting your local time zone, the values you get for this property may be off for most dates and times. In the eastern part of North America, for instance, the eastern standard time zone is five hours earlier than Greenwich Mean Time. With the `getTimezoneOffset()` method producing a value of minutes' difference between GMT and the PC's time zone, the five hours difference of eastern standard time is rendered as a value of 300 minutes. On the Windows platform, the value automatically changes to reflect changes in daylight saving time in the user's area (if applicable). Offsets to the east of GMT (to the date line) are expressed as negative values.

Dates as strings

When you generate a date object, JavaScript automatically applies the `toString()` method to the object if you attempt to display that date either in a page or alert box. The format of this string varies with browser and operating system platforms. For example, in IE8 for Windows XP, the string is in the following format:

```
Sun Dec 5 16:47:20 PST 2010
```

But in Firefox 3 for Windows XP, the string is

```
Sun Dec 05 2010 16:47:20 GMT-0800 (Pacific Standard Time)
```

Other browsers return their own variations on the string. The point is not to rely on a specific format and character location of this string for the components of dates. Use the date object methods to read date object components.

JavaScript does, however, provide two methods that return the date object in more constant string formats. One, `dateObj.toGMTString()`, converts the date and time to the GMT equivalent on the way to the variable that you use to store the extracted data. Here is what such data looks like:

```
Mon, 06 Dec 2010 00:47:20 GMT
```

If you're not familiar with the workings of GMT and how such conversions can present unexpected dates, exercise great care in testing your application. A quarter to five on a Sunday afternoon on the North American west coast is well after midnight Monday morning at the Royal Observatory in Greenwich, London.

If time zone conversions make your head hurt, you can use the second string method, `dateObj.toLocaleString()`. In Firefox for North American Windows users, the returned value can look like this:

```
Sunday, December 05, 2010 4:47:20 PM
```

Ever since IE5.5 and NN6/Moz1, you can also have JavaScript convert a date object to just the date or time portions in a nicely formatted version. The best pair of methods for this are `toLocaleDateString()` and `toLocaleTimeString()`, because these methods return values that make the most sense to the user, based on the localization settings of the user's operating system and browser.

Friendly date formats for older browsers

If you don't have the luxury of writing script code only for modern browsers, you can create your own formatting function to do the job for a wide range of browsers. Listing 17-1 demonstrates one way of creating this kind of string from a date object (in a form that will work back to version 4 browsers).

Note

The function to assign event handlers throughout the code in this chapter and much of the book is `addEvent()`**, a cross-browser event handler explained in detail in Chapter 32, "Event Objects."**

The `addEvent()` **function is part of the script file** `jsb-global.js` **located on the accompanying CD-ROM in the** `Content/` **folder, where it is accessible to all chapters' scripts.** ■

LISTING 17-1

Creating a Friendly Date String

HTML: jsb-17-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Date String Maker</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-17-01.js"></script>
   </head>
   <body>
      <h1>Date String Maker</h1>
      <p id="output">Today's date</p>
   </body>
</html>
```

JavaScript: jsb-17-01.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

monthNames = ["January", "February", "March", "April", "May", "June", "July",
   "August", "September", "October", "November", "December"];
dayNames = ["Sunday", "Monday", "Tuesday", "Wednesday", "Thursday", "Friday",
   "Saturday"];

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to the paragraph to contain the date
      oOutput = document.getElementById('output');

         // if it exists, replace its contents with the date
```

```
        if (oOutput)
        {
           // remove all child nodes from the paragraph
           while (oOutput.firstChild)
           {
              oOutput.removeChild(oOutput.firstChild);
           }

           // create a text node with the date
           var sDate = customDateString(new Date());
           var oNewText = document.createTextNode(sDate);

           // insert that content into the paragraph
           oOutput.appendChild(oNewText);
        }
   }
}

// generate a formatted date
function customDateString(oDate)
{
   var theDay = dayNames[oDate.getDay()];
   var theMonth = monthNames[oDate.getMonth()];
   var theYear = oDate.getFullYear();
   return theDay + ", " + theMonth + " " + oDate.getDate() + ", " + theYear;
}
```

Assuming the user has the PC's clock set correctly (a big assumption), the date appearing just below the opening headline is the current date — making it appear as though the document had been updated today. The downside to this approach (as opposed to the newer `toLocaleDateString()` method) is that international users are forced to view dates in the format you design, which may be different from their local custom.

More conversions

The last two methods shown in Listing 17-1 are methods of the static `Date` object. These utility methods convert dates from string or numeric forms into millisecond values of those dates. The primary beneficiary of these actions is the `dateObj.setTime()` method, which requires a millisecond measure of a date as a parameter. You use this method to throw an entirely different date into an existing `date` object.

`Date.parse()` accepts as a parameter date strings similar to the ones you've seen in this section, including the internationally approved version. `Date.UTC()`, on the other hand, requires the comma-delimited list of values (in proper order: `yy,mm,dd,hh,mm,ss`) in the GMT zone. The `Date.UTC()` method gives you a backward-compatible way to hard-code a GMT time (you can do the same in version 4 browsers via the UTC methods). The following is an example that creates a new date object for 6 p.m. on October 1, 2011, GMT in WinIE8:

```
var newObj = new Date(Date.UTC(2011, 9, 1, 18, 0, 0));
result = newObj.toString();    // result = "Sat Oct 1 11:00:00 PDT2011"
```

The second statement returns a value in a local time zone, because all non-UTC methods automatically convert the GMT time stored in the object to the client's local time.

Date and time arithmetic

You may need to perform some math with dates for any number of reasons. Perhaps you need to calculate a date at some fixed number of days or weeks in the future or figure out the number of days between two dates. When calculations of these types are required, remember the *lingua franca* of JavaScript date values: milliseconds.

What you may need to do in your date-intensive scripts is establish some variable values representing the number of milliseconds for minutes, hours, days, or weeks, and then use those variables in your calculations. Here is an example that establishes some practical variable values, building on each other:

```
var oneMinute = 60 * 1000;
var oneHour = oneMinute * 60;
var oneDay = oneHour * 24;
var oneWeek = oneDay * 7;
```

With these values established in a script, I can use one to calculate the date one week from today:

```
var targetDate = new Date();
var dateInMs = targetDate.getTime();
dateInMs += oneWeek;
targetDate.setTime(dateInMs);
```

Another example uses components of a date object to assist in deciding what kind of greeting message to place in a document, based on the local time of the user's PC clock. Listing 17-2 adds to the scripting from Listing 17-1, bringing some quasi-intelligence to the proceedings.

LISTING 17-2

A Dynamic Welcome Message

HTML: jsb-17-02.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Date String Maker</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-17-02.js"></script>
   </head>
   <body>
      <h1>Welcome!</h1>
      <p id="date">Today's date</p>
      <p>We hope you are enjoying the <span id="day-part">day</span>.</p>
   </body>
</html>
```

JavaScript: jsb-17-02.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

monthNames = ["January", "February", "March", "April", "May", "June", "July",
   "August", "September", "October", "November", "December"];
dayNames = ["Sunday", "Monday", "Tuesday", "Wednesday", "Thursday", "Friday",
   "Saturday"];

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to the target paragraphs
      var oDateDisplay = document.getElementById('date');
      var oGreeting = document.getElementById('greeting');

         // if they exist, plug in new content
         if (oDateDisplay && oGreeting)
         {
            // plug in date
            var oNow = new Date();
            var sDate = customDateString(oNow);
            replaceTextContent(oDateDisplay, sDate);

            // plug day-part into greeting
            var sDayPart = dayPart(oNow);
            replaceTextContent(oGreeting, sDayPart);
         }
   }
}

// generate a formatted date
function customDateString(oDate)
{
   var theDay = dayNames[oDate.getDay()];
   var theMonth = monthNames[oDate.getMonth()];
   var theYear = oDate.getFullYear();
   return theDay + ", " + theMonth + " " + oDate.getDate() + ", " + theYear;
}

// get the part of the day
function dayPart(oDate)
{
   var theHour = oDate.getHours();
   if (theHour < 6 )
      return "wee hours";
   if (theHour < 12)
      return "morning";
   if (theHour < 18)
```

continued

LISTING 17-2 *(continued)*

```
      return "afternoon";
   return "evening";
}

// replaces the text contents of a page element
function replaceTextContent(oElement, sContent)
{
   // if the object exists
   if (oElement)
   {
      // remove all child nodes
      while (oElement.firstChild)
      {
         oElement.removeChild(oElement.firstChild);
      }

      // create a text node with the new content
      var oNewText = document.createTextNode(sContent);

      // insert that content
      oElement.appendChild(oNewText);
   }
}
```

The script divides the day into four parts and presents a different greeting for each part of the day. The greeting that plays is based, simply enough, on the hour element of a date object representing the time the page is loaded into the browser. Because this greeting is embedded in the page, the greeting does not change no matter how long the user displays the page, but it will update each time the page is reloaded.

Counting the days . . .

You may find one or two more date arithmetic applications useful. One displays the number of shopping days left until Christmas (in the user's time zone); the other is a countdown timer to the start of the year 2100.

Listing 17-3 demonstrates how to calculate the number of days between the current day and some fixed date in the future. The assumption in this application is that all calculations take place in the user's time zone. The example shows the display of the number of shopping days before the next Christmas day (December 25). The basic operation entails converting the current date and the next December 25 to milliseconds, calculating the number of days represented by the difference in milliseconds. If you let the millisecond values represent the dates, JavaScript automatically takes care of leap years.

The only somewhat tricky part is setting the year of the next Christmas day correctly. You can't just slap the fixed date with the current year, because if the program is run on December 26, the year of the next Christmas must be incremented by one. That's why the constructor for the Christmas date

object doesn't supply a fixed date as its parameters, but rather, sets individual components of the object.

Also, note that while `setDate()` accepts a counting number 1-31, `setMonth()` accepts a whole number 0-11, making December month 11 for that method call.

LISTING 17-3

How Many Days Until Christmas

HTML: jsb-17-03.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Christmas Countdown</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-17-03.js"></script>
   </head>
   <body>
      <h1>Christmas Countdown</h1>
      <p>You have <em id="days-left">too few</em> shopping
         <span id="day-word">days</span> until Christmas.</p>
   </body>
</html>
```

JavaScript: jsb-17-03.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to the target paragraphs
      var oOutput = document.getElementById('days-left');
      var oDayWord = document.getElementById('day-word');

         // if they exist, plug in new content
         if (oOutput && oDayWord)
         {
            // plug in days left
            var sDaysLeft = getDaysUntilXmas();
            replaceTextContent(oOutput, sDaysLeft);
```

continued

LISTING 17-3 *(continued)*

```
            // pluralize day if not one
            var sDayWord = (sDaysLeft == 1) ? 'day' : 'days';
            replaceTextContent(oDayWord, sDayWord);
         }
      }
   }

// calculate the number of days till next Christmas
function getDaysUntilXmas()
{
   var oneMinute = 60 * 1000;
   var oneHour = oneMinute * 60;
   var oneDay = oneHour * 24;

   var today = new Date();
   var nextXmas = new Date();
   nextXmas.setMonth(11);
   nextXmas.setDate(25);
      if (today.getMonth() == 11 && today.getDate() > 25)
      {
         nextXmas.setFullYear(nextXmas.getFullYear() + 1);
      }
   var diff = nextXmas.getTime() - today.getTime();
   diff = Math.floor(diff/oneDay);
   return diff;
}

// replaces the text contents of a page element
function replaceTextContent(oElement, sContent)
{
   [see listing 17-2]
}
```

The second variation on calculating the amount of time before a certain event takes time zones into account. For this demonstration, the page is supposed to display a countdown timer to the precise moment when the flame for the 2008 Summer Games in Beijing is to be lit. That event takes place in a time zone that may be different from that of the page's viewer, so the countdown timer must calculate the time difference accordingly.

Listing 17-4 shows a simplified version that simply displays the ticking timer in a text field. The output, of course, could be customized in any number of ways, depending on the amount of dynamic HTML you want to employ on a page. The time of the lighting for this demo is set at 11:00 GMT on August 8, 2008 (the date is certainly accurate, but the officials may set a different time closer to the actual event).

Because this application is implemented as a live ticking clock, the code starts by setting some global variables that should be calculated only once so that the function that gets invoked repeatedly has a minimum of calculating to do (to be more efficient). The `Date.UTC()` method

provides the target time and date in standard time. The `getTimeUntil()` function accepts a millisecond value (as provided by the `targetDate` variable) and calculates the difference between the target date and the actual internal millisecond value of the client's PC clock.

The core of the `getCountDown()` function peels off the number of whole days, hours, minutes, and seconds from the total number of milliseconds difference between now and the target date. Notice that each chunk is subtracted from the total so that the next-smaller chunk can be calculated from the leftover milliseconds.

One extra touch on this page is a display of the local date and time of the actual event.

LISTING 17-4

Summer Games Countdown

HTML: jsb-17-04.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Time Since the First Moon Landing</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-17-04.js"></script>
   </head>
   <body>
      <h1>Time Since the First Moon Landing</h1>
      <p>It is now <span id="now">the present</span> in your timezone.</p>
      <p><span id="time-since">Many days</span> have passed since the first
         moon landing on <span id="past-day">a day long ago</span>.</p>
   </body>
</html>
```

JavaScript: jsb-17-04.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to the target elements
      oOutputNow = document.getElementById('now');
      oOutputTimeSince = document.getElementById('time-since');
      var oOutputPastDay = document.getElementById('past-day');

         // if they exist, plug in new content
```

continued

LISTING 17-4 *(continued)*

```
            if (oOutputNow && oOutputTimeSince && oOutputPastDay)
            {
               // globals -- calculate only once
               // set target date to 20:17 UTC on July 20, 1969
               targetDate = Date.UTC(1969, 6, 20, 20, 17, 0, 0);
               oneSecond = 1000;
               oneMinute = oneSecond * 60;
               oneHour = oneMinute * 60;
               oneDay = oneHour * 24;

               // plug in the past date
               var sPastDay = (new Date(targetDate)).toLocaleString();
               replaceTextContent(oOutputPastDay, sPastDay);

               // plug in current time & time since
               updateCounter();
            }
      }
}

// timer loop to display changing values
function updateCounter()
{
   // plug in current time
   var sNow = (new Date()).toLocaleString();
   replaceTextContent(oOutputNow, sNow);

   // plug in days since
   var sTimeSince = formatTimeSince();
   replaceTextContent(oOutputTimeSince, sTimeSince);

   setTimeout("updateCounter()", 1000);
}

// format elapsed time
function formatTimeSince()
{
   var ms = getTimeDiff(targetDate);
   var days, hrs, mins, secs;

   days = Math.floor(ms/oneDay);
   output = days + " Day";
      if (days != 1) output += 's';

   ms -= oneDay * days;
   hrs = Math.floor(ms/oneHour);
   output += ", " + hrs + " Hour";
      if (hrs != 1) output += 's';
```

```
   ms -= oneHour * hrs;
   mins = Math.floor(ms/oneMinute);
   output += ", " + mins + " Minute";
      if (mins != 1) output += 's';

   ms -= oneMinute * mins;
   secs = Math.floor(ms/oneSecond);
   output += ", and " + secs + " Second";
      if (secs != 1) output += 's';

   return output;
}

// get the difference between two datetimes in milliseconds
function getTimeDiff(targetMS)
{
   var today = new Date();
   var diff = Math.abs(today.valueOf() - targetMS);
   return Math.floor(diff);
}

// replaces the text contents of a page element
function replaceTextContent(oElement, sContent)
{
   [see listing 17-2]
}
```

Early browser date bugs and gremlins

Each new browser generation improves the stability and reliability of scripted date objects. For example, Netscape Navigator 2 had so many bugs and crash problems that it made scripting complex world-time applications for this browser impossible. NN3 improved matters a bit, but some glaring problems still existed. And lest you think I'm picking on Netscape, rest assured that early versions of Internet Explorer also had plenty of date and time problems. IE3 couldn't handle dates before January 1, 1970 (GMT), and also completely miscalculated the time zone offset, following the erroneous pattern of NN2. Bottom line — you're asking for trouble if you must work extensively with dates and times while supporting legacy browsers.

You should be aware of one more discrepancy between Mac and Windows versions of Navigator through Version 4. In Windows, if you generate a date object for a date in another part of the year, the browser sets the time zone offset for that object according to the time zone setting for that time of year. On the Mac, the current setting of the control panel governs whether the normal or daylight savings time offset is applied to the date, regardless of the actual date within the year. This discrepancy affects Navigator 3 and 4 and can throw off calculations from other parts of the year by one hour.

It may sound as though the road to `Date` object scripting is filled with land mines. Although date and time scripting is far from hassle free, you can put it to good use with careful planning and a lot of testing. Better still, if you make the plausible assumption that the majority of users have a modern browser (WinIE6+, NN6+, Moz1+, FF1+, Cam1+, Safari1+, etc.), then things should go very smoothly.

Validating Date Entries in Forms

Given the bug horror stories in the previous section, you may wonder how you can ever perform data entry validation for dates in forms. The problem is not so much in the calculations as it is in the wide variety of acceptable date formats around the world. No matter how well you instruct users to enter dates in a particular format, many will follow their own habits and conventions. Moreover, how can you know whether an entry of 03/04/2010 is the North American March 4, 2010 or the European April 3, 2010? The answer: you can't.

My recommendation is to divide a date field into three components: month, day, and year. Let the user enter values into each field and validate each field individually for its valid range. Listing 17-5 shows an example of how this is done. The page includes a form that is to be validated before it is submitted. Each component field does its own range checking on-the-fly as the user enters values. But because this kind of validation can be defeated, the page includes one further check triggered by the form's `onsubmit` event handler. If any field is out of whack, the form submission is cancelled.

LISTING 17-5

Date Validation in a Form

// **END GENERIC VALIDATION FUNCTIONS**
```

As a general rule, JavaScript validation is only the first line of defense and must be backed up by server-side validation using PHP or another server scripting language. Because some users and user agents are going to be running without JavaScript, the server-side program will need to perform the validation all over again, but for those using JavaScript the validation feedback will be immediate.

Not every date entry validation must be divided in this way. For example, an intranet application can be more demanding in the way users are to enter data. Therefore, you can have a single field for date entry, but the parsing required for such a validation is quite different from that shown in Listing 17-5. See Chapter 46 on the CD-ROM for an example of such a one-field date validation routine.

Data entry validation is also an area of scripting that can benefit from asynchronous JavaScript, also known as Ajax, when it's necessary to look up values on the server to validate input. However, the advantages should be considered carefully since every Ajax operation requires a round-trip to the server and might not be any faster than submitting the whole page.

Cross-Reference

Check out Chapter 39, "Ajax, E4X, and XML," for more on how Ajax can be used to carry out dynamic data entry validation. ■

CHAPTER 18

The Array Object

IN THIS CHAPTER

Working with ordered collections of data

Simulating multidimensional arrays

Manipulating information stored in an array

New additions to JavaScript array handling

An array is one of the major JavaScript structures provided for storing and manipulating ordered collections of data. But unlike some other programming languages, JavaScript's arrays are very forgiving as to the kind of data you store in each cell or entry of the array. This allows, for example, an array of arrays, providing the equivalent of multidimensional arrays customized to the kind of data your application needs.

If you have not done a lot of programming in the past, the notion of arrays may seem like an advanced topic. But if you ignore their capabilities, you set yourself up for a harder job when implementing many kinds of tasks. Whenever we approach a script, one of our first thoughts is about the data being controlled by the application and whether handling it as an array will offer some shortcuts for creating the document and handling interactivity with the user.

We hope that by the end of this chapter you will not only be familiar with the properties and methods of JavaScript arrays but you will also begin to look for ways to make arrays work for you.

Structured Data

In programming, an *array* is defined as an ordered collection of data. You can best visualize an array as a table, not much different from a spreadsheet. In JavaScript, arrays are limited to a table holding one column of data, with as many rows as needed to hold your data. As you have seen in many chapters in Part IV, a JavaScript-enabled browser creates a number of internal arrays for the objects in your HTML documents and browser properties. For example, if your document contains five links, the browser maintains a table of those links. You access them by number (with 0 being the first link) in the array syntax: the array name is followed by the index number in square brackets, as in `document.links[0]`, which represents the first link in the document.

For many JavaScript applications, you will want to use an array as an organized warehouse for data that users of your page access, depending on their interaction

with form elements. In the application shown in Chapter 53, "Application: A Lookup Table" on the CD-ROM, for example, we demonstrate an extended version of this usage in a page that lets users search a small table of data for a match between the first three digits of their U.S. Social Security numbers and the state in which they registered with the agency. Arrays are one way JavaScript-enhanced pages can re-create the behavior of more sophisticated server-side applications such as CGI scripts and Java servlets. When the collection of data you embed in the script is no larger than a typical `.gif` image file, the user won't experience significant delays in loading your page; yet he or she has the full power of your small database collection for instant searching without any calls back to the server. Such database-oriented arrays are important applications of JavaScript for what we call *serverless CGIs*.

As you design an application, look for clues as to potential uses of arrays. If you have a number of objects or data points that interact with scripts the same way, you have a good candidate for array structures. For example, you can assign like names to every text field in a column of an order form. In that sequence, like-named objects are treated as elements of an array. To perform repetitive row calculations down an order form, your scripts can use array syntax to perform all the extensions within a handful of JavaScript statements, rather than perhaps dozens of statements hard-coded to each field name. Chapter 54, "Application: A 'Poor Man's' Order Form" (on the CD-ROM) shows an example of this application.

You can also create arrays that behave like the Java hash table: a lookup table that gets you to a desired data point instantaneously if you know the name associated with the entry.

If you can somehow conceive your data in a table format, an array is in your future.

Creating an Empty Array

Full-fledge array objects in JavaScript go all the way back to NN3 and IE4. It was possible to simulate some array characteristics in even earlier browsers, but since those first-generation browsers have thankfully disappeared from most users' computers, this chapter focuses on the modern array and its hefty powers.

To create a new array object, use the static `Array` object's constructor method. For example:

```
var myArray = new Array();
```

An array object automatically has a `length` property (0 for an empty array).

Should you want to presize the array (for example, preload entries with `null` values), you can specify an initial size as a parameter to the constructor. For example, here is how to create a new array to hold information about a 500-item compact disc collection:

```
var myCDCollection = new Array(500);
```

Unlike with many other programming languages, presizing a JavaScript array does not give you any particular advantage, because you can assign a value to any slot in an array at any time: The `length` property adjusts itself accordingly. For instance, if you assign a value to `myCDCollection[700]`, the array object adjusts its length upward to meet that slot (with the count starting at 0):

```
myCDCollection [700] = "The Smiths/Louder Than Bombs";
collectionSize = myCDCollection.length;    // result = 701
```

Since the count of array elements starts at 0, assigning a value to location 700 results in an array that contains 701 items.

A true array object features a number of methods and the capability to add prototype properties, described later in this chapter.

Populating an Array

Entering data into an array is as simple as creating a series of assignment statements, one for each element of the array. Listing 18-1 generates an array containing a list of the eight planets of the solar system.

LISTING 18-1

Generating and Populating a New Array

```
solarSys = new Array();
solarSys[0] = "Mercury";
solarSys[1] = "Venus";
solarSys[2] = "Earth";
solarSys[3] = "Mars";
solarSys[4] = "Jupiter";
solarSys[5] = "Saturn";
solarSys[6] = "Uranus";
solarSys[7] = "Neptune";
```

This way of populating a single array is a bit tedious when you're writing the code, but after the array is set, it makes accessing collections of information as easy as any array reference:

```
onePlanet = solarSys[4];     // result = "Jupiter"
```

A variant of this method takes advantage of the fact that, because JavaScript arrays are zero-based, the array length property always points past the end of the array at the next item to be filled. The following code produces an array identical to the one above:

```
solarSys = new Array();
solarSys[solarSys.length] = "Mercury";
solarSys[solarSys.length] = "Venus";
solarSys[solarSys.length] = "Earth";
solarSys[solarSys.length] = "Mars";
solarSys[solarSys.length] = "Jupiter";
solarSys[solarSys.length] = "Saturn";
solarSys[solarSys.length] = "Uranus";
solarSys[solarSys.length] = "Neptune";
```

This makes sense if you think about it: a newly created empty array has a length of zero, and the first item to be added to it is `array[0]`. The length is then one and the next item to be added is `array[1]`; and so on.

Assigning array elements like this makes it easy to edit the script later to add or remove elements without having to change all the subsequent subscripts:

```
solarSys = new Array();
solarSys[solarSys.length] = "Mercury";
```

```
solarSys[solarSys.length] = "Venus";
solarSys[solarSys.length] = "Earth";
solarSys[solarSys.length] = "Mars";
solarSys[solarSys.length] = "asteroid belt";
solarSys[solarSys.length] = "Jupiter";
solarSys[solarSys.length] = "Saturn";
solarSys[solarSys.length] = "Uranus";
solarSys[solarSys.length] = "Neptune";
```

A more compact way to create an array is available if you know that the data will be in the desired order (such as the preceding `solarSys` array). Instead of writing a series of assignment statements (as in Listing 18-1), you can create what is called a *dense array* by supplying the data as comma-delimited parameters to the `Array()` constructor:

```
solarSys = new Array("Mercury","Venus","Earth","Mars","Jupiter","Saturn",
   "Uranus","Neptune");
```

The term "dense array" simply means that data is packed into the array, without gaps, starting at index position 0.

The example in Listing 18-1 shows what you may call a vertical collection of data. Each data point contains the same type of data as the other data points — the name of a planet — and the data points appear in the relative order of the planets from the Sun.

JavaScript Array Creation Enhancements

JavaScript provides one more way to create a dense array and also clears up a bug in the way older browsers handled arrays. This improved approach does not require the `Array` object constructor. Instead, JavaScript (as of version 1.2) accepts what is called *literal notation* to generate an array. To demonstrate the difference, the following statement is the regular dense array constructor that works all the way back to NN3:

```
solarSys = new Array("Mercury","Venus","Earth","Mars","Jupiter","Saturn",
   "Uranus","Neptune");
```

While JavaScript 1.2+ fully accepts the preceding syntax, it also accepts the new literal notation:

```
solarSys = ["Mercury","Venus","Earth","Mars","Jupiter","Saturn",
   "Uranus","Neptune"];
```

The square brackets stand in for the call to the `Array` constructor. If you use this streamlined approach to array creation, be aware that it may stop JavaScript execution cold in old browsers.

The bug fix we mentioned has to do with how to treat the earlier dense array constructor if the scripter enters only the numeric value 1 as the parameter — `new Array(1)`. In NN3 and IE4, JavaScript erroneously creates an array of length 1, but that element is `undefined`. For NN4 and all later browsers, the same statement creates that one-element array and places the value 1 in that element.

Deleting Array Entries

You can easily wipe out any data in an array element by setting the value of the array entry to `null` or an empty string. But until the `delete` operator came along in version 4 browsers, you could not completely remove an element.

Deleting an array element eliminates the index from the list of accessible index values but does not reduce the array's length, as in the following sequence of statements:

```
myArray.length    // result: 5
delete myArray[2]
myArray.length    // result: 5
myArray[2]        // result: undefined
```

The process of deleting an array entry does not necessarily release memory occupied by that data. The JavaScript interpreter's internal garbage collection mechanism (beyond the reach of scripters) is supposed to take care of such activity. See the `delete` operator in Chapter 22, "JavaScript Operators," for further details.

If you want tighter control over the removal of array elements, you might want to consider using the `splice()` method, which is supported in modern browsers. The `splice()` method can be used on any array and lets you remove an item (or sequence of items) from the array — causing the array's length to adjust to the new item count. See the `splice()` method later in this chapter.

Parallel Arrays

Using an array to hold data is frequently desirable so that a script can do a lookup to see if a particular value is in the array (perhaps verifying that a value typed into a text box by the user is permissible); however, even more valuable is if, upon finding a match, a script can look up some related information in another array. One way to accomplish this is with two or more parallel arrays: the same indexed slot of each array contains related information.

Consider the following three arrays:

```
var regionalOffices = ["New York", "Chicago", "Houston", "Portland"];
var regionalManagers = ["Shirley Smith", "Todd Gaston",
   "Leslie Jones", "Harold Zoot"];
var regOfficeQuotas = [300000, 250000, 350000, 225000];
```

The assumption for these statements is that Shirley Smith is the regional manager out of the New York office, and her office's quota is 300,000. This represents the data that is included with the document, perhaps retrieved by a server-side program that gets the latest data from a SQL database and embeds the data in the form of array constructors. Listing 18-2 shows how this data appears in a simple page that looks up the manager name and quota values for whichever office is chosen in the `select` element. The order of the items in the list of `select` is not accidental: the order is identical to the order of the array for the convenience of the lookup script.

Lookup action in Listing 18-2 is performed by the `getData()` function. Because the index values of the options inside the `select` element match those of the parallel arrays index values, the `selectedIndex` property of the `select` element makes a convenient way to get directly at the corresponding data in other arrays.

Cross-Reference

The property assignment event-handling technique employed throughout the code in this chapter and much of the book is `addEvent()`, a cross-browser event handler explained in detail in Chapter 32, "Event Objects."

The `addEvent()` function is part of the script file `jsb-global.js` located on the accompanying CD-ROM in the `Content/` folder where it is accessible to all chapters' scripts. ■

      aRegionalOffices = ["New York", "Chicago", "Houston", "Portland"];
      aRegionalManagers = ["Shirley Smith", "Todd Gaston", "Leslie Jones",
                           "Harold Zoot"];
      aRegOfficeQuotas = [300000, 250000, 350000, 225000];

      // point to the critical input fields & save in global variables
      oSelect = document.getElementById('offices');
      oManager = document.getElementById('manager');
      oQuota = document.getElementById('quota');

         // if they all exist...
         if (oSelect && oManager && oQuota)
         {
            // build the drop-down list of regional offices
            for (var i = 0; i < aRegionalOffices.length; i++)
            {
               oSelect.options[i] = new Option(aRegionalOffices[i]);
            }

            // set the onchange behavior
            addEvent(oSelect, 'change', getData);
         }
      // plug in data for the default select option
      getData();
   }
}

// when a new option is selected, do the lookup into parallel arrays
function getData(evt)
{
   // get the offset of the selected option
   var index = oSelect.selectedIndex;

   // get data from the same offset in the parallel arrays
   oManager.value = aRegionalManagers[index];
   oQuota.value = aRegOfficeQuotas[index];
}
```

On the other hand, if the content to be looked up is typed into a text box by the user, you have to loop through one of the arrays to get the matching index. Listing 18-3 is a variation of Listing 18-2, but instead of the `select` element, a text field asks users to type in the name of the region. Assuming that users will always spell the input correctly (admittedly an outrageous assumption), the version of `getData()` in Listing 18-3 performs actions that more closely resemble what you may think a "lookup" should be doing: looking for a match in one array, and displaying corresponding results from the parallel arrays. The `for` loop iterates through items in the `aRegionalOffices` array. An

if condition compares all uppercase versions of both the input and each array entry. If there is a match, the for loop breaks, with the value of i still pointing to the matching index value. Outside the for loop, another if condition makes sure that the index value has not reached the length of the array, which means that no match is found. Only when the value of i points to one of the array entries does the script retrieve corresponding entries from the other two arrays.

LISTING 18-3

A Looping Array Lookup

           // advise user
           alert("No match found for '" + sInputText + "'.");
        }
     }
   // return the focus to the office input field
   oOffice.focus();
}
```

Multidimensional Arrays

An alternate to parallel arrays is the simulation of a multidimensional array. While it's true that JavaScript arrays are one-dimensional, you can create a one-dimensional array of arrays or other objects. A logical approach is to make an array of custom objects, because the objects easily allow for naming of object properties, making references to multidimensional array data more readable. (Custom objects are discussed at length in Chapter 23, "Function Objects and Custom Objects." See also Chapter 19, "JSON–Native JavaScript Object Notation.")

Using the same data from the examples of parallel arrays, the following statements define an object constructor for each "data record." A new object is then assigned to each of four entries in the main array.

```
// custom object constructor
function officeRecord(city, manager, quota)
{
   this.city = city;
   this.manager = manager;
   this.quota = quota;
}

// create new main array
var regionalOffices = new Array();

// stuff main array entries with objects
regionalOffices[0] = new officeRecord("New York", "Shirley Smith", 300000);
regionalOffices[1] = new officeRecord("Chicago", "Todd Gaston", 250000);
regionalOffices[2] = new officeRecord("Houston", "Leslie Jones", 350000);
regionalOffices[3] = new officeRecord("Portland", "Harold Zoot", 225000);
```

The object constructor function (`officeRecord()`) assigns incoming parameter values to properties of the object. Therefore, to access one of the data points in the array, you use both array notations to get to the desired entry in the array and the name of the property for that entry's object:

```
var eastOfficeManager = regionalOffices[0].manager;
```

You can also assign string index values for this kind of array, as in:

```
regionalOffices["east"] = new officeRecord("New York", "Shirley Smith",
   300000);
```

and access the data via the same index:

```
var eastOfficeManager = regionalOffices["east"].manager;
```

But if you're more comfortable with the traditional multidimensional array (from your experience in other programming languages), you can also implement the above as an array of arrays with less code:

```
// create new main array
var regionalOffices = new Array();
// stuff main array entries with arrays
regionalOffices[0] = new Array("New York", "Shirley Smith", 300000);
regionalOffices[1] = new Array("Chicago", "Todd Gaston", 250000);
regionalOffices[2] = new Array("Houston", "Leslie Jones", 350000);
regionalOffices[3] = new Array("Portland", "Harold Zoot", 225000);
```

or with the extreme brevity of literal notation:

```
// create new main array
var regionalOffices = [
                         ["New York", "Shirley Smith", 300000],
                         ["Chicago", "Todd Gaston", 250000],
                         ["Houston", "Leslie Jones", 350000],
                         ["Portland", "Harold Zoot", 225000]
                      ];
```

Accessing a single data point of an array of arrays requires a double array reference. For example, retrieving the manager's name for the Houston office requires the following syntax:

```
var HoustonMgr = regionalOffices[2][1];
```

The first index in brackets is for the outermost array (`regionalOffices`); the second index in brackets points to the item of the array returned by `regionalOffices[2]`.

Simulating a Hash Table

Nearly all arrays shown so far in this chapter have used integers as their index values. A JavaScript array is a special type of object (the `object` type is covered in Chapter 23, "Function Objects and Custom Objects"). As a result, you can also assign values to customized properties of an array without interfering with the data stored in the array or the length of the array. In other words, you can "piggy-back" data in the array object. You may reference the values of these properties either using "dot" syntax (`array.propertyName`) or through array-looking syntax consisting of square brackets and the property name as a string inside the brackets (`array["propertyName"]`). An array used in this fashion is also known as an *associative array*. If you use the dot syntax, then you can't use characters such as hyphens, spaces, periods, and quotation marks in the `propertyName` values,

whereas the only limitation on the quoted bracket syntax is that the values not contain the same type of quotation marks as you're using to quote the expressions.

These do *not* work:

```
// Dot notation:
oArray.Chris Smith              // space
oArray.Chris-Smith              // hyphen
oArray.Chris.Smith              // period
oArray.Smith,Chris              // comma
oArray.Chris"Punky"Smith        // quotes

// Quoted bracket notation:
oArray["Chris "Punky" Smith"]   // matching quotes
oArray['Chris 'Punky' Smith']   // matching quotes
```

These *do* work:

```
// Dot notation:
oArray.ChrisSmith               // one word
oArray.Chris_Smith              // underscore

// Quoted bracket notation (nearly everything works):
oArray["Chris_Smith"]
oArray["Chris.Smith"]
oArray["Chris Smith"]
oArray["Smith, Chris"]
oArray["Chris 'Punky' Smith"]   // non-matching quotes
oArray['Chris "Punky" Smith']   // non-matching quotes
```

Addressing object properties by way of string indexes is sometimes very useful. For example, the multidimensional array described in the previous section consists of four objects. If your page contains a form whose job is to look through the array to find a match for a city chosen from a `select` list, the typical array lookup would loop through the length of the array, compare the chosen value against the `city` property of each object, and then retrieve the other properties when there was a match. For a four-item list, this isn't a big deal. But for a 100-item list, the process could get time consuming. A faster approach would be to jump directly to the array entry whose `city` property is the chosen value. That's what a simulated hash table can do for you (some programming languages have formal hash table constructions especially designed to act like a lookup table).

Create a simulated hash table after the array is populated by looping through the array and assigning properties to the array object as string values. Use string values that you expect to use for lookup purposes. For example, after the `regionalOffices` array has its component objects assigned, run through the following routine to make the hash table:

```
for (var i = 0; i < regionalOffices.length; i++)
{
   regionalOffices[regionalOffices[i].city] = regionalOffices[i];
}
```

You can retrieve the manager property of the Houston office object as follows:

```
var HoustonMgr = regionalOffices["Houston"].manager;
```

With the aid of the hash table component of the array, your scripts have the convenience of both numeric lookup (if the script needs to cycle through all items) and an immediate jump to an item.

Array Object

Properties	Methods
`constructor`	`concat()`
`length`	`every()*`
`prototype`	`filter()*`
	`forEach()*`
	`indexOf()*`
	`join()`
	`lastIndexOf()*`
	`map()*`
	`pop()`
	`push()`
	`reduce()`
	`reduceRight()`
	`reverse()`
	`shift()`
	`slice()`
	`some()*`
	`sort()`
	`splice()`
	`toLocaleString()`
	`toString()`
	`unshift()`

*Items marked with an asterisk in the list of `Array` object properties and methods are relatively recent additions with JavaScript 1.6 and later. They are supported by Mozilla browsers such as Firefox 2.0+ but not by Internet Explorer as of version 8, which has a browser market share too large to ignore. We have provided code in this chapter that adds these new methods to the `Array` object if they don't already exist.

Array object properties

constructor

(See *string*.constructor in Chapter 15, "The String Object")

length

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

A true array object's length property reflects the number of entries in the array. An entry can be any kind of JavaScript value, including null. If an entry is in the 10th cell and the rest are null, the length of that array is 10. Note that because array index values are zero-based, the index of the last cell of an array is one less than the length (9 in this case). This characteristic makes it convenient to use the property as an automatic counter to append a new item to an array:

```
myArray[myArray.length] = valueOfAppendedItem;
```

Thus, a generic function does not have to know which specific index value to apply to an additional item in the array.

prototype

Value: Variable or function Read/Write

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Inside JavaScript, an array object has its dictionary definition of methods and length property — items that all array objects have in common. The prototype property enables your scripts to ascribe additional properties or methods that apply to all the arrays you create in the currently loaded documents. You can override this prototype, however, for any individual object.

Example

To demonstrate how the prototype property works, Listing 18-4 creates a prototype property for all array objects generated from the static Array object. As the script generates new arrays (instances of the Array object, just as a date object is an instance of the Date object), the property automatically becomes a part of those arrays. In one array, c, you override the value of the prototype sponsor property. By changing the value for that one object, you don't alter the value of the prototype for the Array object. Therefore, another array created afterward, d, still gets the original sponsor property value.

LISTING 18-4

Adding a prototype Property

HTML: jsb-18-04.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
```

```
      <title>Array prototypes</title>
      <script type="text/javascript" src="jsb-18-04.js"></script>
   </head>
   <body>
      <h1>Array prototypes</h1>
   </body>
</html>
```

JavaScript: jsb-18-04.js

```
// add prototype to all Array objects
Array.prototype.sponsor = "DG";

// create new arrays
var a = new Array();
var b = new Array();
var c = new Array();

// override prototype property for one 'instance'
c.sponsor = "JS";

// this one picks up the original prototype
var d = new Array();

// display results
var sMsg = "Array a is brought to you by: " + a.sponsor + "\n";
sMsg += "Array b is brought to you by: " + b.sponsor + "\n";
sMsg += "Array c is brought to you by: " + c.sponsor + "\n";
sMsg += "Array d is brought to you by: " + d.sponsor;
alert(sMsg);
```

You can assign properties and functions to a prototype. To assign a function, define the function as you normally would in JavaScript. Then assign the function to the `prototype` by name:

```
function newFunc(param1)
{
   // statements
}
Array.prototype.newMethod = newFunc;  // omit parentheses in this reference
```

where `newMethod` is whatever you want to name the method (the function name will not be retained).

When you need to call upon that function (which has essentially become a new temporary method for the `Array` object), invoke it as you would any object method. Therefore, if an array named `CDCollection` has been created and a prototype method `showCoverImage()` has been attached to the array, the call to invoke the method for a tenth listing in the array is

```
CDCollection.showCoverImage(9);
```

where the parameter of the function uses the index value to perhaps retrieve an image whose URL is a property of an object assigned to the 10th item of the array.

Array object methods

After you have information stored in an array, JavaScript provides several methods to help you manage that data. These methods, all of which belong to array objects you create, have evolved over time, so pay close attention to browser compatibility if you're in need of supporting legacy (pre-version 4) browsers.

array.concat(*array2*)

Returns: Array object

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `array.concat()` method allows you to join two array objects into a new, third array object. The action of concatenating the arrays does not alter the contents or behavior of the two original arrays. To join the arrays, you refer to the first array object to the left of the period before the method; a reference to the second array is the parameter to the method. For example:

```
var array1 = new Array(1,2,3);
var array2 = new Array("a","b","c");
var array3 = array1.concat(array2);
    // result: array with values 1,2,3,"a","b","c"
```

If an array element is a string or number value (not a string or number object), the values are copied from the original arrays into the new one. All connection with the original arrays ceases for those items. But if an original array element is a reference to an object of any kind, JavaScript copies a reference from the original array's entry into the new array; so, if you make a change to either array's entry, the change occurs to the object, and both array entries reflect the change to the object.

Example

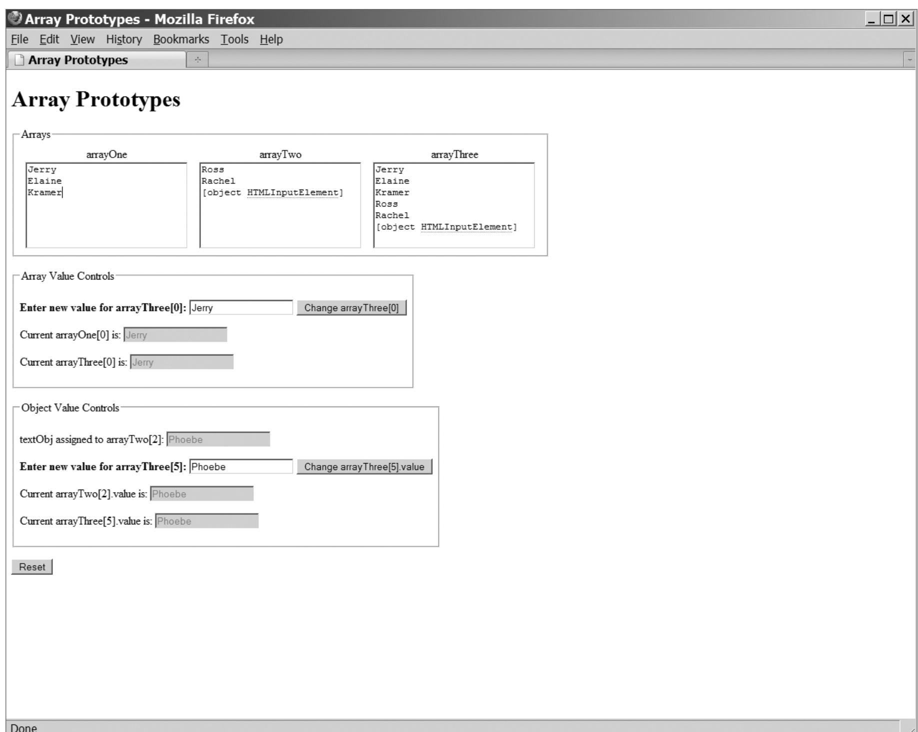
Listing 18-5 is a bit complex, but it demonstrates both how arrays can be joined with the `array.concat()` method and how values and objects in the source arrays do or do not propagate based on their data type. The page is shown in Figure 18-1.

After you load the page, you see readouts of three arrays. The first array consists of all string values; the second array has two string values and a reference to a form object on the page (a text box named "original" in the HTML). In the initialization routine of this page, not only are the two source arrays created, but they are joined with the `array.concat()` method, and the result is shown in the third box. To show the contents of these arrays in columns, we use the `array.join()` method, which brings the elements of an array together as a string delimited in this case by a return character — giving us an instant column of data.

Two series of fields and buttons let you experiment with the way values and object references are linked across concatenated arrays. In the first group, if you enter a new value to be assigned to `arrayThree[0]`, the new value replaces the string value in the combined array. Because regular values do not maintain a link back to the original array, only the entry in the combined array is changed. A call to `showArrays()` proves that only the third array is affected by the change.

FIGURE 18-1

Object references remain ''alive'' in a concatenated array.



More complex is the object relationship for this demonstration. A reference to the first text box of the second grouping has been assigned to the third entry of `arrayTwo`. After concatenation, the same reference is now in the last entry of the combined array. If you enter a new value for a property of the object in the last slot of `arrayThree`, the change goes all the way back to the original object — the first text box in the lower grouping. Thus, the text of the original field changes in response to the change of `arrayThree[5]`. And because all references to that object yield the same result, the reference in `arrayTwo[2]` points to the same text object, yielding the same new answer. The display of the array contents doesn't change, because both arrays still contain a reference to the same object (and the `value` attribute showing in the `<input>` tag of the column listings refers to the default value of the tag, not to its current algorithmically retrievable value shown in the last two fields of the page).

Related Item: `array.join()` method

array.every(*callback[, thisObject]*)
array.some(*callback[, thisObject]*)

Returns: Boolean

Compatibility: FF2+, Safari3+, Chrome1+, Opera 9.5+, WinIE−, MacIE−

`every()` and `some()` let you test the elements of an array with a callback function of your choice. (A *callback* is a function that is passed as an argument to another function.) The difference between the two methods is that `every()` returns `true` only if every array element tests true, while `some()` returns `true` if even one element tests true. The original array is not modified unless your callback function explicitly modifies it.

The callback function can contain any logic you want but in this case is required to return a Boolean value (either `true` or `false`). It takes three arguments: the value of the array element being examined, its index in the array, and a reference to the array object being traversed. `every()` uses the callback to test each member of the array in turn until a false value is returned or the end of the array is reached. `some()` uses the callback to test each member of the array until a true value is returned or the end of the array is reached. Note that if the array is empty, `every()` will return true because it hasn't encountered a value that would test false!

Here's a simple example that checks whether an array contains all positive numbers:

```
function isPositive(iValue, iIndex, aArray)
{
   return (iValue > 0);
}

var a = new Array(5, 4, 3, 2, 1);

var bResult = a.every(isPositive);
// returns true because there are no non-positive elements

bResult = a.some(isPositive);
// returns true because there is at least one positive element

a = [5, 4, 3, 2, 1, 0];

bResult = a.every(isPositive);
// returns false because zero is non-positive
```

```
bResult = a.some(isPositive);
// returns true because there is at least one positive element

a = new Array();

bResult = a.every(isPositive);
// returns true since there are no non-positive elements in an empty array!

bResult = a.some(isPositive);
// returns false because there are no positive elements in an empty array
```

The following example takes advantage of the callback function's other arguments to use other array elements to evaluate the current one. A *Fibonacci sequence* is one in which each number is the sum of the previous two. Of course, the first two numbers in the sequence are exceptions to this algorithm and are "hard-coded" as zero and one, but the rest are calculable:

```
function isFibonacci(iValue, iIndex, aArray)
{
   switch (iIndex)
   {
      case 0:
         return (iValue == 0);
      break;

      case 1:
         return (iValue == 1);
      break;

      default:
         return (iValue == aArray[iIndex-2] + aArray[iIndex-1]);
   }
}

var a = new Array(0, 1, 1, 2, 3, 5, 8, 13, 21);
var bResult = a.every(isFibonacci);
// returns true

a = [0, 1, 1, 2, 3, 5, 8, 13, 22];
var bResult = a.every(isFibonacci);
// returns false because 22 isn't 8 + 13
```

This same functionality could be gotten from a `for()` loop. The advantage of using `every()` is the encapsulation of program logic in discrete functions that can be re-used in different places in your script.

To equip browsers that don't yet support the `every()` method of JavaScript 1.6, you can supply that functionality to the array object using code supplied by Mozilla.org:

```
if (!Array.prototype.every)
{
   Array.prototype.every = function(fun /*, thisp*/)
```

```
    {
       var len = this.length >>> 0;
       if (typeof fun != "function")
       {
          throw new TypeError();
       }

       var thisp = arguments[1];
       for (var i = 0; i < len; i++)
       {
          if (i in this &&
                !fun.call(thisp, this[i], i, this))
             return false;
       }

       return true;
    };
 }
```

Related Items: `array.filter()`,`array.forEach()`, `array.map()` methods

`array``.filter(`*`callback[, thisObject]`*`)`

Returns: Array

Compatibility: FF2+, Safari3+, Chrome1+, Opera 9.5+, WinIE−, MacIE−

Similar to `every()`, the `filter()` method lets you test every element of an array with a callback function of your choice, and then returns a new array consisting of every element that tested `true`. The original array is not modified unless your callback function explicitly modifies it.

The callback function examines a single array element and returns Boolean `true` or `false`. It takes three arguments: the value of the array element being examined, its index in the array, and a reference to the array object being traversed. Every element that tests true is added to the result array.

This example uses our previous callback function to check for positive numbers:

```
function isPositive(iValue, iIndex, aArray)
{
   return (iValue > 0);
}

var a = new Array(1, -2, -3, 4, 5, -6);
var aResult = a.filter(isPositive);
// result: [1, 4, 5]
```

Mozilla suggests the following code to compensate for browsers that don't yet support the `filter()` method of JavaScript 1.6:

```
if (!Array.prototype.filter)
{
   Array.prototype.filter = function(fun /*, thisp*/)
```

```
      {
         var len = this.length >>> 0;
         if (typeof fun != "function")
            throw new TypeError();

         var res = new Array();
         var thisp = arguments[1];
         for (var i = 0; i < len; i++)
         {
            if (i in this)
            {
               var val = this[i]; // in case fun mutates this
               if (fun.call(thisp, val, i, this))
                  res.push(val);
            }
         }

         return res;
      };
   }
```

Related Items: `array.every()`, `array.forEach()`, `array.map()`, `array.some()` methods

array.forEach(*callback[, thisObject]*)

Returns: Array

Compatibility: FF2+, Safari3+, Chrome1+, Opera 9.5+, WinIE−, MacIE−

`forEach()` executes a function on every element of an array. It does not return a value and the original array is not modified unless your callback function explicitly modifies it.

The callback function takes three arguments: the value of the array element being examined, its index in the array, and a reference to the array object being traversed.

The following example builds a message that displays the contents of an array. Note that in the callback function `buildMsg()`, the keyword `this` refers to the custom object `oMsg` that we're passing to `forEach()`:

```
function sendMessages(sValue, iIndex, aArray)
{
   sendMsg(sValue, this.text);  // where sendMsg() is defined elsewhere ...
}

var a = new Array('chris@example.com', 'pat@example.net', 'jessie@example.org');

var oMessage = {text: "Dear friend,\nYou are cordially invited..."};
a.forEach(sendMessages, oMessage);
```

Alternatively, the preceding example could be written using the more universally supported `for()` method:

```
var a = new Array('apple', 'banana', 'cardamom', 'dandelion');
var oMsg = {buffer: 'This array contains:'};
```

```
for (var i = 0; i < a.length; i++)
{
   oMsg.buffer += '\n' + i + ':' + a[i];
}
alert(oMsg.buffer);
```

Mozilla suggests the following code to equip browsers that don't yet support the `forEach()` method of JavaScript 1.6:

```
if (!Array.prototype.forEach)
{
   Array.prototype.forEach = function(fun /*, thisp*/)
   {
      var len = this.length >>> 0;
      if (typeof fun != "function")
         throw new TypeError();

      var thisp = arguments[1];
      for (var i = 0; i < len; i++)
      {
         if (i in this)
            fun.call(thisp, this[i], i, this);
      }
   };
}
```

Related Items: `array.every()`,`array.filter()`, `array.map()`, `array.some()` methods

array.indexOf(*searchString[, startFrom]*)
array.lastIndexOf(*searchString[, startFrom]*)

Returns: Index value of the array element whose value matches searchString, or −1 if not found

Compatibility: FF2+, Safari3+, Chrome1+, Opera 9.5+, WinIE−, MacIE−

These two methods search for an array element that matches `searchString` exactly and return the index of the first (or last) matching element, or return −1 if no match is found.

The principle difference between these two methods is that `indexOf()` searches from left to right, starting at the beginning of the array ascending and `lastIndexOf()` searches from right to left, from the end of the array descending. In either case, the value that's returned is the index of the found item — its offset from the beginning of the array. Therefore, if there's only one matching element in the array and `startFrom` is not specified, both `indexOf()` and `lastIndexOf()` will return the same value because they'll find the same matching element.

The optional `startFrom` argument tells the method how far from the beginning or end of the array to begin the search. If it's missing, it's assumed to be zero — that is, begin the search at the first (with `indexOf()`) or last (with `lastIndexOf()`) element. If `startFrom` is a positive number, it's used as a starting offset from the beginning of the array; if it's negative, it's used as an offset from the end of the array.

Examples:

```
var a = new Array('cat', 'dog', 'cat');

// indexOf searches left to right:
a.indexOf('cat');         // result = 0 (search elements 0, 1, and 2)
a.indexOf('cat', 1);      // result = 2 (search elements 1 and 2)
a.indexOf('cat', 2);      // result = 2 (search element 2)
a.indexOf('cat', 3);      // result = -1 (no elements to search)
a.indexOf('cat', -1);     // result = 2 (search element 2)
a.indexOf('cat', -2);     // result = 2 (search elements 1 and 2)
a.indexOf('cat', -3);     // result = 0 (search elements 0, 1, and 2)

// lastIndexOf searches right to left:
a.lastIndexOf('cat');     // result = 2 (search elements 2, 1, and 0)
a.lastIndexOf('cat', 1);  // result = 0 (search elements 1 and 0)
a.lastIndexOf('cat', 2);  // result = 2 (search elements 2, 1, and 0)
a.lastIndexOf('cat', 3);  // result = 2 (search whole array)
a.lastIndexOf('cat', -1); // result = 2 (search elements 2, 1, and 0)
a.lastIndexOf('cat', -2); // result = 0 (search elements 1 and 0)
a.lastIndexOf('cat', -3); // result = 0 (search element 0)
```

Mozilla suggests the following code to equip browsers that don't yet support the `indexOf()` method of JavaScript 1.6:

```
if (!Array.prototype.indexOf)
{
   Array.prototype.indexOf = function(elt /*, from*/)
   {
      var len = this.length >>> 0;

      var from = Number(arguments[1]) || 0;
      from = (from < 0)
             ? Math.ceil(from)
             : Math.floor(from);
      if (from < 0)
         from += len;

      for (; from < len; from++)
      {
         if (from in this &&
               this[from] === elt)
            return from;
      }
      return -1;
   };
}
```

And the following to equip browsers that don't yet support `lastIndexOf()`:

```
if (!Array.prototype.lastIndexOf)
{
   Array.prototype.lastIndexOf = function(elt /*, from*/)
   {
      var len = this.length;

      var from = Number(arguments[1]);
      if (isNaN(from))
      {
         from = len - 1;
      }
      else
      {
         from = (from < 0)
              ? Math.ceil(from)
              : Math.floor(from);
         if (from < 0)
            from += len;
         else if (from >= len)
            from = len - 1;
      }

      for (; from > -1; from--)
      {
         if (from in this &&
             this[from] === elt)
            return from;
      }
      return -1;
   };
}
```

array.join(*separatorString*)

Returns: String of entries from the array delimited by the *separatorString* value

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

You cannot directly view data that is stored in an array. Nor can you put an array into a form element for transmittal to a server-side program that expects a string of text. To make the transition from discrete array elements to string, the `array.join()` method handles what would otherwise be a nasty string manipulation exercise.

The sole parameter for this method is a string of one or more characters that you want to act as a delimiter between entries. For example, if you want commas between array items in their text version, the statement is

```
var arrayText = myArray.join(",");
```

***arrayObject*.join**

Invoking this method does not change the original array in any way. Therefore, you need to assign the results of this method to another variable or a value property of a form element.

Example

The script in Listing 18-6 converts an array of planet names into a text string. The page provides you with a field to enter the delimiter string of your choice and shows the results in a text area.

LISTING 18-6

Using the Array.join() Method

HTML: jsb-18-06.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Array.join()</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-18-06.js"></script>
   </head>
   <body>
      <h1>Array.join(): Converting arrays to strings</h1>
      <form>
         <p>This document contains an array of planets in our solar system.</p>
         <p>
            <label for="delimiter">Enter a string to act
                                   as a delimiter between entries:</label>
            <input type="text" id="delimiter" name="delim" value="," size="5">
         </p>
         <p>
            <input id="displayButton" type="button" value="Display as String">
            <input type="reset">
         </p>
         <p>
            <textarea id="output" name="output" rows="4" cols="40"
                         wrap="virtual"></textarea>
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-18-06.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
```

```
   if (document.getElementById)
   {
      // point to critical elements
      oDelimiter = document.getElementById('delimiter');
      oOutput = document.getElementById('output');
      var oButton = document.getElementById('displayButton');

         // if they all exist...
         if (oDelimiter && oOutput && oButton)
         {
            // apply behavior to button
            oButton.onclick = convert;

            // set global array
            solarSys = new Array("Mercury", "Venus", "Earth", "Mars", "Jupiter",
                                 "Saturn", "Uranus", "Neptune");
         }
   }
}

// join array elements into a string
function convert(evt)
{
   var delimiter = oDelimiter.value;
   oOutput.value = decodeURIComponent(solarSys.join(delimiter));
}
```

Notice that this method takes the parameter very literally. If you want to include non-alphanumeric characters, such as a newline or tab, do so with URL-encoded characters (`%0D` for a carriage return; `%09` for a tab) instead of inline string literals. Coming up in Listing 18-7, the results of the `array.join()` method are subjected to the `decodeURIComponent()` function in order to display them in the `textarea`.

Related Items: `string.split()` method

array.map(*callback[, thisObject]*)

Returns: Array

Compatibility: FF2+, Safari3+, Chrome1+, Opera 9.5+, WinIE−, MacIE−

`map()` creates a new array by running a user-provided function on each element of the original array.

The callback function returns a value that is used to build the result array. It takes three arguments: the value of the array element being examined, its index in the array, and a reference to the array object being traversed.

If provided, `thisObject` will be used as the `this` value within the callback function.

Example:

```
function square(iValue, iIndex, aArray)
{
```

```
    return iValue * iValue;
}

var a = new Array(0, 1, 2, 3, 4, 5, 6, 7);
var b = a.map(square);
// result: b == [0, 1, 4, 9, 16, 25, 36, 49]
```

You could also write this by creating the callback function on-the-fly:

```
var a = new Array(0, 1, 2, 3, 4, 5, 6, 7);
var b = a.map(function(i) { return i * i; });
```

Mozilla suggests the following code to equip browsers that don't yet support the `map()` method of JavaScript 1.6:

```
if (!Array.prototype.map)
{
   Array.prototype.map = function(fun /*, thisp*/)
   {
      var len = this.length >>> 0;
      if (typeof fun != "function")
         throw new TypeError();

      var res = new Array(len);
      var thisp = arguments[1];
      for (var i = 0; i < len; i++)
      {
         if (i in this)
            res[i] = fun.call(thisp, this[i], i, this);
      }

      return res;
   };
}
```

Related Items: `array.every()`, `array.filter()`,`array.forEach()`, `array.some()` methods

array.pop()
array.push(*valueOrObject*)
array.shift()
array.unshift(*valueOrObject*)

Returns: One array entry value

Compatibility: WinIE5.5+, MacIE−, NN4+, Moz+, Safari+, Opera+, Chrome+

The notion of a *stack* is well known to experienced programmers, especially those who know about the inner workings of assembly language at the CPU level. Even if you've never programmed a stack before, you have encountered the concept in real life many times. The classic analogy is the spring-loaded pile of cafeteria trays. If the pile were created one tray at a time, each tray would be pushed onto the top of the stack of trays. When a customer comes along, the topmost tray (the last

one to be pushed onto the stack) gets popped off. The last one to be put on the stack is the first one to be taken off.

JavaScript in modern browsers lets you turn an array into one of these spring-loaded stacks. But instead of placing trays on the pile, you can place any kind of data at either end of the stack, depending on which method you use to do the stacking. Similarly, you can extract an item from either end.

Perhaps the most familiar terminology for this is *push* and *pop*. When you `push()` a value onto an array, the value is appended as the last entry in the array. When you issue the `array.pop()` method, the last item in the array is removed from the stack and is returned, and the array shrinks in length by one. In the following sequence of statements, watch what happens to the value of the array used as a stack:

```
var source = new Array("Homer","Marge","Bart","Lisa","Maggie");
var stack = new Array();
    // stack = <empty>
stack.push(source[0]);
    // stack = "Homer"
stack.push(source[2]);
    // stack = "Homer","Bart"
var Simpson1 = stack.pop();
    // stack = "Homer" ; Simpson1 = "Bart"
var Simpson2 = stack.pop();
    // stack = <empty> ; Simpson2 = "Homer"
```

While `push()` and `pop()` work at the end of an array, another pair of methods works at the front. Their names are not as picturesque as `push()` and `pop()`. To insert a value at the front of an array, use the `array.unshift()` method; to grab the first element and remove it from the array, use `array.shift()`. Of course, you are not required to use these methods in matching pairs. If you `push()` a series of values onto the back end of an array, you can `shift()` them off from the front end without complaint. It all depends on how you need to process the data.

Related Items: `array.concat()`, `array.slice()` method

array.reduce(*callback[, initialValue]*)
array.reduceRight(*callback[, initialValue]*)

Returns: A single value

Compatibility: FF3+, Safari4+

These methods reduce an array down to a single value. `reduce()` operates on the array elements starting with the first element, whereas `reduceRight()` begins with the last element. Both methods accept as arguments a callback function and an optional initial value (since the very first iteration will have only one array element to work on). The callback function has two arguments, (`firstValue`, `secondValue`), which it processes in some way to derive a single return value.

For example, the following code reduces an array of numbers down to their sum:

```
function addEmUp(a, b)
{
   return a + b;
}
```

```
var a = new Array(1, 2, 3, 4, 5);
var b = a.reduce(addEmUp);
// result: b == 15
```

For simple addition, it doesn't matter whether the reduction occurred frontward or backward, but look at what happens when we apply that same callback to text. (Remember that in JavaScript the plus sign adds numbers but concatenates text.)

```
var a = new Array('d', 'e', 's', 's', 'e', 'r', 't', 's');

var b = a.reduce(addEmUp);
// result: b == 'desserts'

var b = a.reduceRight(addEmUp);
// result: b == 'stressed'
```

Mozilla suggests the following code to equip browsers that don't yet support the `reduce()` method of JavaScript 1.8:

```
if (!Array.prototype.reduce)
{
  Array.prototype.reduce = function(fun /*, initial*/)
  {
    var len = this.length >>> 0;
    if (typeof fun != "function")
      throw new TypeError();

    // no value to return if no initial value and an empty array
    if (len == 0 && arguments.length == 1)
      throw new TypeError();

    var i = 0;
    if (arguments.length >= 2)
    {
      var rv = arguments[1];
    }
    else
    {
      do
      {
        if (i in this)
        {
          rv = this[i++];
          break;
        }

        // if array contains no values, no initial value to return
        if (++i >= len)
          throw new TypeError();
      }
      while (true);
```

```
      }

      for (; i < len; i++)
      {
        if (i in this)
          rv = fun.call(null, rv, this[i], i, this);
      }

      return rv;
    };
  }
```

... and likewise for `reduceRight()`:

```
  if (!Array.prototype.reduceRight)
  {
    Array.prototype.reduceRight = function(fun /*, initial*/)
    {
      var len = this.length >>> 0;
      if (typeof fun != "function")
        throw new TypeError();

      // no value to return if no initial value, empty array
      if (len == 0 && arguments.length == 1)
        throw new TypeError();

      var i = len - 1;
      if (arguments.length >= 2)
      {
        var rv = arguments[1];
      }
      else
      {
        do
        {
          if (i in this)
          {
            rv = this[i--];
            break;
          }

          // if array contains no values, no initial value to return
          if (--i < 0)
            throw new TypeError();
        }
        while (true);
      }

      for (; i >= 0; i--)
      {
        if (i in this)
```

```
                rv = fun.call(null, rv, this[i], i, this);
            }

            return rv;
        };
    }
```

array.reverse()

Returns: Array of entries in the opposite order of the original

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Occasionally, you may find it more convenient to work with an array of data in reverse order. Although you can concoct repeat loops to count backward through index values, a server-side program may prefer the data in a sequence opposite to the way it was most convenient for you to script it.

You can have JavaScript switch the contents of an array for you: Whatever element was last in the array becomes the 0 index item in the array. Bear in mind that if you do this, you're restructuring the original array, not copying it, even though the method also returns a copy of the reversed version. A reload of the document restores the order as written in the HTML document.

Example

Listing 18-7 is an enhanced version of Listing 18-6, which includes another button and function that reverse the array and display it as a string in a text area.

LISTING 18-7

Array.reverse() Method

HTML: jsb-18-07.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Array.reverse()</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-18-07.js"></script>
   </head>
   <body>
      <h1>Array.reverse(): Reversing array element order</h1>
      <form>
         <p>This document contains an array of planets in our solar system.</p>
         <p>
            <label for="delimiter">Enter a string to act as
                                 a delimiter between entries:</label>
            <input type="text" id="delimiter" name="delim" value="," size="5">
         </p>
         <p>
            <input type="button" id="showAsIs" value="Array as-is">
```

```
            <input type="button" id="reverseIt" value="Reverse the array">
            <input type="reset">
            <input type="button" id="reload" value="Reload">
         </p>
         <p>
            <textarea id="output" name="output" rows="4" cols="40"
                      wrap="virtual"></textarea>
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-18-07.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to critical elements
      oDelimiter = document.getElementById('delimiter');
      oOutput = document.getElementById('output');
      var oButtonShowAsIs = document.getElementById('showAsIs');
      var oButtonReverseIt = document.getElementById('reverseIt');
      var oReload = document.getElementById('reload');

         // if they all exist...
         if (oDelimiter && oOutput && oButtonShowAsIs && oButtonReverseIt)
         {
            // apply behaviors to buttons
            oButtonShowAsIs.onclick = showAsIs;
            oButtonReverseIt.onclick = reverseIt;
            oReload.onclick = function() { location.reload(); };

            // set global array
            solarSys = new Array("Mercury", "Venus", "Earth", "Mars", "Jupiter",
                                 "Saturn", "Uranus", "Neptune");
         }
   }
}

// show array as currently in memory
function showAsIs(evt)
{
   var delimiter = oDelimiter.value;
   oOutput.value = decodeURIComponent(solarSys.join(delimiter));
}

// reverse array order, then display as string
```

continued

LISTING 18-7 *(continued)*

```
function reverseIt(evt)
{
   var delimiter = oDelimiter.value;
   solarSys.reverse();   // reverses original array
   oOutput.value = decodeURIComponent(solarSys.join(delimiter));
}
```

Notice that the `solarSys.reverse()` method stands by itself (meaning, nothing captures the returned value) because the method modifies the `solarSys` array. You then run the now-inverted `solarSys` array through the `array.join()` method for your text display.

Related Items: `array.sort()` method

array.slice(*startIndex* [, *endIndex*])

Returns: Array

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Behaving as its like-named string method, `array.slice()` lets you extract a contiguous series of items from an array. The extracted segment becomes an entirely new array object. Values and objects from the original array have the same kind of behavior as arrays created with the `array.concat()` method.

One parameter is required — the starting index point for the extraction. If you don't specify a second parameter, the extraction goes all the way to the end of the array; otherwise the extraction goes to, *but does not include,* the index value supplied as the second parameter. For example, extracting Earth's neighbors from an array of planet names looks like the following:

```
var solarSys = new Array("Mercury","Venus","Earth","Mars",
   "Jupiter","Saturn","Uranus","Neptune","Pluto");
var nearby = solarSys.slice(1,4);
    // result: new array of "Venus", "Earth", "Mars"
```

Related Items: `array.splice()`, `string.slice()` methods

array.sort([*compareFunction*])

Returns: Array of entries in the order as determined by the *compareFunction* algorithm

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

JavaScript array sorting is both powerful and a bit complex to script if you haven't had experience with this kind of sorting methodology. The purpose, obviously, is to let your scripts sort entries of an array by almost any kind of criterion that you can associate with an entry. For entries consisting of strings, the criterion may be their alphabetical order or their length; for numeric entries, the criterion may be their numerical order.

Look first at the kind of sorting you can do with the `array.sort()` method by itself (for example, without calling a comparison function). When no parameter is specified, JavaScript takes a snapshot of

the contents of the array and converts items to strings. From there, it performs a string sort of the values. ASCII values of characters govern the sort, which means that numbers are sorted by their string values, not their numeric values. This fact has strong implications if your array consists of numeric data: The value 201 sorts before 88, because the sorting mechanism compares the first characters of the strings ("2" versus "8") to determine the sort order. For simple alphabetical sorting of string values in arrays, the plain `array.sort()` method does the trick.

Fortunately, additional intelligence is available that you can add to array sorting. The key tactic is to define a function that helps the `sort()` method compare items in the array. A comparison function is passed two values from the array (what you don't see is that the `array.sort()` method rapidly sends numerous pairs of values from the array to help it sort through all entries). The comparison function lets the `sort()` method know which of the two items comes before the other, based on the value the function returns. Assuming that the function compares two values, `a` and `b`, the returned value reveals information to the `sort()` method, as shown in Table 18-1.

TABLE 18-1

Comparison Function Return Values

Return Value Range	Meaning
< 0	Value `b` should sort later than `a`.
0	The order of `a` and `b` should not change.
> 0	Value `a` should sort later than `b`.

Consider the following example:

```
myArray = new Array(12, 5, 200, 80);
function compare(a,b)
{
   return a - b;
}
myArray.sort(compare);
```

The array has four numeric values in it. To sort the items in numerical order, you define a comparison function (arbitrarily named `compare()`), which is called from the `sort()` method. Note that unlike invoking other functions, the parameter of the `sort()` method uses a reference to the function, which lacks parentheses.

When the `compare()` function is called, JavaScript automatically sends two parameters to the function in rapid succession until each element has been compared with the others. Every time `compare()` is called, JavaScript assigns two of the array's values to the parameter variables (`a` and `b`). In the preceding example, the returned value is the difference between `a` and `b`. If `a` is larger than `b`, then a positive value goes back to the `sort()` method, telling it to sort `a` later than `b` (that is, position `a` at a higher value index position than `b`). Therefore, `b` may end up at `myArray[0]`, whereas `a` ends up at a higher index-valued location. On the other hand, if `a` is smaller than `b`, the returned negative value tells `sort()` to put `a` in a lower index value spot than `b`.

Evaluations within the comparison function can go to great lengths, as long as some data connected with array values can be compared. For example, instead of numerical comparisons, as just shown,

you can perform string comparisons. The following function sorts alphabetically by the last character of each array string entry:

```
function compare(a,b)
{
   // last character of array strings
   var aComp = a.charAt(a.length - 1);
   var bComp = b.charAt(b.length - 1);
   if (aComp < bComp)
      return -1;
   if (aComp > bComp)
      return 1;
   return 0;
}
```

First, this function extracts the final character from each of the two values passed to it. Then, because strings cannot be added or subtracted like numbers, you compare the ASCII values of the two characters, returning the corresponding values to the `sort()` method to let it know how to treat the two values being checked at that instant.

When an array's entries happen to be objects, you can even sort by properties of those objects. If you bear in mind that the `a` and `b` parameters of the sort function are references to two array entries, then by extension you can refer to properties of those objects. For example, if an array contains objects whose properties define information about employees, one of the properties of those objects can be the employee's age as a string. You can then sort the array based on the numeric equivalent of the `age` property of the objects by way of the following comparison function:

```
function compare(a,b) {
   return parseInt(a.age) - parseInt(b.age);
}
```

Array sorting, unlike sorting routines you may find in other scripting languages, is not a stable sort. Not being stable means that succeeding sort routines on the same array are not cumulative. Also, remember that sorting changes the sort order of the original array. If you don't want the original array harmed, make a copy of it before sorting or reload the document to restore an array to its original order. Should an array element be `null`, the method sorts such elements at the end of the sorted array.

JavaScript array sorting is extremely powerful stuff. Array sorting is one reason why it's not uncommon to take the time during the loading of a page containing an IE XML data island, for example, to make a JavaScript copy of the data as an array of objects (see Chapter 60, "Application: Transforming XML Data," on the CD-ROM). Converting the XML to JavaScript arrays makes the job of sorting the data much easier and faster than cobbling together your own sorting routines on the XML elements.

Example

You can look to Listing 18-8 for a few examples of sorting an array of string values (see Figure 18-2). Four buttons summon different sorting routines, three of which invoke comparison functions. This listing sorts the planet array alphabetically (forward and backward) by the last character of the planet name and also by the length of the planet name. Each comparison function demonstrates different ways of comparing data sent during a sort.

FIGURE 18-2

Sorting an array of planet names alphabetically by name length.

JavaScript: jsb-18-08.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // do this only if the browser can handle DOM methods
   if (document.getElementById)
   {
      // point to critical elements
      oOutput = document.getElementById('output');
      var oButtonSortAsc = document.getElementById('sortAsc');
      var oButtonSortDesc = document.getElementById('sortDesc');
      var oButtonSortLastChar = document.getElementById('sortLastChar');
      var oButtonSortLength = document.getElementById('sortLength');
      var oReload = document.getElementById('reload');

         // if they all exist...
         if (oOutput && oButtonSortAsc && oButtonSortDesc && oButtonSortLastChar
                     && oButtonSortLength && oReload)
         {
            // apply behaviors to buttons
            oButtonSortAsc.onclick = function() { sortIt(null) };
            oButtonSortDesc.onclick = function() { sortIt(compare1) };
            oButtonSortLastChar.onclick = function() { sortIt(compare2) };
            oButtonSortLength.onclick = function() { sortIt(compare3) };
            oReload.onclick = function() { location.reload(); };

            // set global array
            solarSys = new Array("Mercury", "Venus", "Earth", "Mars", "Jupiter",
                                 "Saturn", "Uranus", "Neptune");
         }
   }
}
```

```
// comparison functions
function compare1(a,b)
{
   // reverse alphabetical order
   if (a > b)
      return -1;
   if (b > a)
      return 1;
   return 0;
}

function compare2(a,b)
{
   // last character of planet names
   var aComp = a.charAt(a.length - 1);
   var bComp = b.charAt(b.length - 1);
   if (aComp < bComp)
      return -1;
   if (aComp > bComp)
      return 1;
   return 0;
}

function compare3(a,b)
{
   // length of planet names
   return a.length - b.length;
}

// sort and display array
function sortIt(compFunc)
{
   if (compFunc == null)
   {
         solarSys.sort();
   }
   else
   {
         solarSys.sort(compFunc);
   }

   // display results in field
   var delimiter = ";";
   oOutput.value = decodeURIComponent(solarSys.join(delimiter));
}
```

Related Items: `array.reverse()` method

Note

As we show you in Chapter 45, many regular expression object methods generate arrays as their result (for example, an array of matching values in a string). These special arrays have a custom set of named properties that assist your script in analyzing the findings of the method. Beyond that, these regular expression result arrays behave like all others. ■

array.splice(*startIndex* , *deleteCount*[, *item1*[, *item2*[,...*itemN*]]])

Returns: Array

Compatibility: WinIE5.5+, MacIE−, NN4+, Moz+, Safari+, Opera+, Chrome+

If you need to remove items from the middle of an array, the `array.splice()` method simplifies a task that would otherwise require assembling a new array from selected items of the original array. The first of two required parameters is a zero-based index integer that points to the first item to be removed from the current array. The second parameter is another integer that indicates how many sequential items are to be removed from the array. Removing array items affects the length of the array, and those items that are removed are returned by the `splice()` method as their own array.

You can also use the `splice()` method to replace array items. Optional parameters beginning with the third let you provide data elements that are to be inserted into the array in place of the items being removed. Each added item can be any JavaScript data type, and the number of new items does not have to be equal to the number of items removed. In fact, by specifying a second parameter of zero, you can use `splice()` to insert one or more items into any position of the array.

Example

Use The Evaluator (see Chapter 4) to experiment with the `splice()` method. Begin by creating an array with a sequence of numbers:

```
a = new Array(1,2,3,4,5)
```

Next, remove the center three items, and replace them with one string item:

```
a.splice(1, 3, "two/three/four")
```

The Results box shows a string version of the three-item array returned by the method. To view the current contents of the array, enter `a` into the top text box.

To put the original numbers back into the array, swap the string item with three numeric items:

```
a.splice(1, 1, 2, 3, 4)
```

The method returns the single string, and the `a` array now has five items in it again.

Related Item: `array.slice()` method

array.toLocaleString()

Returns: String

Compatibility: WinIE5.5+, MacIE−, NN6+, Moz+, Safari+, Opera+, Chrome+

array.toString()

Returns: String

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The `array.toLocaleString()` and the older, more compatible `array.toString()` are methods to retrieve the contents of an array in string form. Browsers use the `toString()` method on their own whenever you attempt to display an array in text boxes, in which case the array items are comma-delimited.

The precise string conversion of the `toLocaleString()` is left up to the specific browser implementation. That browsers differ in some details is not surprising, even in the U.S. English versions of operating systems and browsers. For example, if the array contains integer values, the `toLocaleString()` method in IE5.5+ returns the numbers comma-and-space-delimited, formatted with two digits to the right of the decimal (as if dollars and cents). Mozilla-based browsers, on the other hand, return just the integers, but these are also comma-delimited.

If you need to convert an array to a string for purposes of passing array data to other venues (for example, as data in a hidden text box submitted to a server or as search string data conveyed to another page), use the `array.join()` method instead. `Array.join()` gives you more reliable and flexible control over the item delimiters, and you are assured of the same results regardless of locale.

Related Item: `array.join()` method

Array Comprehensions

Compatibility: FF2+

A feature of JavaScript 1.7 is an enhancement to JavaScript syntax called *array comprehensions*, a shortcut for building a new array based on another. Comprehensions can often replace the `map()` and `filter()` methods.

Here's an example that uses a comprehension to produce a modified version of every element in an array:

```
var aIntegers = new Array(0, 1, 2, 3, 4, 5, 6, 7);
var aResults = [i * i for each (i in aIntegers)];

// result: aResults == [0, 1, 4, 9, 16, 25, 36, 49]
```

This is the equivalent of the `map()` syntax:

```
function square(iValue)
{
   return iValue * iValue;
}

var aIntegers = new Array(0, 1, 2, 3, 4, 5, 6, 7);
var aResults = aIntegers.map(square);
```

Array comprehensions can also be used to select certain elements from an array:

```
var aNumbers = new Array(1, -2, -3, 4, 5, -6);
var aResult = [i for each (i in aNumbers) if (i > 0)];

// result: aResult == [1, 4, 5]
```

This is the equivalent of the `filter()` syntax:

```
function isPositive(iValue, iIndex, aArray)
{
   return (iValue > 0);
}

var aNumbers = new Array(1, -2, -3, 4, 5, -6);
var aResult = aNumbers.filter(isPositive);
```

The square brackets of an array comprehension introduce an implicit block for scoping purposes. New variables (such as `i` in the preceding examples) have local scope (are treated as if they had been declared using `let`) and are not available outside of the comprehension.

The input to an array comprehension does not itself need to be an array; *iterators* and *generators* can also be used (see Chapter 21).

Destructuring Assignment

Compatibility: FF2+, Opera 9.5 (partial)

Destructuring assignment (introduced with JavaScript 1.7 and corrected in 1.8) makes it easy to extract an array from another array, object, or function. You can view it as setting one array equal to another:

```
[a, b, c] = [1, 2, 3]
// result: a == 1, b == 2, and c == 3
```

This syntax provides a succinct way to swap the values of variables:

```
var x = 1;
var y = 2;

[x, y] = [y, x]
// result: x == 2 and y == 1
```

... replacing the more conventional technique that employs a third temporary variable to swap two values:

```
temp = x;
x = y;
y = temp;
```

Another example is receiving an array of values from a function:

```
function fun()
{
   return [3, 'aardvark', 0];
}

[a, b, c] = fun()
// result: a == 3, b == 'aardvark', and c == 0
```

As of this writing, destructuring assignment is supported by Firefox 2.0+ and partially by Opera 9.5 but not at all by Internet Explorer 8 and other browsers. We can't use JavaScript to test a browser's ability to execute this code because an older version will simply crash trying to compile it. We can "firewall" this code with a special script tag:

```
<script type="application/javascript;version=1.8" src="scriptname.js"></script>
```

However, we question the usefulness of this if we also have to provide more conventional syntax for other browsers. Unless we're in a special circumstance in which we can guarantee that our code will be running in a browser that incorporates JavaScript 1.8, we may just have to wait until destructuring assignment syntax is more universally adopted by the other browser manufacturers.

Compatibility with Older Browsers

Some of the features described in this chapter were introduced with JavaScript 1.6 and later. They run in Firefox 2.0+ or 3.0+ and occasional others but are not supported in many other browsers, including Internet Explorer 8. New array object methods such as `every()` and `filter()` can be used in our cross-browser scripts simply by adding them to the object prototype when they're not already there, as we've listed in this chapter. However, innovations of syntax, including array comprehensions and destructuring assignment, cannot be included in blocks of script run by legacy browsers because older versions of JavaScript will simply stop cold during the compile phase and will not run any of the script on the page.

Should we then refrain from using the new syntax until it's universally supported?

As mentioned in Chapter 4, there is a way to identify a block of code so that it will run only in a given version of JavaScript or greater — for example:

```
<script type="text/javascript" src="for-everyone.js"></script>
<script type="application/javascript;version=1.7" src="new-stuff.js"></script>
```

You can isolate sections of code in this way to execute only if the browser is capable, separated safely from older user agents.

The question then comes, what alternative code will you run if the browser is older? If you have to write code that performs the same operation as an array comprehension to support older browsers, why not simply use that code for all browsers?

As with any facet of web development, and JavaScript in particular, make sure that all basic functionality on a page is intact even in the absence of JavaScript or any specific features of the language; then add enhancements when scripting and any of its advanced features are available. This principle of progressive enhancement ensures that while your pages may work better or faster for those with fancier tools, they will work fundamentally for everyone.

CHAPTER 19

JSON — Native JavaScript Object Notation

JSON (JavaScript Object Notation) is a lightweight way to represent data structures that many programming languages can easily read and write. This makes it (similarly to XML) a useful data interchange format among applications written in a variety of languages, for example, between server-side PHP and client-side JavaScript. With the ECMAScript Fifth Edition standard, JSON is now formally part of the language and will be increasingly supported by more browsers over the coming years. In the meantime, there is freely available code to assist older browsers.

JSON was developed by Douglas Crockford and presented to the Internet community in 2006. It was formally made part of the ECMAScript standard, on which JavaScript is based, as of the Fifth Edition finalized in April 2010.

IN THIS CHAPTER

- **How JSON works**
- **Sending and receiving JSON data**
- **JSON object methods**
- **Security concerns**

How JSON Works

JSON combines two aspects of JavaScript syntax for representing arrays and objects to present data structures — simple array notation using brackets `[ ]`:

```
[ "item1", "item2", "item3" ]
```

and the notation for objects and associative arrays using curly braces `{ }`:

```
{ "key": "value" }
```

We have access to the embedded values by numerical index in the first case (remember that the first item has an index of zero):

```
var aItems = [ "item1", "item2", "item3" ];
// e.g., aItems[0] == "item1"
```

and by key name in the second:

```
var oExample = { "charlie": "horse" };
// oExample["charlie"] == "horse"
// oExample.charlie == "horse"
```

Using these two conventions, one can describe many data structures with sub-records having either named or numerically indexed keys:

```
var oNovelist =
{
   "firstName": "Joanna",
   "lastName": "Russ",
   "novels":
   [
      {
         "title": "And Choas Died",
         "year": "1970"
      },
      {
         "title": "The Female Man",
         "year": "1975"
      }
   ]
};
```

In this example, `firstName` and `lastName` have simple string values, while `novels` is a numerically indexed array. Here are two ways to refer to these values:

```
var sMsg = oNovelist['firstName'] + ' ' + oNovelist['lastName'] + "'s novel " +
 oNovelist['novels'][0]['title'] + ' was published in ' +
 oNovelist['novels'][0]['year'] + '.';

var sMsg = oNovelist.firstName + ' ' + oNovelist.lastName + "'s novel " +
 oNovelist.novels[0].title + ' was published in ' +
 oNovelist.novels[0].year + '.';

// result: Joanna Russ's novel And Chaos Died was published in 1970.
```

In the first example, we're treating the structure as an associative array with bracketed keys. In the second, we're using dot-notation to retrieve the object's properties. The first syntax will always work because the keys, when strings, are quoted. We got away with using dot-notation in the second example because none of these keys contained characters such as hyphens, periods, and other characters that are legal key values but would throw JavaScript a curve:

```
var sMsg = oNovelist['first-name'];   // this works
var sMsg = oNovelist.first-name;      // oh no! JavaScript tries to subtract
```

Cross-Reference

For more on this point, see the section "Simulating a Hash Table" in Chapter 18, "The Array Object." ■

Data types

Six types of data can occur as a JSON value:

- String (a collection of zero or more Unicode characters, wrapped in double quotes, using backslash escapes)
- Number (integer or real; no octal and hexadecimal formats)

- Object (a collection of key:value pairs, comma-separated and enclosed in curly braces)
- Array (an ordered sequence of values, comma-separated and enclosed in square brackets)
- Boolean (`true` or `false`)
- `null`

Whitespace can be inserted between any pair of tokens.

Sending and Receiving JSON Data

Because JSON grammar uses JavaScript's normal object and array syntax, we don't need any add-ons to the language in order to be able to build and read JSON data structures within a single script. It's when we need to share these structures between scripts that complications arise.

In order to read, write, send, and receive a JSON data object, we need to convert it to and from a string. The standard way of doing this is to read and write exactly the same syntax we'd use in JavaScript:

```
{"firstName":"Joanna","lastName":"Russ","novels":[{"title":"And Choas
Died","year":"1970"},{"title":"The Female Man","year":"1975"}]}
```

This string can then be imported into any of the programming languages that work with JSON.

Performing this conversion between object and string in JavaScript is simple enough. There are functions at `http://json.org` that we're encouraged to use for older browsers so that we don't have to reinvent the wheel.

Because the JSON data is stored in a string exactly as it is in JavaScript source code, on first glance it might seem that the most expedient way to convert it from a string back to an object is by using the JavaScript method `eval()`:

```
var sStringJSON = readJSONDataFromWhateverSource();

eval("var oJSON = " + sStringJSON);
// or:
var oJSON = eval('(' + sStringJSON + ')');
```

Now `oJSON.firstName` will yield 'Joanna' for the example above. (In the second use of `eval()`, note the necessary inclusion of parentheses around the JSON string to satisfy the JavaScript interpreter.)

However, we can't over-emphasize that `eval()` opens up a doorway for malicious exploits in JavaScript and should be avoided on any public page. A proper JSON parser will walk through the data string character by character to build the JSON object rather than yielding to the temptation to use `eval()`.

JSON goes native

The JSON object was made part of the language with the ECMAScript Fifth Edition standard, published in December 2009. Mozilla implemented this in JavaScript 1.8.1, in the Gecko layout engine version 1.9.1 that drives Firefox 3.5, Thunderbird 3, and SeaMonkey 2. Other browser development teams are sure to follow their lead.

The JSON object has two methods, `parse()` and `stringify()`. The `toJSON()` method is also added to the Date object.

JSON Object

Properties	Methods
	`parse()`
	`stringify()`

Methods

`JSON.parse(`*`string [, translator]`*`)`

Returns: JSON object reference

Compatibility: Moz1.9.1+, Firefox3.5+

Use the `JSON.parse()` method to convert a JSON string to a JSON object.

```
object = JSON.parse(string, translator)
```

The `string` parameter is the "stringified" JSON to be converted to an object.

Related Item: `JSON.stringify()` method

`JSON.stringify(`*`object [, replacer [, space]]`*`)`

Returns: JSON string

Compatibility: Moz1.9.1+, Firefox3.5+

`JSON.stringify()` converts a JSON object to a JSON string.

```
string = JSON.stringify(object, replacer, space)
```

The `object` parameter is the JSON object to be converted to a string.

`replacer` is an optional parameter that is either a function that alters the behavior of the stringification process or an array of String and Number objects that serve as a whitelist for selecting the properties of the object to be stringified. If this value is null or not provided, all properties of the object are included in the resulting JSON string.

`space` is a String or Number object that's used to insert white space into the output JSON string for readability purposes. If this is a Number, it indicates the number of space characters to use as white space; this number is capped at 10 if it's larger than that. Values less than 1 indicate that no space should be used. If this is a String, the string (or the first 10 characters of the string, if it's longer than that) is used as white space. If this parameter is not provided (or is null), no white space is used.

Related Item: `JSON.parse()` method

Security Concerns

Some concern has been expressed about the vulnerability JSON presents in web security. We feel that these issues can be dismissed with sufficiently careful use of the technology.

Using `eval()` to convert a JSON string to an object (or for any other purpose on a public page) is an easy pitfall to avoid. If a method (function) is embedded in serialized JSON and `eval()` is used to convert it, JavaScript code can be executed without the permission of the page author's script. The obvious solution is to use a non-`eval()` parsing algorithm, such as that published by Douglas Crockford, on older browsers and the new JSON object method `parse()` on newer browsers.

The DOM method `XMLHttpRequest()` is commonly used to exchange information between server and client. By default it permits exchanges only with the server from which the current page has originated. However, by injecting a `script` tag that links to an off-site JavaScript file, this protection can be circumvented. The solution here is to be vigilant when it comes to allowing JavaScript from third parties to execute on your page.

CHAPTER 20

E4X — Native XML Processing

IN THIS CHAPTER

Using the XML object

Adding elements and attributes

Selecting records

Serializing XML objects to text

With the rise in popularity of Ajax (Asynchronous JavaScript and XML) connectivity in recent years, it's become commonplace for web developers who might otherwise never stray beyond the bounds of HTML to work with XML (Extensible Markup Language). In fact, XML has been considered so fundamental to everyday web development that the ECMA has incorporated it into the very syntactical fabric of JavaScript. We can now write unquoted XML markup right into our JavaScript statements — as permitted by the most recent browsers.

This new feature of JavaScript syntax places XML uniquely on both sides of a major divide. Every other aspect of scripting is either part of the core JavaScript language or part of the DOM (Document Object Model). XML is now a member of both camps.

We discuss techniques for transmitting XML between client and server in Chapter 39, "Ajax, E4X, and XML" (on the CD).

XML

Briefly, XML is a markup language designed to contain and transmit textual data. It consists of nested elements marked up with three types of tag — matching begin- and end-tags

```
<hobby>music</hobby>
```

and empty-element tags

```
<breathe/>
```

Elements can contain attributes, which are name/value pairs that reside within the opening or empty tag:

```
<fax location="home" call-first="true">123-456-7890</fax>;
```

Unlike HTML and XHTML, in which element and attribute name choices are constrained by the Document Type Declaration or XMLSchema, XML element and attribute names are completely arbitrary and defined by the author of the data to suit the current purpose.

For a complete formal description of XML, see the W3C specification at `http://w3.org/TR/REC-xml/`.

ECMAScript for XML (E4X)

Prior to E4X, the only way to access XML documents with JavaScript was through the DOM at the object level. With the advent of E4X, XML is treated as a primitive, at the same level as strings, numbers, and Booleans. What does this mean to us? The short story is that XML access is now simpler for us as web developers, and faster for the end user. An `XML` object created with the XML primitive is not part of the DOM; neither is it a DOM representation of XML. Because it is a primitive, you use it in ways similar to how you use other JavaScript objects.

Using the XML object

With E4X you declare an `XML` object, in much the same way that you declare a string or numeric or Boolean object, with the `XML` constructor:

```
var oCopyright = new XML();
```

You can initialize the object using text:

```
var sXMLText = "<copyright>"
                + "<date>2010</date>"
                + "<author>Danny Goodman</author>"
                + "</copyright>";

var oCopyright = new XML(sXMLText);
```

Remarkably, you can also use unquoted XML markup in an assignment statement, which implicitly creates the XML object:

```
var oCopyright = <copyright>
                    <date>2010</date>
                    <author>Danny Goodman</author>
                 </copyright>;
```

This type of syntax, in which specially constructed text can be assigned without quotation marks, may be reminiscent of JavaScript's native regular expression syntax, as described in Chapter 45, "The Regular Expression and RegExp Objects."

XML elements

The XML elements within the `XML` object are its properties. You can use both the familiar `object.property` dot-notation and the `object[property]` bracket-notation to reference elements and their values:

```
var sText = "Copyright " + oCopyright.date + " by " + oCopyright.author;
var sText = "Copyright " + oCopyright['date'] + " by " + oCopyright['author'];
```

The outermost XML element is the root of the object, so the first top-level property within our `oCopyright` object above is the `date` element:

```
alert(oCopyright.name());           // result = 'copyright'
alert(oCopyright.child(0).name());  // result = 'date'
alert(oCopyright.date);             // result = '2010'
```

Of course, as with other JavaScript objects, you won't be able to use object dot-notation successfully when an element tag name contains any characters that would confuse JavaScript. For example:

```
var oXML = <author>
              <first-name>Danny</first-name>
           </author>;

var sText = oXML['first-name'];   // result: Danny
var sText = oXML.first-name;      // result: JavaScript stops cold!
```

In the preceding example, JavaScript attempts to subtract the value of a variable called `name` from the value of the XML element `oXML.first`. If either one doesn't exist or if they do exist but don't both have numerical values that can be subtracted, JavaScript fails. The moral of the story: if you want to use dot notation and you are guaranteed to have complete control over the elements' tag names, you can restrict their character set to alphanumerics and underscores. If you're working with data coming in from a source that you might not always control, use bracket-quote notation, which will always succeed.

Adding elements

The `appendChild()` method of the `XML` object works similarly to the DOM method of the same name, inserting a child element into the referent:

```
var oBook = <book/>;
var oAuthor = <author/>;
oBook.appendChild(oAuthor);

result: <book>
           <author/>
        </book>
```

Elements can also be appended to an XML element using the same concatenation syntax that we typically use with strings:

```
oCopyright += <addendum>All rights reserved.</addendum>;
```

This results in:

```
<copyright>
   <date>2010</date>
   <author>Danny Goodman</author>
</copyright>;
<addendum>All rights reserved.<addendum>
```

In order to insert the new element inside the `copyright` element, we need to write:

```
oCopyright.author += <addendum>All rights reserved.</addendum>;
```

resulting in:

```
<copyright>
   <date>2010</date>
   <author>Danny Goodman</author>
   <addendum>All rights reserved.<addendum>
</copyright>
```

Embedded JavaScript expressions

E4X becomes really exciting when you want the `XML` object to dynamically interact with JavaScript expressions. You do this with curly braces:

```
var oDate = new Date();

var oCopyright = <copyright>
                    <date>{oDate.getFullYear()}</date>
                    <author>Danny Goodman</author>
                 </copyright>;
```

Whatever is inside the curly braces is evaluated as a JavaScript expression and its result plugged into the XML stream. In the year 2020, the preceding example will resolve to:

```
<copyright>
   <date>2020</date>
   <author>Danny Goodman</author>
</copyright>;
```

XML element attributes

Just as in XML documents, the elements in your `XML` objects can have attributes. Those attribute values can be set dynamically with curly brace notation as well. You can extract the value of an element's attribute by using dot notation with the @ operator in front of the attribute name, as we do with the `location` attribute in this example:

```
var oPhonebook = <phonebook>
                    <entry>
                       <name>Janis Joplin</name>
                       <phone location="home">123-456-7890</phone>
                    </entry>
                 </phonebook>;

var sText = oPhonebook.entry.name + "'s "
            + oPhonebook.entry.phone.@location + " phone is "
            + oPhonebook.entry.phone + ".";
// or:
var sText = oPhonebook['entry']['name'] + "'s "
            + oPhonebook['entry']['phone']['@type'] + " phone is "
            + oPhonebook['entry']['phone'] + ".";

// result == Janis Joplin's home phone is 123-456-7890.
```

You can also use the @ notation to create and modify attribute values:

```
oPhonebook.entry.phone.@location = "work";
```

The XMLList object

Most XML documents contain repeating sets of elements. You can create such sets in your XML object simply by repeating a tag name for elements with the same parent:

```
var oBook = <book>
               <title>The JavaScript Bible 7th Edition</title>
               <author>Danny Goodman</author>
               <coauthor>Michael Morrison</coauthor>
               <coauthor>Paul Novitski</coauthor>
               <coauthor>Cynthia Gustaff Rayl</coauthor>
            </book>;
```

When you point to the repeating set, you get back an XMLList object. It can be processed almost the same as you would an array. There are two primary differences: length() is a method and not a property, and therefore requires the parentheses (); and other Array object methods are not supported by XMLList.

```
var sText = "The number of co-authors is " + oBook.coauthor.length() + ".";
```

In our current example XML, oBook.coauthor comprises a list within the overall data structure because there is more than one sibling element with the same tag name.

```
// extract the XMLList of coauthor elements
var oCoauthors = oBook.coauthor;

var sText = oBook.title + ' was written by ' + oBook.author + ' with ';

// loop through co-authors
var sConj = '';
var iCoauthors = oCoauthors.length();
var sLastAuthor = oCoauthors[iCoauthors-1];

for (var i=0; i < iCoauthors; i++)
{
      // comma before item if more than two items
      if (i > 0 && iCoauthors > 2)
      {
         sConj = ', ';
      }
      // 'and' before item if last in a series
      if (i == iCoauthors-1 && iCoauthors > 1)
      {
         sConj += ' and ';
      }

   // add item to list
   sText += sConj + oCoauthors[i];
}
```

```
sText += '.';

// result == The JavaScript Bible 7th Edition was written by Danny Goodman
             with Michael Morrison, Paul Novitski, and Cynthia Gustaff Rayl.
```

The asterisk (*) can be used to represent all items in a collection. Using the preceding XML:

```
var iCount = oBook.*.length();
```

The result is 5 — the root parent has a `title`, an `author`, and three `coauthor` elements.

Adding list items

To add a new item to an `XMLList`, use the same concatenation syntax as mentioned above and name the list by its repeating element:

```
oBook.coauthor += <coauthor>John Lennon</coauthor>;
```

resulting in:

```
<book>
   <title>The JavaScript Bible 7th Edition</title>
   <author>Danny Goodman</author>
   <coauthor>Michael Morrison</coauthor>
   <coauthor>Paul Novitski</coauthor>
   <coauthor>Cynthia Gustaff Rayl</coauthor>
   <coauthor>John Lennon</coauthor>
</book>
```

Note

A cautionary note: if you extract an `XMLList` **object from an** `XML` **object as we did above:**

```
// extract the XMLList of coauthor elements
var oCoauthors = oBook.c  oauthor;
```

the list is a static copy of the XML elements with no dynamic linkage. Any subsequent change to either the `XML` **object or the** `XMLList` **object will not be reflected in the other. In this example, adding a new** `coauthor` **element to the** `oCoauthors` **list does not modify the original** `XML` **object.** ■

Selecting list items

The power of E4X really shines in its ability to select `XMLList` items based on attributes and values. Consider the following example:

```
var oPhonebook = <phonebook>
                    <entry>
                       <name>Janis Joplin</name>
                       <phone location="home">123-456-7890</phone>
                       <phone location="work">234-567-8901</phone>
                       <phone location="cell">345-678-9012</phone>
                    </entry>
                    <entry>
```

```
        <name>John Lennon</name>
        <phone location="home">987-654-3210</phone>
        <phone location="work">876-543-2109</phone>
      </entry>
    </phonebook>;
```

We've seen that we can select a list of all elements of a matching name quite easily:

```
// extract a list of all the phone elements
var oPhones = oPhonebook.entry.phone;

result:
<phone location="home">123-456-7890</phone>
<phone location="work">234-567-8901</phone>
<phone location="cell">345-678-9012</phone>
<phone location="home">987-654-3210</phone>
<phone location="work">876-543-2109</phone>
```

Note that this finds the phone elements in more than one `entry` record. The selection statement essentially says, "Find all the `phone` elements whose parent is a root `entry` element." If we wanted to limit the search to a single `entry` element, we need only specify its index:

```
var oPhones = oPhonebook.entry[0].phone;
```

Similarly, we can select elements by attribute value:

```
var oWorkPhones = oPhonebook.entry.phone.(@location == 'work');

result:
<phone location="work">234-567-8901</phone>
<phone location="work">876-543-2109</phone>
```

This narrows the selection to just those phone elements that have a type attribute of "work" — when the expression in parentheses evaluates to `true`. Note that we're using the double equal sign == of an equality comparison, not the single = of a value assignment!

One of the handy aspects of this syntax is being able to extract the value of one element after searching for its sibling:

```
var oPhone = oPhonebook.entry.(name == 'Janis Joplin').phone.
  (@location == 'home');

result:
<phone location="home">123-456-7890</phone>
```

The selector says, "Get me the home phone number of the entry with the name 'Janis Joplin.'" The statement locates an `entry` with a child element name that has the value '`Janis Joplin`' but then returns a `phone` element that is the sibling of the `name` element. Is that cool or what? Of course, like so many dead rock stars, Janis currently has an unlisted number, but we can always dream.

XML selector expressions can contain JavaScript functions, and without having to use curly brace syntax:

```
function checkExchange(sExchange, sPhone)
{
```

```
      sExchange = '-' + sExchange + '-';
      return (sPhone.indexOf(sExchange) > 0);
   }
   var sPhone = oPhonebook.entry.(checkExchange('543', phone.
     (@location=='work'))).name;
```

This returns "John Lennon" since we've selected the entry in which the `checkExchange()` function returns true.

Serializing XML objects

XML can be a handy format for keeping track of information within a script, but its primary use is communicating structured data between programs. To send an XML structure to the server, we translate the JavaScript object into a text string. The `XML` object has two interchangeable methods for doing this — `toXMLString()` and `toString()`.These methods can operate on any subset of the object as well as the whole thing at once:

```
var sXMLText = oPhonebook.toXMLString();
var sXMLText = oPhonebook.entry.(name == 'John Lennon').toString();
```

Embedding E4X in HTML

Although you can use the standard MIME type with E4X

```
<script type="text/javascript">
```

you might end up with inexplicable syntax errors. This usually occurs for one of two reasons: you are using HTML comments to hide script from older browsers; or you are putting your scripts into XML CDATA sections. If either of these is the case, then you can add the E4X argument to the standard MIME type:

```
<script type="text/javascript;e4x=1">
```

Methods

`child()`

Returns: XML object

Compatibility: WinIE5-, MacIE-, NN-, FF3.5+, Safari-, Opera-, Chrome-

The `child()` method returns an XML element that is an immediate descendant of the referent:

```
var oPhonebook = <phonebook>
                    <person>
                       <name>Janis Joplin</name>
                       <phone location="home">123-456-7890</phone>
                    </person>
                 </phonebook>;

alert(oPhonebook.person.child(1));        // result = '123-456-7890'
```

Remember that `child()` is a method, even though we use it much as we would an array, so use parentheses around the index, not brackets. Like an array, the `child()` collection is a zero-based list, so `child(1)` finds the second child element. Unlike an array, we cannot use `forEach` syntax.

Related Item: `childNodes()` DOM property

copy()

Returns: XML object

Compatibility: WinIE5-, MacIE-, NN-, FF3.5+, Safari-, Opera-, Chrome-

The `copy()` method returns a deep copy of the selected portion of an `XML` object. For example:

```
var oPhonebook = <phonebook>
                    <person>
                       <name>Janis Joplin</name>
                       <phone location="home">123-456-7890</phone>
                    </person>
                 </phonebook>;

var oPerson = oPhonebook.person.copy();
```

The result of this operation is the following `XML` object:

```
<person>
   <name>Janis Joplin</name>
   <phone location="home">123-456-7890</phone>
</person>
```

Note that this can also be accomplished using a simple assignment statement:

```
var oPerson = oPhonebook.person;
```

name()

Returns: String

Compatibility: WinIE5-, MacIE-, NN-, FF3.5+, Safari-, Opera-, Chrome-

The `name()` method returns a string that is the XML element's tag name:

```
var oPhonebook = <phonebook>
                    <person>
                       <name>Janis Joplin</name>
                       <phone location="home">123-456-7890</phone>
                    </person>
                 </phonebook>;

alert(oPhonebook.child(0).name());          // result = 'person'
alert(oPhonebook.person.child(1).name());   // result = 'phone'
alert(oPhonebook.person.child(1));          // result = '123-456-7890'
```

Remember that `child()` is a method, even though we use it much as we would an array, so use parentheses around the index, not brackets. Like an array, the `child()` collection is a zero-based list, so `child(1)` finds the second child element.

Related Item: `childNodes()` DOM property

toString(), toXMLString()

Returns: String

Compatibility: WinIE5-, MacIE-, NN-, FF1.5+, Safari-, Opera-, Chrome-

The `toString()` and `toXMLString()` methods return a string that is the concatenated text of all the text nodes of the XML object.

Related Item: *string*.toString()

CHAPTER

21

Control Structures and Exception Handling

IN THIS CHAPTER

Branching script execution down multiple paths

Looping through ordered collections of data

Applying exception handling techniques

You get up in the morning, go about your day's business, and then end the day by walking the dog, changing into comfy footwear, and relaxing. That's not much different from what a program does from the time it starts to the time it ends. But along the way, both you and a program take lots of tiny steps, not all of which advance the processing in a straight line. At times, you have to control what's going on by making a decision or repeating tasks until the whole job is finished. Control structures are the facilities that make these tasks possible in JavaScript.

Control structures in JavaScript follow along the same lines as they do in many programming languages. Basic decision-making and looping constructions satisfy the needs of just about all programming tasks.

Another vital program control mechanism — error (or exception) handling — is formally addressed in the ECMA-262 language standard. The concept of exception handling was added to the JavaScript version introduced in IE5.5 and NN6, but it is well known to programmers in many other environments. Adopting exception-handling techniques in your code can greatly enhance recovery from processing errors beyond your control, such as those caused by errant user input or network glitches.

If and If. . .Else Decisions

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

JavaScript programs frequently have to make decisions based on the current values of variables or object properties. Such decisions can have only two possible outcomes at a time. The factor that determines the path that the program takes at these decision points is if a statement evaluates to true or false. For example, when you come back from walking the dog at night, the statement under test is something such as, "Is my comfy footwear in the living room?" If that statement is false, you look for your comfy footwear; if that statement is true, you put on your comfy footwear and relax.

Simple decisions

JavaScript syntax for this kind of simple decision always begins with the keyword `if`, followed by the condition to test, and then the statements that execute if the condition yields a true result. JavaScript uses no "then" keyword (as some other languages do); the keyword is implied by the way parentheses and braces surround the various components of this construction. The formal syntax is:

```
if (condition)
{
   statementsIfTrue
}
```

This construction means that if the condition is true, program execution takes a detour to execute statements inside the braces. No matter what happens, the program continues executing statements beyond the closing brace (`}`). If a comfy footwear search were part of the scripting language, the code would look like this:

```
if (comfyFootwearInLivingRoom == false)
{
   look for them
}
```

If you're not used to C/C++, the double equals sign may have caught your eye. You learn more about this type of operator in the next chapter, but for now, know that this operator compares the equality of items on either side of it. In other words, the `condition` statement of an `if` construction must always yield a Boolean (`true` or `false`) value. Some object properties, you may recall, are Booleans, so you can stick a reference to that property into the `condition` statement by itself. Otherwise, the `condition` statement consists of two values separated by a comparison operator, such as == (equals) or `!=` (does not equal).

Next, look at some real JavaScript. The following function receives a text input object:

```
function notTooHigh(oInput)
{
      if (parseInt(oInput.value) > 100)
      {
         alert("Sorry, the value you entered is too high. Try again.");
         return false;
      }
   return true;
}
```

The condition (in parentheses) tests the contents of the field against a hard-wired value of `100`. If the entered value is larger than that, the function alerts you and returns a `false` value to the calling statement elsewhere in the script. But if the value is less than `100`, all intervening code is skipped and the function returns `true`.

About (*condition*) expressions

A lot of condition testing for control structures compares a value against some very specific condition, such as a string being empty or a value being `null`. You can use a couple of shortcuts to take care of many circumstances. Table 21-1 details the values that evaluate to `true` or `false` (or equivalent) to satisfy a control structure's *condition* expression.

TABLE 21-1

Condition Value Equivalents

True	False
Nonempty string	Empty string
Nonzero number	0
Nonnull value	`null`
Object exists	Object doesn't exist
Property is defined	Undefined property

Instead of having to spell out an equivalency expression for a condition involving these kinds of values, you can simply supply the value to be tested. For example, if a variable named `myVal` is capable of reaching an `if` construction with a value of `null`, an empty string, or a string value for further processing, you can use the following shortcut:

```
if (myVal)
{
   // do processing on myVal
}
```

All `null` or empty string conditions evaluate to `false`, so that only the cases of `myVal` being a processable value get inside the `if` construction. This mechanism is the same that you have seen elsewhere in this book to employ object detection for browser branching. For example, the code nested inside the following code segment executes only if the `document` object has an `images` array property:

```
if (document.images)
{
   // do processing on image objects
}
```

Complex decisions

The simple type of `if` construction described earlier is fine when the decision is to take a small detour before returning to the main path. But not all decisions — in programming or in life — are like that. To present two alternate paths in a JavaScript decision, you can add a component to the construction. The syntax is

```
if (condition)
{
   // statementsIfTrue
}
else
{
   // statementsIfFalse
}
```

By appending the else keyword, you give the if construction a path to follow in case the condition evaluates to false. The statementsIfTrue and statementsIfFalse do not have to be balanced in any way: One statement can be one line of code, the other 100 lines. But when either one of those branches completes, execution continues after the last closing brace. To demonstrate how this construction can come in handy, the following example is a script fragment that assigns the number of days in February based on whether or not the year (the Date object is explained in Chapter 17) is a leap year (using modulo arithmetic, explained in Chapter 22, to determine if the year is evenly divisible by four, and setting aside all other leap year calculation details for the moment):

```
var howMany = 0;
var currentTime = new Date();
var theYear = currentTime.getFullYear();
   if (theYear % 4 == 0)
   {
      howMany = 29;
   }
   else
   {
      howMany = 28;
   }
```

Here is a case where execution has to follow only one of two possible paths to assign the number of days to the howMany variable. Had the else portion not been used, as in

```
var howMany = 0;
var currentTime = new Date();
var theYear = currentTime.getFullYear();
   if (theYear % 4 == 0)
   {
       howMany = 29;
   }
howMany = 28;
```

then the variable would always be set to 28, occasionally after momentarily being set to 29. The else construction is essential in this case. However, by initializing your variable to 28, it is possible to achieve the correct end without the else portion, as in

```
var howMany = 28;
var currentTime = new Date();
var theYear = currentTime.getFullYear();
   if (theYear % 4 == 0)
   {
       howMany = 29;
   }
```

Nesting if. . .else statements

Designing a complex decision process requires painstaking attention to the logic of the decisions your script must process and the statements that must execute for any given set of conditions. The need for repetitive logic disappeared with the advent of switch construction in version 4 browsers (described later in this chapter), but there may still be times when you must fashion complex decision behavior

out of a series of nested `if. . .else` statements. Without a JavaScript-aware text editor to help keep everything properly indented and properly terminated (with closing braces), you have to monitor the authoring process very carefully. Moreover, the error messages that JavaScript provides when a mistake occurs (see Chapter 48, “Debugging Scripts,” on the CD-ROM) may not point directly to the problem line, but only to the region of difficulty.

To demonstrate a nested set of `if. . .else` constructions, Listing 21-1 presents a simple user interface to a complex problem. A single text object asks the user to enter one of three letters — A, B, or C. The script behind that field processes a different message for each of the following conditions:

- The user enters no value.
- The user enters A.
- The user enters B.
- The user enters C.
- The user enters something entirely different.

Note

The function to assign event handlers throughout the code in this chapter and much of the book is `addEvent()`, a cross-browser event handler explained in detail in Chapter 32: See “A cross-browser event binding solution.” ■

What’s with the Formatting?

Indentation of the `if` construction, and the further indentation of the statements executed on a `true` condition, are not required by JavaScript. What you see here, however, is a convention that most JavaScript scripters follow. As you write the code in your text editor, you can use the Tab key to establish each level of indentation; some developers prefer using a setting in their editor that converts tabs to spaces, which guarantees that indentations are consistent across different editors. The browser ignores these tab characters (and/or spaces) when loading your scripts.

There are many styles of indenting. The style we use most often in this book is known as Allman — in which opening and closing braces occupy their own lines — while many programmers prefer 1TBS (The One True Brace Style), in which the opening brace is on the same line as the control statement.

LISTING 21-1

Nested if. . .else Constructions

<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Nested if...else</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
```

continued

LISTING 21-1 *(continued)*

```
      <script type="text/javascript" src="jsb-21-01.js"></script>
   </head>
   <body>
      <h1>Nested if...else</h1>
      <form id="theForm" action="validate.php" method="get">
         <fieldset>
            <label for="theText">Please enter A, B, or C: </label>
            <input id="theText" type="text">
            <input type="submit">
         </fieldset>
      </form>
   </body>
</html>
```

JavaScript: jsb-21-01.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // add an event to the form
   addEvent(document.getElementById('theForm'), 'submit',
     suppressFormSubmission);

   // add an event to the input box
   addEvent(document.getElementById('theText'), 'change', testLetter);
}

function suppressFormSubmission(evt)
{
      // consolidate event handling
      if (!evt) evt = window.event;

   // cancel default behavior
      // W3C DOM method (hide from IE)
      if (evt.preventDefault) evt.preventDefault();

   // IE method
   return false;
}

function testLetter()
{
   // assign to shorter variable name
   var inpVal = this.value;

      if (inpVal != "")
      {  // if entry is not empty then dive in...
```

```
      if (inpVal == "A")
      {  // Is it an "A"?
         alert("Thanks for the A.");
      }
      else if (inpVal == "B")
      {  // No.  Is it a "B"?
         alert("Thanks for the B.");
      }
      else if (inpVal == "C")
      {  // No.  Is it a "C"?
         alert("Thanks for the C.");
      }
      else
      { // Nope.  None of the above
         alert("Sorry, wrong character or case.");
      }
   }
   else
   {   // value was empty, so skipped all other stuff above
      alert("You did not enter anything.");
   }
}
```

Each condition executes only the statements that apply to that particular condition, even if it takes several queries to find out what the entry is. You do not need to break out of the nested construction, because when a `true` response is found, the relevant statement executes, and no other statements occur in the execution path to run.

You might have noticed the `action` on the `form` element identifies a PHP script called `validate.php`. In Chapter 7, "Scripts and HTML Documents," we talked about the advisability of always specifying a server-side program in case the user has turned off JavaScript.

Conditional Expressions

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

While we're showing you decision-making constructions in JavaScript, now is a good time to introduce a special type of expression that you can use in place of an `if...else` control structure for a common type of decision — the instance where you want to assign one of two values to a variable, depending on the outcome of some condition. The formal definition for the conditional expression is as follows:

```
variable = (condition) ? val1 : val2;
```

This expression means that if the Boolean result of the `condition` statement is `true`, JavaScript assigns `val1` to the variable; otherwise, it assigns `val2` to the variable. Like other instances of conditional expressions, this one must also be written inside parentheses. The question mark is key here, as is the colon separating the two possible values.

A conditional expression, though not particularly intuitive or easy to read inside code, is very compact. Compare an `if...else` version of an assignment decision that follows

```
var collectorStatus;
   if (CDCount > 500)
   {
      collectorStatus = "fanatic";
   }
   else
   {
      collectorStatus = "normal";
   }
```

with the conditional expression version:

```
var collectorStatus = (CDCount > 500) ? "fanatic" : "normal";
```

The latter saves a few code lines, although the internal processing is the same as that of an `if...else` construction. Of course, if your decision path contains more statements than just one setting the value of a variable, the `if...else` or `switch` construction is preferable. This shortcut, however, is a handy one to remember if you need to perform binary actions, such as setting a true-or-false flag in a script.

The switch Statement

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

In some circumstances, a binary — true or false — decision path is not enough to handle the processing in your script. An `object` property or `variable` value may contain any one of several values, and a separate execution path is required for each one. The most obvious way to establish such a decision path is with a series of `if...else` constructions. However, in addition to quickly getting unwieldy with nested code, the more conditions you must test, the less efficient the processing is, because each condition must be tested. The end result is a sequence of clauses and braces that can get very confusing.

Starting in version 4 browsers, a control structure in use by many languages was introduced to JavaScript. The implementation is similar to that of PHP, Java, and C/C++, which use the `switch` and `case` keywords. The basic premise is that you can create any number of execution paths based on the value of some expression. At the beginning of the structure, you identify what that expression is and then, for each execution path, assign a label matching a particular value.

The formal syntax for the `switch` statement is as follows:

```
switch (expression)
{
   case label1:
      [statements]
      [break;]
   case label2:
      [statements]
      [break;]
   ...
```

```
    [default:
       statements]
}
```

For example:

```
switch (TimeOfDay)
{
   case 'morning':
      meal = 'breakfast';
      break;

   case 'midday':
      meal = 'lunch';
      break;

   case 'afternoon':
   case 'evening':
      meal = 'dinner';
      break;

   default:
      meal = 'fast';
}
```

The `expression` parameter of the `switch` statement can evaluate to any string or number value. Labels are surrounded by quotes when the labels represent string values of the expression. Notice that the `break` statements are optional. A `break` statement forces the switch expression to bypass all other checks of succeeding labels against the expression value. It's important to understand that without a `break` statement at the end of each `case`, every line of code in the `switch` expression will get executed. However, since Boolean operators are not allowed (each label must be for one and only one value), you can use careful placement of the `break` statement. (In the preceding example, if the time of day is either afternoon or evening, the meal is dinner.) Another option is the `default` statement, which provides a catchall execution path when the expression value does not match any of the `case` statement labels. If you'd rather not have any execution take place with a non-matching expression value, omit the default part of the construction.

To demonstrate the syntax of a working `switch` statement, Listing 21-2 provides the skeleton of a larger application of this control structure. The page contains two separate arrays of different product categories. Each product has its name and price stored in its respective array. A `select` list displays the product names. After a user chooses a product, the script looks up the product name in the appropriate array and displays the price.

The trick behind this application is the values assigned to each product in the select list. While the displayed text is the product name, the `value` attribute of each `<option>` tag is the array category for the product. That value is the expression used to decide which branch to follow. Notice, too, that we assign a label to the entire switch construction. The purpose of that is to let the deeply nested repeat loops for each case completely bail out of the switch construction (via a labeled `break` statement) whenever a match is made. You can extend this example with any number of product category arrays with additional `case` statements to match.

               <option value="ICs">Septium Pro 1.0GHz</option>
               <option value="ICs">Octium BFD 750MHz</option>
               <option value="snacks">Rays Potato Chips</option>
               <option value="snacks">Cheezey-ettes</option>
               <option value="snacks">Tortilla Flats</option>
               <option>Poker Chipset</option>
            </select>
            <label for="cost">  Price:</label>
            <input type="text" id="cost" size="10">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-21-02.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // add an event to the drop down list
   addEvent(document.getElementById('chips'), 'change', getPrice);
}

// build two product arrays with a custom object, simulating two database tables
```

```
function product(name, price)
{
   this.name = name;
   this.price = price;
}

var ICs = new Array();
ICs[0] = new product("Septium 900MHz", "$149");
ICs[1] = new product("Septium Pro 1.0GHz", "$249");
ICs[2] = new product("Octium BFD 750MHz", "$329");

var snacks = new Array();
snacks[0] = new product("Rays Potato Chips", "$1.79");
snacks[1] = new product("Cheezey-ettes", "$1.59");
snacks[2] = new product("Tortilla Flats", "$2.29");

// lookup in the 'table' the cost associated with the product
function getPrice()
{
   var chipName = this.options[this.selectedIndex].text;
   var chipType = this.options[this.selectedIndex].value;
   var outField = document.getElementById('cost');

   master:
   switch(chipType)
   {
      case "ICs":
         for (var i = 0; i < ICs.length; i++)
         {
            if (ICs[i].name == chipName)
            {
               outField.value = ICs[i].price;
               break master;
            }
         }
         break;
      case "snacks":
         for (var i = 0; i < snacks.length; i++)
         {
            if (snacks[i].name == chipName)
            {
               outField.value = snacks[i].price;
               break master;
            }
         }
         break;
      default:
         outField.value = "Not Found";
   }
}
```

Repeat (for) Loops

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

As you have seen in numerous examples throughout other chapters, the capability to cycle through every entry in an array or through every item of a form element is vital to many JavaScript scripts. Perhaps the most typical operation is inspecting a property of many similar items in search of a specific value, such as to determine which radio button in a group is selected. One JavaScript structure that allows for these repetitious excursions is the `for` loop, so-named after the keyword that begins the structure. Two other structures, the `while` loop and the `do-while` loop, are covered in the following sections.

The JavaScript `for` loop repeats a series of statements any number of times and includes an optional loop counter that can be used in the execution of the statements. The following is the formal syntax definition:

```
for ( [initial expression]; [condition]; [update expression])
{
   statements
}
```

The three statements inside the parentheses (parameters to the `for` statement) play a key role in the way a `for` loop executes.

An initial expression in a `for` loop is executed one time, the first time the `for` loop begins to run. The most common application of the initial expression is to assign a name and starting value to a loop counter variable. Thus, seeing a `var` statement that both declares a variable name and assigns an initial value (generally `0` or `1`) to it is not uncommon. An example is

```
var i = 0;
```

You can use any variable name, but conventional usage calls for the letter `i`, which is short for *index*. If you prefer the word `counter` or another word that reminds you of what the variable represents, that's fine, too. In any case, the important point to remember about this statement is that it executes once at the outset of the `for` loop.

The second statement is a *condition*, precisely like the `condition` statement you saw in `if` constructions earlier in this chapter. When a loop-counting variable is established in the initial expression, the `condition` statement usually defines how high the loop counter should go before the looping stops. Therefore, the most common statement here is one that compares the loop counter variable against some fixed value — is the loop counter less than the maximum allowed value? If the condition is false at the start, the body of the loop is not executed. But if the loop does execute, then when execution comes back around to the top of the loop, JavaScript reevaluates the condition to determine the current result of the expression. If the loop counter increases with each loop, eventually the counter value goes beyond the value in the `condition` statement, causing the `condition` statement to yield a Boolean value of `false`. The instant that happens, execution drops out of the `for` loop entirely.

The final statement, the *update expression*, is executed at the end of each loop execution — after all statements nested inside the `for` construction have run. Again, the loop counter variable can be a factor here. If you want the counter value to increase by one the next time through the loop (called incrementing the value), you can use the JavaScript operator that makes that happen: the ++ operator appended to the variable name. That task is the reason for the appearance of all those `i++` symbols in the `for` loops that you've already seen in this book. You're not limited to incrementing by one. You

can increment by any multiplier you want, or even drive a loop counter backward by decrementing the value (i--).

Now, take this knowledge and beef up the formal syntax definition with one that takes into account a typical loop-counting variable, i, and the common ways to use it:

```
//incrementing loop counter
for (var i = minValue; i <= maxValue; i++)
{
   // statements
}
//decrementing loop counter
for (var i = maxValue; i >= minValue; i--)
{
   // statements
}
```

In the top loop counter, the variable, i, is initialized at the outset to a value equal to that of minValue. Variable i is immediately compared against maxValue. If i is less than or equal to maxValue, processing continues into the body of the loop. At the end of the loop, the update expression executes. The value of i is incremented by 1. Therefore, if i is initialized as 0, then the first time through the loop, the i variable maintains that 0 value during the first execution of statements in the loop. The next time around, the variable has the value of 1.

As you may have noticed in the formal syntax definition, each of the parameters to the for statement is optional. For example, the statements that execute inside the loop may control the value of the loop counter based on data that gets manipulated in the process. Therefore, the update statement would probably interfere with the intended running of the loop. But we suggest that you use all three parameters until such time as you feel absolutely comfortable with their roles in the for loop. If you omit the condition statement, for instance, and you don't program a way for the loop to exit on its own, your script may end up in an infinite loop — which does your users no good.

Putting the loop counter to work

Despite its diminutive appearance, the i loop counter (or whatever name you want to give it) can be a powerful tool for working with data inside a repeat loop. For example, examine a version of the classic JavaScript function that creates an array while initializing entries to a value of 0:

```
// initialize array with n entries
function MakeArray(n)
{
   this.length = n;
   for (var i = 0; i < n; i++)
   {
      this[i] = 0;
   }
   return this;
}
```

The loop counter, i, is initialized to a value of 0 because the first element of any JavaScript array is element zero. In the condition statement, the loop continues to execute as long as the value of the counter is less than the number of entries being created (n). (For example, if n is 10, the array

is initialized with ten elements, 0–9.) After each loop, the counter increments by 1. In the nested statement that executes within the loop, you use the value of the i variable to substitute for the index value of the assignment statement:

```
this[i] = 0;
```

The first time the loop executes, the value expression evaluates to

```
this[0] = 0;
```

The next time, the expression evaluates to

```
this[1] = 0;
```

and so on, until all n entries are created and stuffed with 0.

Recall the HTML page in Listing 18-2, where a user chooses a regional office from a select list (triggering a script to look up the manager's name and sales quota for that region). Because the regional office names are stored in an array, the page could be altered so that a script populates the select element's options from the array. That way, if there is ever a change to the alignment of regional offices, there need be only one change to the array of offices, and the HTML doesn't have to be modified. As a reminder, here is the definition of the regional offices array, created while the page loads:

```
var aRegionalOffices = ["New York", "Chicago", "Houston", "Portland"];
```

Code inside the external JavaScript file can be used to dynamically generate the select list as follows:

```
for (var i = 0; i < aRegionalOffices.length; i++)
{
   oSelect.options[i] = new Option(aRegionalOffices[i]);
}

// pre-select the first option
oSelect.options[0].selected = true;
```

Notice one important point about the condition statement of the for loop: JavaScript extracts the length property from the array to be used as the loop counter boundary. From a code maintenance and stylistic point of view, this method is preferable to hard-wiring a value there. If the company added a new regional office, you would make the addition to the array "database," whereas everything else in the code would adjust automatically to those changes, including creating a longer pop-up menu in this case.

Notice, too, that the operator for the condition statement is less-than (<): The zero-based index values of arrays means that the maximum index value we can use is one less than the actual count of items in the array. This is vital information, because the index counter variable (i) is used as the index to the regionalOffices array each time through the loop to read the string for each item's entry. You also use the index of the first option (0) to add the selected attribute to the first option's definition.

The utility of the loop counter in for loops often influences the way you design data structures, such as two-dimensional arrays (see Chapter 18, "The Array Object") for use as databases. Always keep "the loop-counter mechanism" in the back of your mind when you begin writing JavaScript script that relies on collections of data that you embed in your documents.

Breaking out of a loop

Some loop constructions perform their job as soon as a certain condition is met, at which point they have no further need to continue looping through the rest of the values in the loop counter's range. A common scenario for this is the cycling of a loop through an entire array in search of a single entry that matches some criterion. That criterion test is set up as an `if` construction inside the loop. If that criterion is met, you break out of the loop and let the script continue with the more meaningful processing of succeeding statements in the main flow. To accomplish that exit from the loop, use the `break` statement. The following schematic shows how the `break` statement may appear in a `for` loop:

```
for (var i = 0; i < array.length; i++)
{
   if (array[i].property == magicValue)
   {
      // statements that act on entry array[i]
      break;
   }
}
```

The `break` statement tells JavaScript to bail out of the nearest `for` loop (in case you have nested `for` loops). Script execution then picks up immediately after the closing brace of the `for` statement. The variable value of `i` remains whatever it was at the time of the break, so that you can use that variable later in the same script to access, say, that same array entry.

A construction similar to this was used in Chapter 35, "Button Objects." There, the discussion of radio buttons demonstrates this construction, where, in Listing 35-6, you see a set of radio buttons whose `value` attributes contain screen sizes, in pixels. A function uses a `for` loop to find out which button was selected and then uses that item's index value — after the `for` loop breaks out of the loop — to alert the user. Listing 21-3 shows the relevant function.

LISTING 21-3

Breaking Out of a for Loop

JavaScript: jsb-21-03.js

```
function showMegapixels()
{
   var theForm = document.getElementById('sizesForm');
      if (theForm)
      {
         var sizeChoices = theForm.choices;
         for (var i = 0; i < sizeChoices.length; i++)
         {
            if (sizeChoices[i].checked)
            {
               break;
            }
         }
```

continued

LISTING 21-3 *(continued)*

```
         alert("That image size requires " + sizeChoices[i].value +
            " megapixels.");
      }
}
```

In this case, breaking out of the `for` loop is more than a matter of mere efficiency; the value of the loop counter (frozen at the break point) is used to summon a different property outside of the `for` loop. Starting back in version 4 browsers, the `break` statement gained additional powers in cooperation with the new `label` feature of control structures. This subject is covered later in this chapter.

Directing loop traffic with continue

One other possibility in a `for` loop is that you may want to skip execution of the nested statements for just one condition. In other words, as the loop goes merrily on its way round and round, executing statements for each value of the loop counter, one value of that loop counter may exist for which you don't want those statements to execute. To accomplish this task, the nested statements need to include an `if` construction to test for the presence of the value to skip. When that value is reached, the `continue` command tells JavaScript to immediately skip the rest of the body, execute the `update` statement, and loop back around to the top of the loop.

To illustrate this construction, take a look at an artificial example that skips over execution when the counter variable is the superstitious person's unlucky 13:

```
for (var i = 0; i <= 20; i++)
{
   if (i == 13)
   {
      continue;
   }
   // statements
}
```

In this example, the `statements` part of the loop executes for all values of `i` except `13`. The `continue` statement forces execution to jump to the `i++` part of the loop structure, incrementing the value of `i` for the next time through the loop. In the case of nested `for` loops, a `continue` statement affects the `for` loop in whose immediate scope the `if` construction falls. The `continue` statement was enhanced in version 4 browsers with the `label` feature of control structures, which is covered later in this chapter.

The while Loop

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `for` loop is not the only kind of repeat loop you can construct in JavaScript. Another statement, called a `while` statement, sets up a loop in a slightly different format. Rather than providing a mechanism for modifying a loop counter, a `while` repeat loop assumes that your script statements will reach a condition that forcibly exits the repeat loop.

The basic syntax for a `while` loop is

```
while (condition)
{
   statements
}
```

The `condition` expression is the same kind that you saw in `if` constructions and in the middle parameter of the `for` loop. You introduce this kind of loop if some condition exists in your code (evaluates to `true`) before reaching this loop. The loop then performs some action, which affects that condition repeatedly until that condition becomes `false`. At that point, the loop exits, and script execution continues with statements after the closing brace. If the statements inside the `while` loop do not somehow affect the values being tested in `condition`, your script never exits, and it becomes stuck in an infinite loop.

Many loops can be rendered with either the `for` or `while` loops. In fact, Listing 21-4 shows a `while` loop version of the `for` loop from Listing 21-3.

LISTING 21-4

A while Loop Version of Listing 21-3

JavaScript: jsb-21-04.js

```
function showMegapixels()
{
   var theForm = document.getElementById('sizesForm');
      if (theForm)
      {
         var sizeChoices = theForm.choices;
         var i = 0;
         while (i < sizeChoices.length && !sizeChoices[i].checked)
            {
               i++;
            }
         }
         alert("That image size requires " + sizeChoices[i].value +
            " megapixels.");
      }
}
```

One point you may notice is that if the condition of a `while` loop depends on the value of a loop counter, the scripter is responsible for initializing the counter prior to the `while` loop construction and managing its value within the `while` loop.

Should you need their powers, the `break` and `continue` control statements work inside `while` loops just as they do in `for` loops. But because the two loop styles treat their loop counters and conditions differently, be extra careful (do lots of testing) when applying `break` and `continue` statements to both kinds of loops.

No hard-and-fast rules exist for which type of loop construction to use in a script. Generally, use `while` loops only when the data, or object, to loop through is already part of the script before the loop. In other words, by virtue of previous statements in the script, the values for any condition or loop counting (if needed) are already initialized. But if cycling through an object's properties, or an array's entries, to extract some piece of data for use later in the script is what's needed, favor the `for` loop. The `for` loop is also generally preferred when the looping involves a simple counter from one value to another.

Another point of style, particularly with the `for` loop, is where a scripter should declare the `i` variable. Some programmers prefer to declare (or initialize, if initial values are known) all variables in the opening statements of a script or function. That is why you tend to see a lot of `var` statements in those positions in scripts. If you have only one `for` loop in a function, for example, nothing is wrong with declaring and initializing the `i` loop counter in the initial expression part of the `for` loop (as demonstrated frequently in the previous sections). But if your function utilizes multiple `for` loops that reuse the `i` counter variable (that is, the loops run completely independently of one another), then you can declare the `i` variable once at the start of the function and simply assign a new initial value to `i` in each `for` construction.

The do-while Loop

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

JavaScript brings you one more looping construction, called the `do-while` loop. The formal syntax for this construction is as follows:

```
do
{
   statements
} while (condition)
```

An important difference distinguishes the `do-while` loop from the `while` loop. In the `do-while` loop, the statements in the construction always execute at least one time before the condition can be tested; in a `while` loop, the statements may never execute if the condition tested at the outset evaluates to `false`. So, just think of the `do-while` loop as a `while` loop where the statements get executed at least once, no matter what.

Use a `do-while` loop when you know for certain that the looped statements are free to run at least one time. If the condition may not be met the first time, use the `while` loop. For many instances, the two constructions are interchangeable, although only the `while` loop is compatible with legacy browsers.

Looping through Properties (for-in)

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

JavaScript includes a variation of the `for` loop, called a `for-in` loop, which has special powers of extracting the names and values of any object property currently in the browser's memory. The syntax looks like this:

```
for (varName in object)
{
```

```
        // statements
    }
```

The `object` parameter is not the string name of an object but a reference to the object itself. JavaScript delivers an object reference if you provide the name of the object as an unquoted string, such as `window` or `document`, or via `getElementById`. Recall that although a legal name in HTML is case-insensitive, a legal name in JavaScript is case-sensitive, so remember to use the camelCase convention even in your HTML code. Using the `varName` variable, you can create a script that extracts and displays the range of properties for any given object.

Listings 21-5 shows a page containing a utility function that you can insert into your external JavaScript files during the authoring and debugging stages of designing a JavaScript-enhanced page. In the example, the current `window` object is examined, and its properties are presented in the page (note that Safari 1.0 doesn't expose `window` object properties).

LISTING 21-5

Property Inspector Function

HTML: jsb-21-05.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Property Inspector Function</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-21-05.js"></script>
      <link rel="stylesheet" href="jsb-21-05.css" type="text/css">
   </head>
   <body>
      <h1>Property Inspector Function</h1>
      <p>Here are the properties of the current window:</p>
      <ul id="propertyList"></ul>
   </body>
</html>
```

JavaScript: jsb-21-05.js

```
// initialize when the page has loaded
addEvent(window, 'load', showProps);

// display all the properties of the object
function showProps()
{
   var oOutput = document.getElementById('propertyList');
      if (oOutput)
      {
         var newElem;
         var newText;
         for (var i in window)
```

continued

LISTING 21-5 *(continued)*

```
        {
          newElem = document.createElement('li');
          newElem.className = 'objProperty';
          newText = document.createTextNode('window.' + i + ' = ' + window[i]);

          // insert the text node into the new paragraph
          newElem.appendChild(newText);

          // insert the completed paragraph into propertyList
          oOutput.appendChild(newElem);
        }
      }
}
```

Stylesheet: jsb-21-05.css

```
ul#propertyList li
{
   white-space: pre;
}
```

For debugging purposes, you can revise the function slightly to display the results in an alert dialog box or a `textarea` element. Just use the `\n` carriage return character after each property for a nicely formatted display. If the `showProps()` function looks familiar to you, it is because it closely resembles the property inspector routines of The Evaluator (see Chapter 4). In Chapter 48 (on the CD-ROM), you can see how to embed functionality of The Evaluator into a page under construction so that you can view property values while debugging your scripts.

The with Statement

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `with` statement enables you to preface any number of statements by advising JavaScript on precisely which object your scripts will be talking about, so that you don't have to use full, formal addresses to access properties or invoke methods of the same object. The formal syntax definition of the `with` statement is as follows:

```
with (object)
{
   statements
}
```

The object reference is a reference to any valid object currently in the browser's memory. An example of this appears in Chapter 16, "The Math, Number, and Boolean Objects," when the `Math` object is discussed. By embracing several `Math` statements inside a `with` construction, your scripts can call the

properties and methods without having to make the object part of every reference to those properties and methods. Here's an example:

```
with (Math)
{
   var randInt = round(random() * 100);
}
```

This example uses the `round()` and `random()` methods of the `Math` object to obtain a random integer between 0 and 100. The significance of the code is how the `with` statement allows you to forego using the full notation of `Math.round()` and `Math.random()`.

An advantage of the `with` structure is that it can make heavily object-dependent statements easier to read and understand. Consider this long version of a function that requires multiple calls to the same object (but different properties):

```
function seeColor(form)
{
   var newColor = (form.colorsList.options[form.colorsList.selectedIndex]
   .text);
   return newColor;
}
```

Using the `with` structure, you can shorten the long statement:

```
function seeColor(form)
{
   with (form.colorsList)
   {
      newColor = (options[selectedIndex].text);
   }
   return newColor;
}
```

When JavaScript encounters an otherwise unknown identifier inside a `with` statement, it tries to build a reference out of the object specified as its parameter and that unknown identifier. You cannot, however, nest `with` statements that build on one another. For instance, in the preceding example, you cannot have a `with (colorsList)` nested inside a `with (form)` statement and expect JavaScript to create a reference to options out of the two object names.

As clever as the `with` statement may seem, be aware that there are some cautions associated with its use. It introduces some inherent performance penalties in your script (because of the way the JavaScript interpreter must artificially generate references). You probably won't notice degradation with occasional use of this construction, but if it's used inside a loop that must iterate many times, processing speed will almost certainly be affected negatively. Additionally, some people feel that the `with` statement introduces ambiguity in your code.

Labeled Statements

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Crafting multiple nested loops can sometimes be difficult when the final condition your script is looking for is met deep inside the nests. The problem is that the `break` or `continue` statement by itself

has scope only to the nearest loop level. Therefore, even if you break out of the inner loop, the outer loop(s) continue to execute. If all you want to do is exit the function after the condition is met, a simple `return` statement performs the same job as some other languages' exit command. But if you also need some further processing within that function after the condition is met, you need the JavaScript facility supported in modern browsers that lets you assign labels to blocks of statements. Your `break` and `continue` statements can then alter their scope to apply to a labeled block other than the one containing the statement.

A *label* is any identifier (that is, a name starting with a letter and containing no spaces or odd punctuation other than underscores) followed by a colon preceding a logical block of executing statements, such as an `if...then` or loop construction. The formal syntax looks like the following:

```
labelID:
   statements
```

For a `break` or `continue` statement to apply itself to a labeled group, the label is added as a kind of parameter to each statement, as in

```
break labelID;
continue labelID;
```

Note

If you're arriving at JavaScript from another programming language that has a bit more structure, such as C++ or Java, the thought of labeled code may have you worried about the risks of creating code that is impossible to manage. This worry is likely rooted in the `goto` statement that is found in some languages, such as BASIC, and which is seriously frowned upon in modern structured languages. Labels in JavaScript are much more limited than the infamous `goto` statement in other languages; you can only use the `break` statement to target a label in which your code is nested. So, although we don't necessarily encourage the heavy usage of labels, you can rest easy knowing that they aren't on par with the much maligned `goto` statement. ■

To demonstrate how valuable labels can be in the right situation, Listing 21-6 contains two versions of the same nested loop construction. The goal of each version is to loop through two different index variables until both values equal the target values set outside the loop. When those targets are met, the entire nested loop construction should break off and continue processing afterward. To help you visualize the processing that goes on during the execution of the loops, the scripts output intermediate and final results to a `textarea`.

In the version without labels, only the simple `break` statement is issued when the targets are met. This breaks the inner loop at that point, but the outer loop picks up on the next iteration. By the time the entire construction has ended, a lot of wasted processing has gone on. Moreover, the values of the counting variables max themselves out, because the loops execute in their entirety several times after the targets are met.

But in the labeled version, the inner loop breaks out of the labeled outer loop as soon as the targets are met. Far fewer lines of code are executed, and the loop counting variables are equal to the targets, as desired. Experiment with Listing 21-6 by changing the `break` statements to `continue` statements. Then closely analyze the two results in the Results `textarea` to see how the two versions behave.

LISTING 21-6

Labeled Statements

{
   out.value = "Running WITHOUT labeled break\n";
   for (var i = 0; i <= range; i++)
   {
      out.value += "Outer loop #" + i + "\n";
      for (var j = 0; j <= range; j++)
      {
         out.value += "  Inner loop #" + j + "\n";
         if (i == targetA && j == targetB)
         {
            out.value += "**BREAKING OUT OF INNER LOOP**\n";
            break;
         }
      }
   }
   out.value += "After looping, i = " + i + ", j = " + j + "\n";
}

function run2()
{
   out.value = "Running WITH labeled break\n";
   outerLoop:
   for (var i = 0; i <= range; i++)
   {
      out.value += "Outer loop #" + i + "\n";
      innerLoop:
      for (var j = 0; j <= range; j++)
      {
         out.value += "  Inner loop #" + j + "\n";
         if (i == targetA && j == targetB)
         {
            out.value += "**BREAKING OUT OF OUTER LOOP**\n";
            break outerLoop;
         }
      }
   }
   out.value += "After looping, i = " + i + ", j = " + j + "\n";
}
```

Exception Handling

The subject of exception handling is relatively new to JavaScript. Formalized in Edition 3 of ECMA-262, parts of the official mechanism were implemented in IE5, with more complete implementations in IE6 and NN6, and, of course, in Mozilla, Firefox, Camino, Safari, Opera, and Chrome.

Exceptions and errors

If you've done any scripting, you are certainly aware of JavaScript errors, whether they be from syntax errors in your code, or what are known as *runtime* errors — errors that occur while scripts are processing information. Ideally, a program should be aware of when an error occurs and handle it as gracefully as possible. This self-healing can prevent lost data and help keep users from seeing ugly error messages. Chapter 27, "Window and Frame Objects," covers the `onerror` event handler and `window.onerror` property, which were early attempts at letting scripts gain a level of control over runtime errors. This event-driven mechanism works on a global level (that is, in the `window` object) and processes every error that occurs throughout the page. This event handler ends up being used primarily as a last-ditch defense against displaying any error message to the user, and is a long way from what programmers consider to be proper exception handling.

In the English language, the term "exception" can mean something out of the ordinary, or something abnormal. This definition seems quite distant from the word "error," which usually means a mistake. In the realm of programming languages, however, the two words tend to be used interchangeably, and the difference between the two depends primarily on one's point of view.

Consider, for example, a simple script whose job is to multiply numbers that the user enters into two text fields on the page. The script is supposed to display the results in a third text box. If the script contains no data entry validation, JavaScript will attempt to multiply whatever values are entered into the text boxes. If the user enters two numbers, JavaScript is smart enough to recognize that even though the `value` properties of the two input text fields are strings, the strings contain numbers that can be converted to number types for the proper multiplication. Without complaint, the product of the two numbers gets calculated and displayed into the results.

But what if the user types a letter into one of the text boxes? Again, without any entry validation in the script, JavaScript has a fixed way of responding to such a request: The result of the multiplication operation is the `NaN` (not a number) constant. If you are an untrained user, you have no idea what `NaN` means, but your experience with computers tells you that some kind of error has occurred. You may blame the computer or you may blame yourself — the accurate response may in fact be to blame the JavaScript developer!

To shift the point of view to the programmer, however, the script was designed to be run by a user who never makes a typing mistake, intentional or not. That, of course, is not very good programming practice. Users make mistakes. Therefore, anticipating user input that is not what would be expected is the programmer's job — input that is an exception to the rules your program wants to operate by. You must include some additional code that handles the exceptions gracefully so as to not confuse the user with unintelligible output, and perhaps even to help the user repair the input to get a result. This extra programming code handles the undesirable and erroneous input and makes your scripts considerably more user-friendly and robust.

As it turns out, JavaScript and the W3C Document Object Model liberally mix terms of exception and error within the vocabulary used to handle exceptions. As you see shortly, an exception creates an

error object, which contains information about the exception. It is safe to say that you can think of exceptions and errors as the same things.

The exception mechanism

Newcomers to JavaScript (or any programming environment, for that matter) may at first have a difficult time creating a mental model of how all this exception stuff runs within the context of the browser. It may be easy enough to understand how pages load and create object models, and how event handlers (or listeners, in the W3C DOM terminology) cause script functions to run. But a lot of action also seems to be going on in the background. For example, the event object that is generated automatically with each event action (see Chapter 32, "Event Objects") seems to sit "somewhere," while event handler functions run so that they can retrieve details about the event. After the functions finish their processing, the event object disappears, without even leaving behind a Cheshire Cat smile. Mysterious.

Browsers equipped for exception handling have more of this "stuff" running in the background, ready for your scripts when you need it. Because you have certainly viewed the details of at least one scripting error, you have already seen some of the exception-handling mechanism that is built into browsers. If a script error occurs, the browser creates in its memory an error object, whose properties contain details about the error. The precise details (described later in this chapter) vary from one browser brand to the next, but what you see in the error details readout is the default way the browser handles exceptions/errors. As browsers have matured, their makers have gone to great lengths to tone down the intrusion of script errors. For example, in NN4+, errors appeared in a separate JavaScript Console window (which must be invoked in NN4 by typing `javascript:` into the Location field; or opened directly via the Tools menu in NN6+ and Mozilla-based browsers, including Firefox and Camino). In IE4+ for Windows, the status bar comes into play again, as the icon at the bottom-left corner turns into an alert icon: Double-clicking the icon displays more information about the error. MacIE users can turn off scripting error alerts altogether. Safari 1.0 didn't divulge any script errors but a JavaScript console was added as of version 1.3.

True exception handling, however, goes further than just displaying error messages. It also provides a uniform way to let scripts guard against unusual occurrences. Ideally, the mechanism makes sure that *all* runtime errors get funneled through the same mechanism to help simplify the scripting of exception handling. The mechanism is also designed to be used intentionally as a way for your own code to generate errors in a uniform way so that other parts of your scripts can handle them quietly and intelligently. In other words, you can use the exception handling mechanism as a kind of "back channel" to communicate from one part of your scripts to another.

The JavaScript exception handling mechanism is built around two groups of program execution statements. The first group consists of the `try-catch-finally` statement triumvirate; the second group is the single `throw` statement.

Using try-catch-finally Constructions

The purpose of the `try-catch-finally` group of related statements is to provide a controlled environment in which script statements that may encounter runtime errors can run, such that your scripts can act upon exceptions without alarming the rest of the browser's error mechanisms. Each of the three statements precedes a block of code in the following syntax:

```
try
{
   statements to run
```

```
}

catch (errorInfo)
{
   statements to run if exception occurs in try block
}
finally
{
   statements to run whether or not an exception occurred [optional]
}
```

Each `try` block must be mated with a `catch` and/or `finally` block at the same nesting level, with no intervening statements. For example, a function can have a one-level `try-catch` construction inside it as follows:

```
function myFunc()
{
   try
   {
      // statements
   }
   catch (e)
   {
      // statements
   }
}
```

But if there were another `try` block nested one level deeper, a balancing `catch` or `finally` block would also have to be present at that deeper level:

```
function myFunc()
{
   try
   {
      // statements
      try
      {
         // statements
      }
      catch (e)
      {
         // statements
      }
   }
   catch (e)
   {
      // statements
   }
}
```

The statements inside the `try` block include statements that you believe are capable of generating a runtime error because of user input errors, the failure of some page component to load, or a similar

error. The presence of the `catch` block prevents errors from appearing in the browser's regular script error reporting system (for example, the JavaScript Console of Safari1.3+, NN6+, and Mozilla-based browsers).

An important term to know about exception handling of this type is *throw*. The convention is that when an operation or method call triggers an exception, it is said to "throw an exception." For example, if a script statement attempts to invoke a method of a string object, but that method does not exist for the object (perhaps you mistyped the method name), JavaScript throws an exception. Exceptions have names associated with them — a name that sometimes, but not always, reveals important information about the exception. In the mistyped method example just cited, the name of that exception is a `TypeError` (yet more evidence of how "exception" and "error" become intertwined).

The JavaScript language supported in modern browsers is not the only entity that can throw exceptions. The W3C DOM also defines categories of exceptions for DOM objects. For example, according to the Level 2 specification, the `appendChild()` method (see Chapter 26, "Generic HTML Element Objects") can throw (or *raise*, in the W3C terminology) one of three exceptions:

Exception Name	When Thrown
`HIERARCHY_REQUEST_ERR`	If the current node is of a type that does not allow children of the type of the `newChild` node, or if the node to append is one of this node's ancestors
`WRONG_DOCUMENT_ERR`	If `newChild` was created from a different document than the one that created the current node
`NO_MODIFICATION_ALLOWED_ERR`	If the current node is read-only

Because the `appendChild()` method is capable of throwing exceptions, a JavaScript statement that invokes this method should ideally be inside a `try` block. If an exception is thrown, then script execution immediately jumps to the `catch` or `finally` block associated with the `try` block. Execution does not come back to the `try` block.

A `catch` block has special behavior. Its format looks similar to a function in a way, because the `catch` keyword is followed by a pair of parentheses and an arbitrary variable that is assigned a reference to the error object whose properties are filled by the browser when the exception occurs. One of the properties of that error object is the name of the error. Therefore, the code inside the `catch` block can examine the name of the error and perhaps include some branching code to take care of a variety of different errors that are caught.

To see how this construction may appear in code, look at a hypothetical generic function whose job is to create a new element and append it to some other node. Both the type of element to be created and a reference to the parent node are passed as parameters. To take care of potential misuses of this function through the passage of improper parameter values, it includes extra error handling to treat all possible exceptions from the two DOM methods: `createElement()` and `appendChild()`. Such a function looks like Listing 21-7.

LISTING 21-7

A Hypothetical try-catch Routine

```
// generic appender
function attachToEnd(theNode, newTag)
{
   try
   {
      var newElem = document.createElement(newTag);
      theNode.appendChild(newElem);
   }
   catch (e)
   {
      switch (e.name)
      {
         case "INVALID_CHARACTER_ERR" :
            // statements to handle this createElement() error
            break;
         case "HIERARCHY_REQUEST_ERR" :
            // statements to handle this appendChild() error
            break;
         case "WRONG_DOCUMENT_ERR" :
            // statements to handle this appendChild() error
            break;
         case "NO_MODIFICATION_ALLOWED_ERR" :
            // statements to handle this appendChild() error
            break;
         default:
            // statements to handle any other error
      }
      return false;
   }
   return true;
}
```

The single `catch` block in Listing 21-7 executes only if one of the statements in the `try` block throws an exception. The exceptions may be not only one of the four specific ones named in the `catch` block, but also syntax or other errors that could occur inside the `try` block. That's why you have a last-ditch case to handle truly unexpected errors. Your job as scripter is to anticipate errors and provide clean ways for the exceptions to be handled, whether it be through judiciously worded alert dialog boxes or through self-repair. For example, in the case of the invalid character error for `createElement()`, your script may attempt to salvage the data passed to the `attachToEnd()` function and reinvoke the method, passing `theNode` value as-is and the repaired value originally passed to `newTag`. If your repairs were successful, the `try` block would execute without error and carry on with the user's being completely unaware that a nasty problem had been averted. And that's really the goal of exception handling — to save the day when something "unexpected" goes wrong so that the user isn't left confused or frustrated.

A `finally` block contains code that always executes after a `try` block, whether or not the `try` block succeeds without throwing an error. Unlike the `catch` block, a `finally` block does not receive an error object as a parameter, so it operates very much in the dark about what transpires inside the `try` block. If you include both `catch` and `finally` blocks after a `try` block, the execution path depends on whether an exception is thrown. If no exception is thrown, the `finally` block executes after the last statement of the `try` block runs. But if the `try` block throws an exception, program execution runs first to the `catch` block. After all processing within the `catch` block finishes, the `finally` block executes. In development environments that give programmers complete control over resources, such as memory allocation, a `finally` block may be used to delete some temporary items generated in the `try` block, whether or not an exception occurs in the `try` block. Currently, JavaScript's automatic memory management system reduces the need for that kind of maintenance, but you should be aware of the program execution possibilities of the `finally` block in the `try-catch-finally` context.

Real-life exceptions

The example shown in Listing 21-7 is a bit idealized. The listing assumes that the browser dutifully reports every W3C DOM exception precisely as defined in the formal specification. Unfortunately, even the latest browsers have yet to fully comply with the DOM when it comes to exception reporting. Most browsers implement additional error naming conventions and layers between actual DOM exceptions and what gets reported with the error object at the time of the exception.

If you think these discrepancies make cross-browser exception handling difficult, you're right. Even simple errors are reported differently among the two major browser brands (IE and Mozilla) and the W3C DOM specification. Until the browsers exhibit a greater unanimity in exception reporting, the smoothest development road will be for those scripters who have the luxury of writing for just one of the browser platforms, such as IE for Windows or Safari for Mac.

That said, however, one aspect of exception handling can still be used in all modern browsers without a hitch. You can take advantage of `try-catch` constructions to throw your own exceptions — a practice that is quite common in advanced programming environments.

Throwing Exceptions

The last exception handling keyword not yet covered — `throw` — makes it possible to utilize exception-handling facilities for your own management of processes, such as data entry validation. At any point inside a `try` block, you can manually throw an exception that gets picked up by the associated `catch` block. The details of the specific exception are up to you.

Syntax for the `throw` statement is as follows:

```
throw value;
```

The value you throw can be of any type, but good practice suggests that the value be an error object (described more fully later in this chapter). Whatever value you throw is assigned to the parameter of the `catch` block. Look at the following two examples. In the first, the value is a string message; in the second, the value is an error object.

Listing 21-8 presents one input text box for a number between 1 and 5. Clicking a button looks up a corresponding letter in an array and displays the letter in a second text box. The lookup script has two simple data validation routines to make sure the entry is a number and is in the desired range.

Error checking here is done manually by script. If either of the error conditions occurs, `throw` statements force execution to jump to the `catch` block. The `catch` block assigns the incoming `string` parameter to the variable `e`. The design here assumes that the message being passed is text for an alert dialog box. Not only does a single `catch` block take care of both error conditions (and conceivably any others to be added later), but the `catch` block runs within the same variable scope as the function, so that it can use the reference to the input text box to focus and select the input text if there is an error.

LISTING 21-8

Throwing String Exceptions

HTML: jsb-21-08.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Throwing a String Exception</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-21-08.js"></script>
   </head>
   <body>
      <h1>Throwing a String Exception</h1>
      <form id="theForm" action="validate.php" method="get">
         <p>
            <label for="visitorInput">Enter a number from 1 to 5:</label>
            <input type="text" id="visitorInput" size="5">
            <input type="button" id="getLetterButton" value="Get Letter">
            <label for="output">Matching Letter is:</label>
            <input type="text" id="output" size="5">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-21-08.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // add an event to the Get Letter button
   addEvent(document.getElementById('getLetterButton'), 'click', getLetter);
}

var letters = new Array("A","B","C","D","E");

function getLetter()
{
```

continued

LISTING 21-8 *(continued)*

```
    try
    {
       var inputField = document.getElementById('visitorInput');
       var inp = parseInt(inputField.value, 10);
       var outputField = document.getElementById('output');

          if (isNaN(inp))
          {
             throw "Entry was not a number.";
          }

          if (inp < 1 || inp > 5)
          {
             throw "Enter only 1 through 5.";
          }

       outputField.value = letters[inp - 1];
    }
    catch (e)
    {
       alert(e);
       outputField.value = "";
       inputField.focus();
       inputField.select();
    }
}
```

The flaw with Listing 21-8 is that if some other kind of exception were thrown inside the `try` block, the value passed to the `catch` block would be an error object, not a string. The alert dialog box displayed to the user would be meaningless. Therefore, it is better to be uniform in your `throw-catch` constructions and pass an error object.

Listing 21-9 is an updated version of Listing 21-8, demonstrating how to create an error object that gets sent to the `catch` block via `throw` statements. The HTML code is exactly the same as for listing 21-8, so that is not repeated here.

LISTING 21-9

Throwing an Error Object Exception

JavaScript: jsb-21-09.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // add an event to the Get Letter button
```

```
   addEvent(document.getElementById('getLetterButton'), 'click', getLetter);
}

var letters = new Array("A","B","C","D","E");

function getErrorObj(msg)
{
   var err = new Error(msg);
   return err;
}

function getLetter()
{
   try
   {
      var inputField = document.getElementById('visitorInput');
      var inp = parseInt(inputField.value, 10);
      var outputField = document.getElementById('output');

      if (isNaN(inp))
      {
         throw getErrorObj("Entry was not a number.");
      }

      if (inp < 1 || inp > 5)
      {
         throw getErrorObj("Enter only 1 through 5.");
      }

      outputField.value = letters[inp - 1];
   }
   catch (e)
   {
      alert(e.message);
      outputField.value = "";
      inputField.focus();
      inputField.select();
   }
}
```

The only difference to the `catch` block is that it now reads the `message` property of the incoming error object. This means that if some other exception is thrown inside the `try` block, the browser-generated message will be displayed in the alert dialog box.

In truth, however, the job really isn't complete. In all likelihood, if a browser-generated exception is thrown, the message in the alert dialog box won't mean much to the user. The error message will probably be some kind of syntax or type error — the kind of meaningless error message you often get from your favorite operating system. A better design is to branch the `catch` block so that while "intentional" exceptions thrown by your code are handled through the alert dialog box messages you've put there, other types are treated differently. To accomplish this, you can take over one of the other properties of the error object — `name` — so that your `catch` block treats your custom messages separately.

In Listing 21-10, the `getErrorObj()` function adds a custom value to the `name` property of the newly created error object. The name you assign can be any name, but you want to avoid exception names used by JavaScript or the DOM. Even if you don't know what all of those are, you can probably conjure up a suitably unique name for your error. Down in the `catch` block, a `switch` construction branches to treat the two classes of errors differently. In this simplified example, about the only possible problem other than the ones being trapped for explicitly in the `try` block would be some corruption to the page during downloading. Therefore, for this example, the branch for all other errors simply asks that the user reload the page and try again. The point is, however, that you can have as many classifications of custom and system errors as you want and handle them in a single `catch` block accordingly. Again, the HTML code is exactly the same as for listing 21-8, so it is not repeated here.

LISTING 21-10

A Custom Object Exception

JavaScript: jsb-21-10.js

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

function initialize()
{
   // add an event to the Get Letter button
   addEvent(document.getElementById('getLetterButton'), 'click', getLetter);
}

var letters = new Array("A","B","C","D","E");

function getErrorObj(msg)
{
   var err = new Error(msg);
   err.name = "MY_ERROR";
   return err;
}

function getLetter()
{
   try
   {
      var inputField = document.getElementById('visitorInput');
      var inp = parseInt(inputField.value, 10);
      var outputField = document.getElementById('output');

      if (isNaN(inp))
      {
         throw getErrorObj("Entry was not a number.");
      }

      if (inp < 1 || inp > 5)
      {
         throw getErrorObj("Enter only 1 through 5.");
```

```
      }

      outputField.value = letters[inp - 1];
   }
   catch (e)
   {
      switch (e.name)
      {
         case 'MY_ERROR' :
            alert(e.message);
            outputField.value = "";
            inputField.focus();
            inputField.select();
            break;

         default :
            alert('Reload the page and try again.');
      }
   }
}
```

If you want to see how the alternative branch of Listing 21-10 looks, copy the listing file from the CD-ROM to your hard disk and modify the last line of the `try` block so that one of the characters is dropped from the name of the array:

```
outputField.value = letter[inp - 1];
```

This may simulate the faulty loading of the page. If you enter one of the allowable values, the reload alert appears, rather than the actual message of the error object: letter is undefined. Your users will thank you.

All that's left now on this subject are the details of the error object.

Error Object

Properties	Methods
errorObject.prototype	errorObject.toString()
errorObject.constructor	
errorObject.description	
errorObject.filename	
errorObject.lineNumber	
errorObject.message	
errorObject.name	
errorObject.number	

Syntax

Creating an error object:

```
var myError = new Error("message");
var myError = Error("message");
```

Accessing static `Error` object property:

```
Error.property
```

Accessing error object properties and methods:

```
errorObject.property | method([parameters])
```

Compatibility: WinIE5+, MacIE−, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

An error object instance is created whenever an exception is thrown or when you invoke either of the constructor formats for creating an error object. Properties of the error object instance contain information about the nature of the error so that `catch` blocks can inspect the error and process error handling accordingly.

IE5 implemented an error object in advance of the ECMA-262 formal error object, and the IE5 version ended up having its own set of properties that are not part of the ECMA standard. Those proprietary properties are still part of IE5.5+, which includes the ECMA properties as well. NN6, on the other hand, started with the ECMA properties and adds two proprietary properties of its own. The browser uses these additional properties in its own script error reporting. The unfortunate bottom line for cross-browser developers is that no properties in common among all browsers support the error object. However, there are two common denominators (`name` and `message`) between IE5.5+ and other browsers.

As described earlier in this chapter, you are encouraged to create an error object whenever you use the `throw` statement for your own error control.

Properties

`constructor`

(See Chapter 15, "The String Object.")

`description`

Value: String Read/Write

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `description` property contains a descriptive string that provides some level of detail about the error. For errors thrown by the browser, the description is the same text that appears in the script error dialog box in IE. Although this property continues to be supported, the `message` property is preferred.

Related Item: `message` property

fileName
lineNumber

Value: String Read/Write

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera-, Chrome-

The NN6 browser uses the `fileName` and `lineNumber` properties of an error object for its own internal script error processing — these values appear as part of the error messages that are listed in the JavaScript Console. The `fileName` is the URL of the document causing the error; the `lineNumber` is the source code line number of the statement that threw the exception. These properties are exposed to JavaScript, as well, so that your error processing may use this information if it is meaningful to your application.

See the discussion of the `window.error` property in Chapter 27 for further ideas on how to use this information for bug reporting from users.

Related Item: `window.error` property

message

Value: String Read/Write

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `message` property contains a descriptive string that provides some level of detail about the error. For errors thrown by the browser, the message is the same text that appears in the script error dialog box in IE and the JavaScript Console in Mozilla. By and large, these messages are more meaningful to scripters than to users. Unfortunately, there are no standards for the wording of a message for a given error. Therefore, it is hazardous at best to use the message content in a `catch` block as a means of branching to handle particular kinds of errors. You may get by with this approach if you are developing for a single browser platform, but you have no assurances that the text of a message for a particular exception may not change in future browser versions.

Custom messages for errors that your code explicitly throws can be in user-friendly language if you intend to display such messages to users. See Listings 21-8 through 21-10 for examples of this usage.

Related Item: `description` property

name

Value: String Read/Write

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `name` property generally contains a word that identifies the type of error that has been thrown. The most general kind of error (and the one that is created via the `new Error()` constructor) has a name `Error`. But JavaScript errors can be of several varieties: `EvalError`, `RangeError`, `ReferenceError`, `SyntaxError`, `TypeError`, and `URIError`. Some of these error types are not necessarily intended for exposure to scripters (they're used primarily in the inner workings of the JavaScript engine), but some browsers do expose them. Unfortunately, there are some discrepancies as to the specific name supplied to this property for script errors.

When JavaScript is being used in a W3C-compatible browser, some DOM exception types are returned via the `name` property. But browsers frequently insert their own error types for this property, and, as is common in this department, little uniformity exists among browser brands.

For custom exceptions that your code explicitly throws, you can assign names as convenient. As shown in Listings 21-9 and 21-10, this information can assist a `catch` block in handling multiple categories of errors.

Related Item: `message` property

number

Value: Number Read/Write

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

IE5+ assigns unique numbers to each error description or message. The value of the `number` property must be massaged somewhat to retrieve a meaningful error description. Following is an example of how you must apply binary arithmetic to an error number to arrive at a meaningful result:

```
var errNum = errorObj.number & 0xFFFF;
```

Related Item: `description` property

Methods

toString()

Returns: String (see text)

Compatibility: WinIE5+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `toString()` method for an error object should return a string description of the error. In IE5+, however, the method returns a reference to the very same error object. In Mozilla-based browsers, the method returns the `message` property string, preceded by the string `Error:` (with a space after the colon). Most typically, if you want to retrieve a human-readable expression of an error object, read its `message` (or, in IE5+, `description`) property.

Related Item: `message` property

CHAPTER

22

JavaScript Operators

IN THIS CHAPTER

Understanding operator categories

Exploring the role of operators in script statements

Recognizing operator precedence

JavaScript is rich in operators: words and symbols in expressions that perform operations on one or two values to arrive at another value. Any value on which an operator performs some action is called an operand. An expression may contain one operand and one operator (called a unary operator), as in a++, or two operands separated by one operator (called a binary operator), as in a + b. Many of the same symbols are used in a variety of operators. The combination and order of those symbols are what distinguish their powers.

Note

The vast majority of JavaScript operators have been in the language since the very beginning. But, as you may expect from an evolving language, some entries were added to the lexicon as the language matured and gained wider usage. In the rest of this chapter, compatibility charts typically govern an entire category of operator. If there are version anomalies for a particular operator within a category, they are covered in the text. The good news is that modern browsers support the entire set of JavaScript operators. ■

Operator Categories

To help you grasp the range of JavaScript operators, we group them into seven categories. We assign a wholly untraditional name (connubial) to the second group — but a name that we believe correctly identifies its purpose in the language. Table 22-1 shows the operator types.

Any expression that contains an operator evaluates to a value of some kind, meaning that a value always results from an operation. Sometimes the operator changes the value of one of the operands; other times the result is a new value. Even this simple expression

```
5 + 5
```

shows two integer operands joined by the addition operator. This expression evaluates to 10. The operator (+) is what provides the instruction for JavaScript to follow in its never-ending drive to evaluate every expression in a script.

TABLE 22-1

JavaScript Operator Categories

<table>
<tr><th>Type</th><th>What It Does</th></tr>
<tr><td>Comparison</td><td>Compares the values of two operands, deriving a result of either <code>true</code> or <code>false</code> (used extensively in conditional statements for <code>if...else</code> and <code>for</code> loop constructions)
<code>== != === !== > >= < <=</code></td></tr>
<tr><td>Connubial</td><td>Joins together two operands to produce a single value that is a result of an arithmetical or other operation on the two
<code>+ - * / % ++ -- +val -val</code></td></tr>
<tr><td>Assignment</td><td>Stuffs the value of the expression of the right-hand operand into a variable name on the left-hand side, sometimes with minor modification, as determined by the operator symbol
<code>= += -= *= /= %= <<= >= >>= >>>= &= |= ^= []</code></td></tr>
<tr><td>Boolean</td><td>Performs Boolean arithmetic on one or two Boolean operands
<code>&& || !</code></td></tr>
<tr><td>Bitwise</td><td>Performs arithmetic or column-shifting actions on the binary (base-2) representations of two operands
<code>& | ^ ~ << >> >>></code></td></tr>
<tr><td>Object</td><td>Helps scripts examine the heritage and capabilities of a particular object before they need to invoke the object and its properties or methods
<code>. [] () delete in instanceOf new this</code></td></tr>
<tr><td>Miscellaneous</td><td>A handful of operators that have special behaviors
<code>, ?: typeof void</code></td></tr>
</table>

Doing an equality comparison on two operands that, on the surface, look very different is not at all uncommon. JavaScript doesn't care what the operands look like — only how they evaluate. Two very dissimilar-looking values can, in fact, be identical when they are evaluated. Thus, an expression that compares the equality of two values, such as

```
fred == 25
```

does, in fact, evaluate to `true` if the variable `fred` has the number `25` stored in it from an earlier statement.

Comparison Operators

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Anytime you compare two values in JavaScript, the result is a Boolean `true` or `false` value. You have a wide selection of comparison operators to choose from, depending on the kind of test you want to apply to the two operands. Table 22-2 lists all comparison operators.

TABLE 22-2

JavaScript Comparison Operators

Syntax	Name	Operand Types	Results
==	Equals	All	Boolean
!=	Does not equal	All	Boolean
===	Strictly equals	All	Boolean (IE4+, NN4+, Moz+, W3C)
!==	Strictly does not equal	All	Boolean (IE4+, NN4+, Moz+, W3C)
>	Is greater than	All	Boolean
>=	Is greater than or equal to	All	Boolean
<	Is less than	All	Boolean
<=	Is less than or equal to	All	Boolean

For numeric values, the results are the same as those you'd expect from your high school algebra class. Some examples follow, including some that may not be obvious.

```
10 == 10            // true
10 == 10.0          // true
9 != 10             // true
9 > 10              // false
9.99 <= 9.98        // false
```

Strings can also be compared on all of these levels:

```
"Fred" == "Fred"    // true
"Fred" == "fred"    // false
"Fred" > "fred"     // false
"Fran" < "Fred"     // true
```

To calculate string comparisons, JavaScript converts each character of a string to its ASCII value. Each letter, beginning with the first of the left-hand operand, is compared to the corresponding letter in the right-hand operand. With ASCII values for uppercase letters being less than those of their lowercase counterparts, an uppercase letter evaluates to being less than its lowercase equivalent. JavaScript takes case-sensitivity very seriously.

Values for comparison can also come from object properties or from values passed to functions via event handlers or other functions. A common string comparison used in data-entry validation is the one that checks whether the string has anything in it:

```
form.entry.value != ""    // true if something is in the field
```

Equality of Disparate Data Types

In versions of JavaScript before 1.2 (legacy browsers), when your script tries to compare string values consisting of numerals and real numbers (for example, `"123" == 123` or `"123" != 123`),

JavaScript anticipates that you want to compare apples to apples. Internally, it does some data type conversion that does not affect the data type of the original values (for example, if the values are in variables). But the entire situation is more complex, because other data types, such as objects, need to be dealt with. Therefore, prior to JavaScript 1.2, the rules of comparison are as shown in Table 22-3.

TABLE 22-3

Equality Comparisons for JavaScript 1.0 and 1.1

Operand A	Operand B	Internal Comparison Treatment
Object reference	Object reference	Compare object reference evaluations
Any data type	Null	Convert non-null to its object type and compare against null
Object reference	String	Convert object to string and compare strings
String	Number	Convert string to number and compare numbers

Understanding the logic of the equality comparisons in Table 22-3 requires a lot of thought on the scripter's part, because you have to be very conscious of the particular way data types may or may not be converted for equality evaluation (even though the values themselves are not converted). Supplying the proper conversion where necessary in the comparison statement is best. This ensures that what you want to compare — for example, the string versions of two values or the number versions of two values — is compared, rather than leaving the conversion up to JavaScript.

Backward-compatible conversion from a number to string entails concatenating an empty string to a number:

```
var a = "09";
var b = 9;
a == "" + b;  // result: false, because "09" does not equal "9"
```

For converting strings to numbers, you have numerous possibilities. The simplest is subtracting zero from a numeric string:

```
var a = "09";
var b = 9;
a-0 == b;  // result: true because number 9 equals number 9
```

You can also use the `parseInt()` and `parseFloat()` functions to convert strings to numbers:

```
var a = "09";
var b = 9;
parseInt(a, 10) == b;  // result: true because number 9 equals number 9
```

Of course, the other solution is to reasonably assume that your user base has a modern web browser that supports JavaScript 1.2+. To clear up the ambiguity of JavaScript's equality internal conversions, in version 1.2 JavaScript added two more operators to force the equality comparison to be extremely literal. The strictly equals (===) and strictly does not equal (!==) operators compare both the data type and value. The only time the === operator returns true is if the two operands are of the same

data type (for example, both are numbers) and the same value. Therefore, no number is ever automatically equal to a string version of that same number. Data and object types must match before their values are compared.

JavaScript 1.2+ also provides some convenient global functions for converting strings to numbers and vice versa: `String()` and `Number()`. In the following examples, the `typeof` operator shows the data type of expressions using these functions:

```
typeof 9;              // result: "number"
typeof String(9);      // result: "string"
typeof "9";            // result: "string"
typeof Number("9");    // result: "number"
```

Again, none of these functions alters the data type of the value being converted. The value of the function is what gets compared in an equality comparison:

```
var a = "09";
var b = 9;
a == String(b);    // result: false, because "09" does not equal "9"
typeof b;          // result: still "number"
Number(a) == b;    // result: true, because 9 equals 9
typeof a;          // result: still "string"
```

This discussion should impress upon you the importance of considering data types when testing the equality of two values.

Connubial Operators

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+

Connubial operators is our terminology for those operators that join two operands to yield a value related to the operands. Table 22-4 lists the connubial operators in JavaScript.

The four basic arithmetic operators for numbers are straightforward. The plus operator also works on strings to *concatenate* them (join them together), as in

```
"Scooby " + "Doo" // result = "Scooby Doo"
```

In object-oriented programming terminology, the plus sign is considered *overloaded*, meaning that it performs a different action depending on its context. Remember, too, that string concatenation does not do anything on its own to monitor or insert spaces between words. In the preceding example, the space between the names is part of the first string.

Modulo arithmetic is helpful for those times when you want to know if one number divides evenly into another. You used it in an example in Chapter 21, "Control Structures and Exception Handling," to figure out if a particular year was a leap year. Although some other leap year considerations exist for the turn of each century, the math in the example simply checked whether the year was evenly divisible by four. The result of the modulo math is the remainder after dividing the two values: When the remainder is 0, one divides evenly into the other. Here are some samples of years divided by four:

```
2002 % 4    // result = 2
2003 % 4    // result = 3
2004 % 4    // result = 0 (Bingo! Leap year!)
```

TABLE 22-4

JavaScript Connubial Operators

Syntax	Name	Operand Types	Results
+	Plus	Integer, float, string	Integer, float, string
-	Minus	Integer, float	Integer, float
*	Multiply	Integer, float	Integer, float
/	Divide	Integer, float	Integer, float
%	Modulo	Integer, float	Integer, float
++	Increment	Integer, float	Integer, float
--	Decrement	Integer, float	Integer, float
+*val*	Positive	Integer, float, string	Integer, float
-*val*	Negation	Integer, float, string	Integer, float

Thus, we used this modulo operator in a conditional statement with an `if. . .else` structure:

```
var howMany = 0;
today = new Date();
var theYear = today.getYear();
   if (theYear % 4 == 0)
   {
       howMany = 29;
   }
   else
   {
       howMany = 28;
   }
```

The modulo operator is also handy in special cases where you need to carry out some action in a loop at certain intervals, such as every third time through the loop. Here's an example of a loop that increments a counter every third time through, while looping to 100:

```
for (var i = 1; i < 100; i++)
{
   if (i % 3 == 0)
      threeCounter++;
}
```

Just as the modulo operator gives you the remainder of a division operation, some other languages offer an operator that results in the integer part of a division: integral division, or `div`. Although JavaScript does not have an explicit operator for this behavior, you can re-create it reliably if you know that your operands are always positive numbers. Use the `Math.floor()` or `Math.ceil()` methods with the division operator, as in

```
Math.floor(4/3);    // result = 1
```

In this example, `Math.floor()` replicates integral division only with values greater than or equal to `0`; `Math.ceil()` with values less than `0`.

The increment operator (++) is a *unary* operator (only one operand) and displays two different behaviors, depending on the side of the operand on which the symbols lie. Both the increment and decrement (`--`) operators can be used in conjunction with assignment operators, which we cover next.

As its name implies, the increment operator increases the value of its operand by one. But in an assignment statement, you have to pay close attention to precisely when that increase takes place. An assignment statement stuffs the value of the right operand into a variable on the left. If the ++ operator is located in front of the right operand (prefix), the right operand is incremented before the value is assigned to the variable; if the ++ operator is located after the right operand (postfix), the previous value of the operand is sent to the variable before the value is incremented. Follow this sequence to get a feel for these two behaviors:

```
var a = 10;    // initialize a to 10
var z = 0;     // initialize z to zero
z = a;         // a = 10, so z = 10
z = ++a;       // a becomes 11 before assignment, so a = 11 and z becomes 11
z = a++;       // a is still 11 before assignment, so z = 11; then a becomes 12
z = a++;       // a is still 12 before assignment, so z = 12; then a becomes 13
```

The decrement operator behaves the same way, except that the value of the operand decreases by one.

Increment and decrement operators are used most often with loop counters in `for` and `while` loops. The simpler ++ or `--` symbology is more compact than reassigning a value by adding `1` to it (such as, `z = z + 1` or `z += 1`). Because these are unary operators, you can use the increment and decrement operators without an assignment statement to adjust the value of a counting variable within a loop:

```
function doNothing()
{
   var i = 1;
   while (i < 20)
   {
      ++i;
   }
   alert(i); // loop ends with i = 20
}
```

The last pair of connubial operators are also unary operators (operating on one operand). Both the positive and negation operators can be used as shortcuts to the `Number()` global function, converting a string operand consisting of number characters to a number data type. The string operand is not changed, but the operation returns a value of the number type, as shown in the following sequence:

```
var a = "123";
var b = +a;       // b is now 123
typeof a;         // result: "string"
typeof b;         // result: "number"
```

The negation operator (`-val`) has additional power. By placing a minus sign in front of any numeric value (no space between the symbol and the value), you instruct JavaScript to evaluate a positive value as its corresponding negative value, and vice versa. The operator does not change the operand's value,

but the expression returns the modified value. The following example provides a sequence of statements to demonstrate:

```
var x = 2;
var y = 8;
var z = -x;          // z equals -2, but x still equals 2
z = -(x + y);        // z equals -10, but x still equals 2 and y equals 8
z = -x + y;          // z equals 6, but x still equals 2 and y equals 8
```

To negate a Boolean value, see the `Not (!)` operator in the discussion of Boolean operators.

Assignment Operators

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Assignment statements are among the most common statements you write in your JavaScript scripts. These statements appear everywhere you copy a value or the results of an expression into a variable for further manipulation of that value.

You assign values to variables for many reasons, even though you could probably use the original values or expressions several times throughout a script. Here is a sampling of reasons why you should assign values to variables:

- Variable names are usually shorter
- Variable names can be more descriptive
- You may need to preserve the original value for later in the script
- The original value is a property that cannot be changed
- Invoking the same method several times in a script is not efficient

Newcomers to scripting often overlook the last reason. For instance, if a script is writing a long paragraph to a new document, it would be more efficient to assemble the paragraph as one long string of sentences before invoking the `document.createTextNode()` method to add that text to the document than to add each sentence at a time.

Table 22-5 shows the range of assignment operators in JavaScript.

As clearly demonstrated in the top group (see "Bitwise Operators" later in the chapter for information on the bottom group), assignment operators beyond the simple equals sign can save some characters in your typing, especially when you have a series of values that you're trying to bring together in subsequent statements. You've seen plenty of examples in previous chapters, where you used the add-by-value operator (+=) to work wonders with strings as you assemble a long string variable. Here's a bit of script that builds a paragraph listing regional offices:

```
var aRegionalOffices = ['New York', 'Paris', 'Istanbul', 'Lusaka'];
var sText = 'Our offices are located in ';
var sSuffix = ', ';

for (var i = 0; i < aRegionalOffices.length; i++)
{
     // doing penultimate office?
     if (i == aRegionalOffices.length-2)
```

```
            {
               sSuffix += 'and ';
            }
             // doing final office?
            else if (i == aRegionalOffices.length-1)
            {
               sSuffix = '.';
            }

          // add office to paragraph
          sText += aRegionalOffices[i] + sSuffix;
       }

       // create text node and add to paragraph element
       var oNewText = document.createTextNode(sText);
       var oParagraph = document.getElementById("p1");
       oParagraph.appendChild(oNewText);
```

TABLE 22-5

JavaScript Assignment Operators

Syntax	Name	Example	Means
=	Equals	x = y	x = y
+=	Add by value	x += y	x = x + y
-=	Subtract by value	x -= y	x = x - y
*=	Multiply by value	x *= y	x = x * y
/=	Divide by value	x /= y	x = x / y
%=	Modulo by value	x %= y	x = x % y
<<=	Left shift by value	x <<= y	x = x << y
>=	Right shift by value	x >= y	x = x > y
>>=	Zero fill by value	x >>= y	x = x >> y
>>>=	Right shift by value	x >>>= y	x = x >>> y
&=	Bitwise AND by value	x &= y	x = x & y
|=	Bitwise OR by value	x |= y	x = x | y
^=	Bitwise XOR by value	x ^= y	x = x ^ y
[]=	Destructuring assignment	[a,b]=[c,d]	a=c, b=d

The result is:

```
<p id="p1">Our offices are located in New York, Paris, Istanbul, and Lusaka.</p>
```

The script segment starts with a plain equals assignment operator to initialize the `sText` variable to the beginning of the paragraph. In the loop to add offices, you use the add-by-value operator to tack additional string values onto whatever is in the `sText` variable at the time. Without the add-by-value operator, you would use the plain equals assignment operator for each line of code to concatenate new string data to the existing string data, like this:

```
var sText = 'Our offices are located in ';
...
   sText = sText + aRegionalOffices[i] + sSuffix;
```

These enhanced assignment operators are excellent shortcuts that you should use at every turn.

One more bit of assignment syntax was added to JavaScript with version 1.7:

[ ] *(square brackets to indicate destructuring assignment)*

Compatibility: FF2+, Opera 9.5 (partial)

Square brackets can assign an array of values to a set of variables, including an array returned from a function:

```
[a, b, c] = [12, 23, 34];

function moveSoutheast(x, y)
{
   return [x+1, y+1];
}
[x, y] = moveSoutheast(x, y);
```

See also: Object Operators: [ ] square brackets to enumerate an object member

Boolean Operators

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+

Because a great deal of programming involves logic, it is no accident that the arithmetic of the logic world plays an important role. You've already seen dozens of instances where programs make all kinds of decisions based on whether a statement or expression is the Boolean value `true` or `false`. What you haven't seen much of yet is how to combine multiple Boolean values and expressions — a capacity that scripts with slightly above average complexity may need to have.

In the various conditional expressions required throughout JavaScript (such as in an `if` construction), the condition that the program must test for may be more complicated than, say, whether a variable value is greater than a certain fixed value or whether a field is not empty. Look at the case of validating a text field entry for whether the entry contains all the numbers that your script may want. Without some magical JavaScript function to tell you whether or not a string consists of all numbers, you have to break apart the entry, character by character, and examine whether each character falls within the range of 0 through 9. But that examination actually comprises two tests: You can test for any character whose ASCII value is less than `0` or greater than `9` (i.e., not a digit). Alternatively, you can test whether the character is greater than or equal to `0` and is less than or equal to `9` (i.e., is a digit). What you need is the bottom-line evaluation of both tests.

Boolean math

That's where the wonder of Boolean math comes into play. With just two values — `true` and `false` — you can assemble a string of expressions that yield Boolean results and then let Boolean arithmetic figure out whether the bottom line is `true` or `false`.

But you don't add or subtract Boolean values the same way you add or subtract numbers. Instead, you use one of three JavaScript Boolean operators at your disposal. Table 22-6 shows the three operator symbols. In case you're unfamiliar with the characters in the table, the symbols for the `OR` operator are created by typing Shift+\ (backslash).

TABLE 22-6

JavaScript Boolean Operators

Syntax	Name	Operands	Results
`&&`	`AND`	Boolean	Boolean
`||`	`OR`	Boolean	Boolean
`!`	`NOT`	One Boolean	Boolean

Using Boolean operators with Boolean operands gets tricky if you're not used to it, so we have you start with the simplest Boolean operator: `NOT`. This operator requires only one operand. The `NOT` operator precedes any Boolean value to switch it back to the opposite value (from `true` to `false`, or from `false` to `true`). For instance:

```
!true        // result = false
!(10 > 5)    // result = false
!(10 < 5)    // result = true
!("cat" == "bat")    // result = true
```

As shown here, enclosing the operand of a `NOT` expression inside parentheses is always a good idea. This forces JavaScript to evaluate the expression inside the parentheses before flipping it around with the `NOT` operator. Otherwise, you may accidentally perform the operation on only part of the intended expression, resulting in unexpected consequences.

The `AND` (`&&`) operator joins two Boolean values to reach a `true` or `false` value based on the results of both values. This brings up something called a *truth table*, which helps you visualize all the possible outcomes for each value of an operand. Table 22-7 is a truth table for the `AND` operator.

Only one condition yields a `true` result: Both operands must evaluate to `true`. Which side of the operator a `true` or `false` value lives on doesn't matter. Here are examples of each possibility:

```
5 > 1 && 50 > 10    // result = true
5 > 1 && 50 < 10    // result = false
5 < 1 && 50 > 10    // result = false
5 < 1 && 50 < 10    // result = false
```

Note

You may be wondering why parentheses aren't being used in this code to separate the comparison and Boolean expressions. The reason has to do with operator precedence, which you learn a great deal more about later in

the chapter. The short answer is that comparison operators are evaluated before Boolean operators. Even so, it's never a bad idea to use parentheses to group sub-expressions and make absolutely sure you're getting the desired result and to make your code easier for humans to read. ■

TABLE 22-7

Truth Table for the And Operator

Left Operand	AND Operator	Right Operand	Result
True	&&	True	True
True	&&	False	False
False	&&	True	False
False	&&	False	False

In contrast, the OR (||) operator is more lenient about what it evaluates to true. The reason is that if one or the other (or both) operands is true, the operation returns true. The OR operator's truth table is shown in Table 22-8.

TABLE 22-8

Truth Table for the Or Operator

Left Operand	OR Operator	Right Operand	Result
True	||	True	True
True	||	False	True
False	||	True	True
False	||	False	False

Therefore, if a true value exists on either side of the operator, a true value is the result. Take the previous examples and swap the AND operators with OR operators so that you can see the OR operator's impact on the results:

```
5 > 1 || 50 > 10    // result = true
5 > 1 || 50 < 10    // result = true
5 < 1 || 50 > 10    // result = true
5 < 1 || 50 < 10    // result = false
```

Only when both operands are false does the OR operator return false.

Boolean operators at work

Learning to apply Boolean operators to JavaScript just takes a little effort and some sketches on a pad of paper to help you figure out the logic of the expressions. Earlier, we talked about using a Boolean

operator to see whether a character fell within a range of ASCII values for data-entry validation. Listing 22-1 is a function discussed in more depth in Chapter 46, “Data-Entry Validation” (on the CD). This function accepts any string and sees whether each character of the string has an ASCII value less than 0 or greater than 9 — meaning that the input string is not a number.

LISTING 22-1

Is the Input String a Number?

```
function isNumber(inputStr)
{
   for (var i = 0; i < inputStr.length; i++)
   {
      var oneChar = inputStr.substring(i, i + 1);
         if (oneChar < "0" || oneChar > "9")
         {
            alert("Please make sure entries are numerals only.");
            return false;
         }
   }
   return true;
}
```

This code snippet combines a number of JavaScript powers to read individual characters (substrings) from a `string` object within a `for` loop. The statement that you’re interested in is the condition of the `if` construction:

```
(oneChar < "0" || oneChar > "9")
```

In one conditional statement, you use the `OR` operator to test for both possibilities. If you check the `OR` truth table (Table 22-8), you see that this expression returns `true` if either one or both tests returns `true`. If that happens, the rest of the function alerts the user about the problem and returns a `false` value to the calling statement. Only if both tests within this condition evaluate to `false` for all characters of the string does the function return a `true` value.

From the simple `OR` operator, we go to the opposite extreme, where the function checks — in one conditional statement — whether a number falls within several numeric ranges. The script in Listing 22-2 comes from the array lookup application in Chapter 53, “Application: A Lookup Table” (on the CD-ROM), in which a user enters the first three digits of a U.S. Social Security number.

LISTING 22-2

Is a Number within Discontiguous Ranges?

```
// function to determine if value is in acceptable range for this application
function inRange(inputStr)
{
   num = parseInt(inputStr)
      if (num < 1 || (num > 586 && num < 596) || (num > 599 && num < 700) ||
```

continued

LISTING 22-2 *(continued)*

```
         num > 728)
      {
         alert("Sorry, the number you entered is not part of our database.  Try
            another three-digit number.");
         return false;
      }
   return true;
}
```

By the time this function is called, the user's data entry has been validated enough for JavaScript to know that the entry is a number. Now the function must check whether the number falls outside of the various ranges for which the application contains matching data. The conditions that the function tests here are whether the number is

- Less than 1
- Greater than 586 and less than 596 (using the `AND` operator)
- Greater than 599 and less than 700 (using the `AND` operator)
- Greater than 728

Each of these tests is joined by an `OR` operator. Therefore, if any one of these conditions proves `true`, the whole `if` condition is `true`, and the user is alerted accordingly.

The alternative to combining so many Boolean expressions in one conditional statement would be to nest a series of `if` constructions. But such a construction requires not only a great deal more code but also much repetition of the alert dialog box message for each condition that could possibly fail. The combined Boolean condition is, by far, the best way to go.

Bitwise Operators

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

For scripters, bitwise operations are an advanced subject. Unless you're dealing with external processes on server-side applications or the connection to Java applets, it's rare that you will use bitwise operators. Experienced programmers who concern themselves with more specific data types (such as long integers) are quite comfortable in this arena, so we simply provide an explanation of JavaScript capabilities. Table 22-9 lists JavaScript bitwise operators.

The numeric value operands can appear in any of the JavaScript language's three numeric literal bases (decimal, octal, or hexadecimal). As soon as the operator has an operand, the value is converted to binary representation (32 bits long). For the first three bitwise operations, the individual bits of one operand are compared with their counterparts in the other operand. The resulting value for each bit depends on the operator:

- **Bitwise** `AND`**:** 1 if both digits are 1
- **Bitwise** `OR`**:** 1 if either digit is 1
- **Bitwise** `Exclusive OR`**:** 1 if only one digit is a 1

TABLE 22-9

JavaScript's Bitwise Operators

Operator	Name	Left Operand	Right Operand
&	Bitwise AND	Integer value	Integer value
|	Bitwise OR	Integer value	Integer value
^	Bitwise XOR	Integer value	Integer value
~	Bitwise NOT	(None)	Integer value
<<	Left shift	Integer value	Shift amount
>>	Right shift	Integer value	Shift amount
>>>	Zero fill right shift	Integer value	Shift amount

Bitwise `NOT`, a unary operator, inverts the value of every bit in the single operand. The bitwise shift operators operate on a single operand. The second operand specifies the number of positions to shift the value's binary digits in the direction of the arrows of the operator symbols.

Example

For example, the left shift (<<) operator has the following effect:

```
4 << 2 // result = 16
```

The reason for this shifting is that the binary representation for decimal 4 is 00000100 (to eight digits, anyway). The left shift operator instructs JavaScript to shift all digits two places to the left, giving the binary result 00010000, which converts to 16 in decimal format. If you're interested in experimenting with these operators, use The Evaluator to evaluate sample expressions for yourself (see Chapter 4, "JavaScript Essentials"). More advanced books on C and C++ programming are also of help.

Object Operators

The next group of operators concern themselves with objects (including native JavaScript, DOM, and custom objects) and data types. Most of these have been implemented after the earliest JavaScript browsers, so each one has its own compatibility rating.

. (dot or period)

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The dot operator indicates that the object to its left owns or contains the resource to its right, as in `object.property` and `object.method()`. Examples:

`native JavaScript object`

```
var s = new String('syzygy');
```

```
var len = s.length;
var pos = s.indexOf('zyg'); // result: pos == 2
```

```
custom JavaScript object

function myMethod()
{
   // (custom code goes here)
}

function myCustomObject()
{
   this.myProperty = 'something';
   this.myMethod = myMethod;
}

var o = new myCustomObject();
var p = o.newProperty;
o.myMethod();
```

```
Document Object Model object

var sTitle = document.title;
var oThing = document.getElementById("elementID");
```

[ ] *(square brackets to enumerate object member)*

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Square brackets enumerate a member of an object, such as an array element:

```
define an array:

var a = ['homo erectus', , 'homo sapiens'];

enumerate an array element:

a[5] = 'sixth element';

enumerate an object property:

a['color'] = 'puce';
```

See also: Assignment Operators: [ ] square brackets to indicate destructuring assignment

Delete

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Array objects do not contain a method to remove an element from the collection, nor do custom objects offer a method to remove a property. You can always empty the data in an array item or property by setting its value to an empty string or `null`, but the array element or property remains in the object. With the `delete` operator, you can completely remove the element or property.

There is special behavior about deleting an array item that you should bear in mind. If your array uses numeric indexes, a deletion of a given index removes that index value from the total array, but without collapsing the array (which would alter index values of items higher than the deleted item).

Example

Consider the following simple dense array:

```
var oceans = new Array("Atlantic", "Pacific", "Indian","Arctic");
```

This kind of array automatically assigns numeric indices to its entries for addressing later in constructions such as `for` loops:

```
for (var i = 0; i < oceans.length; i++)
{
   if (oceans[i] == form.destination.value)
   {
      // statements
   }
}
```

If you then issue the statement

```
delete oceans[2];
```

the array undergoes significant changes. First, the third element is removed from the array. Note that the length of the array does not change. Even so, the index value `(2)` is removed from the array, such that, schematically, the array looks like the following:

```
oceans[0] = "Atlantic";
oceans[1] = "Pacific";
oceans[3] = "Arctic";
```

If you try to reference `oceans[2]` in this collection, the result is `undefined`.

The `delete` operator works best on arrays that have named indexes since there is less confusion due to deleted numeric indexes. Your scripts will have more control over the remaining entries and their values, because they don't rely on what could be a missing entry of a numeric index sequence.

One aspect of this deletion action that JavaScript doesn't provide is absolute control over memory utilization. All garbage collection is managed by the JavaScript interpreter engine, which tries to recognize when items occupying memory are no longer needed, at which time the unused browser's application memory may be recovered. But you cannot force the browser to perform its garbage collection task. So, deleting an entry from an array doesn't guarantee an immediate release of its associated memory.

`in`

Compatibility: WinIE5.5+, MacIE−, NN6+, Moz+, Safari+, Opera+, Chrome+

The `in` operator lets a script statement inspect an object to see if it has a named property or method. The operand to the left of the operator is a string reference to the property or method (just the method name, without parentheses); the operand to the right of the operator is the object being inspected. If the object knows the property or method, the expression returns `true`. Thus, you can use the `in` operator in expressions used for conditional expressions.

Example

You can experiment with this operator in The Evaluator (see Chapter 4). For example, to prove that the `write()` method is implemented for the `document` object, the expression you type into the top text box of The Evaluator is:

```
"write" in document
```

But compare the implementation of the W3C DOM `document.defaultView` property in IE5.5+ and modern W3C browsers:

```
"defaultView" in document
```

In NN6+, Mozilla (including Firefox and Camino), and Safari, the result is `true`, while in IE5.5 and IE6, the result is `false`.

Having this operator around for conditional expressions lets you go far beyond simple object detection for branching code. For example, if you intend to use `document.defaultView` in your script, you can make sure that the property is supported before referencing it (assuming your users all have browsers that know the `in` operator).

instanceof

Compatibility: WinIE5+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `instanceof` operator lets a script test whether an object is an instance of a particular JavaScript native object or of a DOM object. The operand to the left side of the operator is the value under test; the value to the right of the operand is a reference to the root class from which the value is suspected of being constructed.

For native JavaScript classes, the kinds of object references to the right of the operator include such static objects as `Date`, `String`, `Number`, `Boolean`, `Object`, `Array`, and `RegExp`. You need to be mindful of how native JavaScript classes can sometimes be children of other native classes, which means that a value may be an instance of two different static objects.

Example

Consider the following sequence (which you can follow along in The Evaluator):

```
a = new Array(1,2,3);
a instanceof Array;
```

The second statement yields a result of `true`, because the `Array` constructor was used to generate the object. But the JavaScript `Array` is, itself, an instance of the root `Object` object. Therefore, both of the following statements evaluate to `true`:

```
a instanceof Object;
Array instanceof Object;
```

new

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Most JavaScript core objects have constructor functions built into the language. To access those functions, you use the `new` operator along with the name of the constructor. The function returns a reference to the object instance, which your scripts can then use to get and set properties or invoke object methods. For example, creating a `new` date object requires invoking the `Date` object's constructor, as follows:

```
var today = new Date();
```

Some object constructor functions require parameters to help define the object. Others, as in the case of the `Date` object, can accept a number of different parameter formats, depending on the format of the date information with which you set the initial object. The `new` operator can be used with the following core language objects, as of each specified JavaScript version:

JavaScript 1.0	JavaScript 1.1	JavaScript 1.2	JavaScript 1.5
`Date`	`Array`	`RegExp`	`Error`
`Object`	`Boolean`		
(Custom object)	`Function`		
	`Image`		
	`Number`		
	`String`		

this

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

JavaScript includes an operator that allows script statements to refer to the very object in which they are located. The self-referential operator is `this`.

The most common application of the `this` operator is in event handlers that pass references of themselves to functions for further processing.

A function receiving the value assigns it to a variable that can be used to reference the sender, its properties, and its methods.

Example

Because the `this` operator references an object, that object's properties can be exposed with the aid of the operator. For example:

```
oInputField.onchange = validateInput;

function validateInput(evt)
{
   var sInputvalue = this.value;
}
```

When the visitor changes the contents of the input field — triggering the `onchange` event, which, in turn, executes the `validateInput()` function — the code inside that function recognizes `this` as being the input field object to which it belongs. In that context, `this.value` represents the value entered by the visitor.

In the bad old days of inline JavaScript, this would look like:

```
<input type="text" name="entry" onchange="validateInput(this)" />
```

The `this` operator also works inside other objects, such as custom objects. When you define a constructor function for a custom object, using the `this` operator to define properties of the object and assign values to those properties is common practice. Consider the following example of an object creation sequence:

```
function bottledWater(brand, ozSize, flavor)
{
   this.brand = brand;
   this.ozSize = ozSize;
   this.flavor = flavor;
}
var myWater = new bottledWater("Eau de Odio", 16, "original");
```

When the new object is created via the constructor function, the `this` operators define each property of the object and then assign the corresponding incoming value to that property. Using the same names for the properties and parameter variables is perfectly fine and makes the constructor easy to maintain.

By extension, if you assign a function as an object's property (to behave as a method for the object), the `this` operator inside that function refers to the object invoking the function, offering an avenue to the object's properties. For example, if we add the following function definition and statement to the `myWater` object created just above, the function can directly access the `brand` property of the object:

```
function adSlogan()
{
   return "Drink " + this.brand + ", it's wet and wild!";
}
myWater.getSlogan = adSlogan;
```

When a statement invokes the `myWater.getSlogan()` method, the object invokes the `adSlogan()` function, but all within the context of the `myWater` object. Thus, the `this` operator applies to the surrounding object, making the brand property available via the `this` operator (`this.brand`).

Miscellaneous Operators

The final group of operators doesn't fit into any of the previous categories, but they are no less important.

,

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The comma operator indicates a series of expressions that are to be evaluated in left-to-right sequence. Most typically, this operator is used to permit multiple variable initializations. For example, you can combine the declaration of several variables in a single `var` statement, as follows:

```
var name, address, serialNumber;
```

Another situation where you could use this operator is within the expressions of a `for` loop construction. In the following example, two different counting variables are initialized and incremented at different rates. When the loop begins, both variables are initialized at zero (they don't have to be, but this example starts that way); for each subsequent trip through the loop, one variable is incremented by one, while the other is incremented by 10:

```
for (var i=0, j=0; i < someLength; i++, j+10)
{
   ...
}
```

Don't confuse the comma operator with the semicolon delimiter between statements.

?:

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The conditional operator is a shortcut way of expressing the `if. . .else` conditional construction covered in Chapter 21, "Control Structures and Exception Handling." This operator is typically used in concert with an assignment operator to assign one of two values to a variable based on the result of a conditional expression. The formal syntax for the conditional operator is:

```
condition ? expressionIfTrue : expressionIfFalse
```

If used with an assignment operator, the syntax is:

```
var = condition ? expressionIfTrue : expressionIfFalse;
```

No matter how you use the operator, the important point to remember is that an expression that contains this operator evaluates to one of the two expressions following the question mark symbol. In truth, either expression could invoke any JavaScript, including calling other functions, or even nesting further conditional operators within one of the expressions to achieve the equivalent of nested `if. . .else` constructions. To assure proper resolution of nested conditionals, surround inner expressions with parentheses to make sure that they evaluate before the outer expression evaluates. As an example, the following statement assigns one of three strings to a variable depending on the date within a month:

```
var monthPart = (dateNum <= 10) ? "early" : ((dateNum <= 20) ?
   "middle" : "late");
```

When the statement is evaluated, the inner conditional expression at the right of the first colon is evaluated, returning either `middle` or `late`; then the outer conditional expression is evaluated, returning either `early` or the result of the inner conditional expression.

typeof

Compatibility: WinIE3+, MacIE3+, NN3+, Moz+, Safari+, Opera+, Chrome+

Unlike most other operators, which are predominantly concerned with arithmetic and logic, the unary `typeof` operator defines the kind of value to which a variable or expression evaluates. Typically, this operator is used to identify whether a variable value is one of the following types: `number`, `string`, `boolean`, `object`, `function`, or `undefined`.

Example

Having this investigative capability in JavaScript is helpful because variables cannot only contain any one of those data types but can change their data type on the fly. Your scripts may need to handle a value differently based on the value's type. The most common use of the `typeof` property is as part of a condition. For example:

```
if (typeof myVal == "number")
{
   myVal = parseInt(myVal);
}
```

The evaluated value of the `typeof` operation is, itself, a string.

void

Compatibility: WinIE3+, MacIE3+, NN3+, Moz+, Safari+, Opera+, Chrome+

In all scriptable browsers you can use the `javascript:` pseudo-protocol to supply the parameter for `href` and `src` attributes in HTML tags, such as links. In the process, you have to be careful that the function or statement being invoked by the URL does not return or evaluate to any values. If a value comes back from such an expression, then that value, or sometimes the directory of the client's hard disk, often replaces the page content. To avoid this possibility, use the `void` operator in front of the function or expression being invoked by the `javascript:` URL.

Example

The best way to use this construction is to place the operator before the expression or function and separate them by a space, as in

```
javascript: void doSomething();
```

On occasion, you may have to wrap the expression inside parentheses after the `void` operator. Using parentheses is necessary only when the expression contains operators of a lower precedence than the `void` operator (see the following section, "Operator Precedence"). But don't automatically wrap all expressions in parentheses, because some browsers can experience problems with these. Even so, it is common practice to assign the following URL to the `href` attribute of an `a` link whose `onclick` event handler does all of the work:

```
href="javascript: void (0)"
```

The `void` operator makes sure the function or expression returns no value that the HTML attribute can use. Such a link's `onclick` event handler should also inhibit the natural behavior of a clicked link (for example, by evaluating to `return false`).

Operator Precedence

When you start working with complex expressions that hold a number of operators (for example, Listing 22-2), knowing the order in which JavaScript evaluates those expressions is vital. JavaScript assigns different priorities or weights to types of operators in an effort to achieve uniformity in the way it evaluates complex expressions.

In the following expression

```
10 + 4 * 5 // result = 30
```

JavaScript uses its precedence scheme to perform the multiplication before the addition — regardless of where the operators appear in the statement. In other words, JavaScript first multiplies 4 by 5 and then adds that result to 10 to get a result of 30. That may not be the way you want this expression to evaluate. Perhaps your intention was to add the 10 and 4 first, and then to multiply that sum by 5. To make that happen, you have to override JavaScript's natural operator precedence. To do that, you must use parentheses to enclose an operator with lower precedence. The following statement shows how you adjust the previous expression to make it behave differently:

```
(10 + 4) * 5 // result = 70
```

That one set of parentheses has a great impact on the outcome. Parentheses have the highest precedence in JavaScript, and if you nest parentheses in an expression, the innermost set evaluates first.

For help in constructing complex expressions, refer to Table 22-10 for JavaScript's operator precedence. Our general practice: When in doubt about complex precedence issues, we build the expression with lots of parentheses according to the way we want the internal expressions to evaluate.

This precedence scheme is devised to help you avoid being faced with two operators from the same precedence level that often appear in the same expression. When it does happen (such as with addition and subtraction), JavaScript begins evaluating the expression from left to right.

One related fact involves a string of Boolean expressions strung together for a conditional statement (see Listing 22-2). JavaScript follows what is called *short-circuit evaluation*. As the nested expressions are evaluated left to right, the fate of the entire condition can sometimes be determined before all expressions are evaluated. Anytime JavaScript encounters an `AND` operator, if the left operand evaluates to `false`, the entire expression evaluates to `false` without JavaScript's even bothering to evaluate the right operand. For an `Or` operator, if the left operand is `true`, JavaScript short-circuits that expression to `true`. This feature can trip you up if you don't perform enough testing on your scripts: If a syntax error or other error exists in a right operand, and you fail to test the expression in a way that forces that right operand to evaluate, you may not know that a bug exists in your code. Users of your page, of course, will find the bug quickly. Do your testing to head bugs off at the pass.

TABLE 22-10

JavaScript Operator Precedence

Precedence Level	Operator	Notes
1	`()`	From innermost to outermost
	`[]`	Array index value
	`function()`	Any remote function call
2	`!`	Boolean `NOT`
	`~`	Bitwise `NOT`
	`-`	Negation
	`++`	Increment
	`--`	Decrement
	`new`	
	`typeof`	
	`void`	
	`delete`	Delete array or object entry
3	`*`	Multiplication
	`/`	Division
	`%`	Modulo
4	`+`	Addition
	`-`	Subtraction
5	`<<`	Bitwise shifts
	`>`	
	`>>`	
6	`<`	Comparison operators
	`<=`	
	`>`	
	`>=`	
7	`==`	Equality
	`!=`	
8	`&`	Bitwise `AND`
9	`^`	Bitwise `XOR`
10	`|`	Bitwise `OR`
11	`&&`	Boolean `AND`
12	`||`	Boolean `OR`

Precedence Level	Operator	Notes
13	?	Conditional expression
14	= += -= *= /= %= <<= >= >>= &= ^= |=	Assignment operators
15	,	Comma (parameter delimiter)

Note

Notice, too, that all math and string concatenation is performed prior to any comparison operators. This enables all expressions that act as operands for comparisons to evaluate fully before they are compared. ■

The key to working with complex expressions is to isolate individual expressions and to try them out by themselves, if you can. See additional debugging tips in Chapter 48, “Debugging Scripts,” on the CD-ROM.

CHAPTER 23

Function Objects and Custom Objects

IN THIS CHAPTER

Creating function blocks

Passing parameters to functions

Creating your own objects

The Object object

By now, you've seen dozens of JavaScript functions in action and probably have a pretty good feel for the way they work. This chapter provides the `Function` object specification and delves into the fun prospect of creating objects in your JavaScript code. If you've missed out on the object-oriented (OO) programming revolution, now is your chance to join. JavaScript is surprisingly full-featured when it comes to supporting OO and allowing you to develop scripts that rely heavily on custom objects.

Function Object

Properties	Methods	Event Handlers
`arguments`	`apply()`	
`arity`	`call()`	
`caller`	`toString()`	
`constructor`	`valueOf()`	
`length`		
`prototype`		

Syntax

Creating a `Function` object:

```
function functionName([arg1,...[,argN]])
{
   statement(s)
}
```

```
var funcName = new Function(["argName1",...[,"argNameN"],
        "statement1;...[;statementN]"])object.eventHandlerName =
        function([arg1,...[,argN]]) {statement(s)}
```

Accessing `Function` object properties and methods:

```
functionObject.property | method([parameters])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+

About this object

JavaScript accommodates what other languages might call procedures, subroutines, and functions all in one type of structure: the *custom function*. A function may return a value (if programmed to do so with the `return` keyword), but it does not have to return any value. With the exception of JavaScript code that executes as the document loads, all deferred processing takes place in functions.

Although you can create functions that are hundreds of lines long, we recommend you break up longer processes into shorter functions. Among the reasons for doing so: smaller chunks are easier to write and debug; building blocks make it easier to visualize the entire script; you can make functions generalizable and reusable for other scripts; and other parts of the script or other open frames can use the functions.

Learning how to write good, reusable functions takes time and experience. But the earlier you understand the importance of this concept, the more you will be on the lookout for good examples in other people's scripts on the web.

Creating functions

The standard way of defining a function in your script involves following a simple pattern and then filling in the details. The formal syntax definition for a function is:

```
function functionName( [arg1] ... [, argN])
{
   statement(s)
}
```

The task of assigning a function name helps you determine the precise scope of activity of the function. If you find that you can't reduce the planned task for the function to a simple one- to three-word name (which is then condensed into one contiguous sequence of characters for the `functionName`), perhaps you're asking the function to do too much. A better idea may be to break the job into two or more functions. As you start to design a function, be on the lookout for functions that you can call from the one you're writing. If you find yourself copying and pasting lines of code from one part of a function to another because you're performing the same operation in different spots within the function, it may be time to break that segment out into its own function.

Here's a quick example of a simple function that accepts a single argument, a name, and then returns a string greeting that includes the name:

```
function sayHello(name)
{
   return ("Hello, " + name + ".");
}
```

You can also create what is called an *anonymous function* using the `new Function()` constructor. In reality, you assign a name to this anonymous function as follows:

```
var funcName = new Function(["argName1",...[,"argNameN"],
                            "statement1;...[;statementN]"]);
```

This other way of building a function is particularly helpful when your scripts need to create a function after a document loads. All the components of a function are present in this definition. Each function parameter name is supplied as a string value, separated from the others by commas. The final parameter string consists of the statements that execute whenever the function is called. (Recall that quoted strings cannot be broken onto several lines; the continuation character at the end of the second line in the code segment below is used only because this book has a finite width to its pages.) Separate each JavaScript statement with a semicolon, and enclose the entire sequence of statements inside quotes, as in the following:

```
var willItFit = new Function("width","height",
                "var sx = screen.availWidth; var sy = screen.availHeight;↩
                return (sx >= width && sy >= height)");
```

The `willItFit()` function takes two parameters; the body of the function defines two local variables (`sx` and `sy`) and then returns a Boolean value of `true` if the incoming parameters are smaller than the local variables. In traditional form, this function is defined as follows:

```
function willItFit(width, height)
{
   var sx = screen.availWidth;
   var sy = screen.availHeight;
   return (sx >= width && sy >= height);
}
```

When this function exists in the browser's memory, you can invoke it like any other function:

```
if (willItFit(400,500))
{
   // statements to load image
}
```

One last function creation format is available in IE4+, NN4+, Moz, and other W3C DOM browsers. This advanced technique, called a *lambda expression,* provides a shortcut for creating a reference to an anonymous function (truly anonymous because the function has no name that you can reference later). The common application of this technique is to assign function references to event handlers when an event object also must be passed. The following is an example of how to assign an anonymous function to an `onchange` event handler for a form control:

```
document.forms[0].age.onchange = function(event)
     {isNumber(document.forms[0].age)}
```

Because an anonymous function evaluates to a reference to a function object, you can use either form of anonymous function in situations where a function reference is called for, including parameters of methods or other functions.

Nesting functions

Modern browsers also provide for nesting functions inside one another. In the absence of nested functions, each function definition is defined at the global level, whereby every function is exposed and available to all other script code. With nested functions, you can encapsulate the exposure of a function inside another and make that nested function private to the enclosing function. Of course, we don't recommend reusing function names with this technique, although you can create nested functions with the same name inside multiple global-level functions, as the following skeletal structure shows:

```
function outerA()
{
   // statements
   function innerA()
   {
      // statements
   }
   // statements
}
function outerB()
{
   // statements
   function innerA()
   {
      // statements
   }
   function innerB()
   {
      // statements
   }
   // statements
}
```

A good time to apply a nested function is when a sequence of statements needs to be invoked in multiple places within a large function, and those statements have meaning only within the context of the larger function. In other words, rather than break out the repeated sequence as a separate global function, you keep it all within the scope of the larger function.

Note

The premise behind nesting a function is to isolate the function and make it private from the overall script. This results in cleaner script code because nothing is exposed globally without a good reason. As an admittedly strange analogy, the water heater in your house could feasibly be placed outside (global), but it's generally safer and more organized to place it inside (local). Unlike your mailbox, which must interact with the outside (global) world, your water heater plays an internal (local) role, and therefore lives inside your house. And after all, we don't want to make our home's hot water globally available. ■

You can access a nested function only from statements in its containing function (but in any order). Moreover, all variables defined in the outer function (including parameter variables) are accessible to the inner function; but variables defined in an inner function are not accessible to the outer function. See the section "Variable scope: Globals and locals" later in this chapter for details on how variables are visible to various components of a script.

Function parameters

The function definition requires a set of parentheses after the `functionName`. If the function does not rely on any information arriving with it when invoked, the parentheses can be empty. But when some kind of data is arriving with a call to the function, you need to assign names to each parameter. Virtually any kind of value can be a parameter: strings, numbers, Boolean operators, and even complete object references such as a form or form element. Choose names for these variables that help you remember the content of those values; also, avoid reusing existing object names as variable names because it's easy to get confused when objects and variables with the same name appear in the same statements. You must avoid using JavaScript keywords (including the reserved words listed in Appendix C, on the CD) and any global variable name defined elsewhere in your script. (See more about global variables in the following sections.)

JavaScript is forgiving about matching the number of parameters in the function definition with the number of parameters passed along from the calling statement. If you define a function with three parameters and the calling statement specifies only two, the third parameter variable value in that function is assigned a `null` value. For example:

```
function saveWinners(first, second, third)
{
   // statements
}
oneFunction("George","Gracie");
```

In the preceding example, the values of `first` and `second` inside the function are `"George"` and `"Gracie"`, respectively; the value of `third` is `null`.

At the opposite end of the spectrum, JavaScript also doesn't balk if you send more parameters from the calling statement than the number of parameter variables specified in the function definition. In fact, the language includes a mechanism — the `arguments` property — that you can add to your function to gather any extraneous parameters that should read your function.

Properties

arguments (deprecated)

Value: Array of arguments Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Chrome+

When a function receives parameter values from the statement that invoked the function, those parameter values are silently assigned to the `arguments` property of the function object. This property is an array of the values, with each parameter value assigned to a zero-based index entry in the array — whether or not parameters are defined for it. You can find out how many parameters are sent by extracting `functionName.arguments.length`. For example, if four parameters are passed, `functionName.arguments.length` returns 4. Then, you can use array notation (`functionName.arguments[i]`) to extract the values of any parameter(s) you want.

Theoretically, you never have to define parameter variables for your functions because you can extract the desired arguments array entry instead. Well-chosen parameter variable names, however, are much more readable, so we recommend them over the `arguments` property in most cases. But you may run into situations in which a single function definition needs to handle multiple calls to the function

when each call may have a different number of parameters. The function knows how to handle any arguments over and above the ones given names as parameter variables.

Note

It is necessary in some cases to create a function that deliberately accepts a varied number of arguments, in which case the `arguments` property is the only way to access and process the arguments. For example, if you wanted to create a function that averages test scores, there's a good chance the number of scores may vary, in which case you would write the function so that it loops through the `arguments` array, adding up the scores as it carries out the calculation. ■

Example

See Listings 23-1 and 23-2 for a demonstration of both the `arguments` and `caller` properties.

arity (deprecated)

Value: Integer Read-Only

Compatibility: WinIE−, MacIE−, NN4+, Moz−, Safari−, Chrome+

See the discussion of the `length` property later in this chapter.

caller

Value: Function object reference Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari−, Chrome+

When one function invokes another, a chain is established between the two, primarily so that a returned value knows where to go. Therefore, a function invoked by another maintains a reference to the function that called it. Such information is automatically stored in a `Function` object as the `caller` property. This relationship reminds me a bit of a subwindow's `opener` property, which points to the window or frame responsible for the subwindow's creation. The value is valid only while the called function is running at the request of another function; when a function isn't running, its `caller` property is `null`.

The value of the `caller` property is a reference to a `Function` object, so you can inspect its `arguments` and `caller` properties (in case it was called by yet another function). Thus, a function can look back at a calling function to see what values it was passed.

The `functionName.caller` property reveals the contents of an entire function definition if the current function was called from another function (including an event handler). If the call for a function comes from a regular JavaScript statement not originating inside a function, the `functionName.caller` property is `null`.

Example

To help you grasp all that these two properties yield, study Listing 23-1.

Note

The function to assign event handlers throughout the code in this chapter and much of the book is `addEvent()`, a cross-browser event handler explained in detail in Chapter 32, "Event Objects." ■

LISTING 23-1

A Function's arguments and caller Properties

HTML: jsb-23-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Function call information</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-23-01.js"></script>
   </head>
   <body>
      <h1>Function call information</h1>
      <div id="placeHolder"></div>
   </body>
</html>
```

JavaScript: jsb-23-01.js

```
// initialize when the page has loaded
addEvent(window, "load", showArgCaller);

var newElem;
var newText;

function showArgCaller ()
{
   // Call the hansel function twice: once directly,
   // second indirectly from the gretel function.
   hansel(1, "two", 3);
   gretel(4, "five", 6, "seven");
}

function hansel(x,y)
{
   var args = hansel.arguments;
   var placeHolderElement = document.getElementById("placeHolder");

      if (placeHolderElement)
      {
         // a header line
         newElem = document.createElement("h3");
         newElem.className = "objProperty";
         newText = document.createTextNode("The caller and the arguments");
         // insert the 1st line (text node) into the new h3
         newElem.appendChild(newText);
         // insert the completed h3 into placeholder
```

continued

functionObject.caller()

LISTING 23-1 *(continued)*

```
         placeHolderElement.appendChild(newElem);

         // the next line is the caller
         newElem = document.createElement("div");
         newElem.className = "objProperty";
         newText = document.createTextNode("hansel.caller is " + hansel.caller);
         newElem.appendChild(newText);
         placeHolderElement.appendChild(newElem);

         // the next line is the number or arguments
         newElem = document.createElement("div");
         newElem.className = "objProperty";
         newText = document.createTextNode("hansel.arguments.length is " +
                                           hansel.arguments.length);
         newElem.appendChild(newText);
         placeHolderElement.appendChild(newElem);

         // the rest of the lines are the arguments
         for (var i = 0; i < args.length; i++) {
            newElem = document.createElement("div");
            newElem.className = "objProperty";
            newText = document.createTextNode("argument " + i + " is " + args[i]);
            newElem.appendChild(newText);
            placeHolderElement.appendChild(newElem);
         }
      }
}

function gretel(x,y,z)
{
   today = new Date();
   thisYear = today.getFullYear();
   hansel(x,y,z,thisYear);
}
```

When you load this page, the following JavaScript results appear in the browser window:

```
The caller and the arguments
hansel.caller is function showArgCaller()
{
  hansel(1, "two", 3);
  gretel(4, "five", 6, "seven");
}
hansel.arguments.length is 3
argument 0 is 1
argument 1 is two
argument 2 is 3
The caller and the arguments
```

```
hansel.caller is function gretel(x, y, z)
{
  today = new Date();
  thisYear = today.getFullYear();
  hansel(x,y,z,thisYear);
}
hansel.arguments.length is 4
argument 0 is 4
argument 1 is five
argument 2 is 6
argument 3 is 2010 (or whatever the current year is)
```

As the document loads, the `hansel()` function is called directly in the onload event handler in the external script. It passes three arguments, even though the `hansel()` function defines only two. The `hansel.arguments` property picks up all three arguments just the same. Then the onload event handler invokes the `gretel()` function, which, in turn, calls `hansel()` again. But when `gretel()` makes the call, it passes four parameters. The `gretel()` function picks up only three of the four arguments sent by the calling statement. It also inserts another value from its own calculations as an extra parameter to be sent to `hansel()`. The `hansel.caller` property reveals the entire content of the `gretel()` function, whereas `hansel.arguments` picks up all four parameters, including the year value introduced by the `gretel()` function.

constructor

(See `object.constructor` later in this chapter.)

length

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+

As the `arguments` property of a function proves, JavaScript is very forgiving about matching the number of parameters passed to a function with the number of parameter variables defined for the function. But a script can examine the `length` property of a `Function` object to see precisely how many parameter variables are defined for the function. A reference to the property starts with the function name representing the object. For example, consider the following function definition shell:

```
function identify(name, rank, serialNum)
{
   // ...
}
```

A script statement anywhere outside of the function can read the number of parameters with the reference:

```
identify.length
```

The value of the property in the preceding example is 3. The `length` property supercedes the NN-only `arity` property.

prototype

(See Chapter 18.)

Methods

apply(*[thisObj[, argumentsArray]]*)
call(*[thisObj[, arg1[, arg2[, ... argN]]]]*)

Returns: Nothing

Compatibility: WinIE5.5+, MacIE−, NN6+, Moz+, Safari+, Chrome+

The `apply()` and `call()` methods of a `Function` object invoke the function. This may seem redundant to the normal way in which script statements invoke functions by simply naming the function, following it with parentheses, passing parameters, and so on. The difference with these methods is that you can invoke the function through the `apply()` and `call()` methods using only a reference to the function. For example, if your script defines a function through the `new Function()` constructor (or other anonymous shortcut supported by the browser), you receive a reference to the function as a result of the constructor. To invoke the function later using only that reference (presumably preserved in a global variable), use either the `apply()` or `call()` method. Both of these methods achieve the same result, but choosing one method over the other depends on the form in which the function's parameters are conveyed (more about that in a moment).

The first parameter of both methods is a reference to the object that the function treats as the current object. For garden-variety functions defined in your script, use the keyword `this`, which means that the function's context becomes the current object (just like a regular function). In fact, if there are no parameters to be sent to the function, you can omit parameters to both methods altogether.

The object reference comes into play when the function being invoked is one that is normally defined as a method to a custom object. (Some of these concepts are covered later in this chapter, so you may need to return here after you are familiar with custom objects.)

Example

Consider the following code that generates a custom object and assigns a method to the object to display an alert about properties of the object:

```
// function to be invoked as a method from a 'car' object
function showCar()
{
   alert(this.make + " : " + this.color);
}
// 'car' object constructor function
function Car(make, color)
{
   this.make = make;
   this.color = color;
   this.show = showCar;
}
// create instance of a 'car' object
var myCar = new Car("Ford", "blue");
```

The normal way of getting the `myCar` object to display an alert about its properties is:

```
myCar.show();
```

At that point, the `showCar()` function runs, picking up the current `Car` object as the context for the `this` references in the function. In other words, when the `showCar()` function runs as a method of the object, the function treats the object as the *current object*.

With the `call()` or `apply()` methods, however, you don't have to bind the `showCar()` function to the `myCar` object. You can omit the statement in the `Car()` constructor that assigns the `showCar` function to a method name for the object. Instead, a script can invoke the `showCar()` method and instruct it to treat `myCar` as the current object:

```
showCar.call(myCar);
```

The `showCar()` function operates just as before, and the object reference in the `call()` method's first parameter slot is treated as the current object for the `showCar()` function.

As for succeeding parameters, the `apply()` method's second parameter is an array of values to be passed as parameters to the current function. The order of the values must match the order of parameter variables defined for the function. The `call()` method, on the other hand, enables you to pass individual parameters in a comma-delimited list. Your choice depends on how the parameters are carried along in your script. If they're already in array form, use the `apply()` method; otherwise, use the `call()` method. The (ECMA) recommended way to invoke a function through this mechanism when no parameters need to be passed is via the `call()` method.

Note

Remember, ECMA is the standards organization that oversees the official JavaScript language standard, which is formally known as ECMAScript. ECMAScript is the language specification, whereas JavaScript is an actual implementation. ■

toString()
valueOf()

Returns: String

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+

Scripts rarely, if ever, summon the `toString()` and `valueOf()` methods of a `Function` object. These methods work internally to allow debugging scripts to display a string version of the function definition. For example, when you enter the name of a function defined in The Evaluator (see Chapter 4) into the top text box, JavaScript automatically converts the function to a string so that its value can be displayed in the Results box. Using these methods or parsing the text they return has little, if any, practical application.

Function Application Notes

Understanding the ins and outs of JavaScript functions is the key to successful scripting, especially for complex applications. Additional topics covered in this section include the ways to invoke functions, variable scope in and around functions, recursion, and the design of reusable functions.

Invoking functions

A function doesn't perform any work until a script calls it by name or reference. Scripts invoke functions (that is, get functions to do something) through four routes: document object event

handlers; JavaScript statements; `href` attributes pointing to a `javascript:` URL; and the more modern `call()` and `apply()` methods of the `Function` object. The one approach not yet discussed at length in this book is the `javascript:` URL (some say pseudo-URL).

Several HTML tags have `href` attributes that normally point to Internet URLs for navigating to another page or loading a MIME file that requires a helper application or plug-in. These HTML tags are usually tags for clickable objects, such as links and client-side image map areas.

A JavaScript-enabled browser has a special built-in URL pseudo-protocol — `javascript:` — that lets the `href` attribute point to a JavaScript function or method rather than to a URL on the Net. For example, it is common practice to use the `javascript:` URL to change the contents of two frames from a single link. Because the `href` attribute is designed to point to only a single URL, you'd be out of luck if it weren't for the convenient way that JavaScript gives you access to multiframe navigation. You implement multiframe navigation by writing a function that sets the `location.href` properties of the two frames; then invoke that function from the `href` attribute. The following example shows what the script may look like:

```
function loadPages()
{
   parent.frames[1].location.href = "page2.html";
   parent.frames[2].location.href = "instrux2.html";
}
// ...
<a href="javascript:loadPages()">Next</a>
```

These kinds of function invocations can include parameters, and the functions can do anything you want. One potential side effect to watch out for occurs when the function returns a value (perhaps the function is also invoked from other script locations where a returned value is expected). Because the `href` attribute sets the `target` window to whatever the attribute evaluates to, the returned value is assigned to the `target` window — probably not what you want.

To prevent the assignment of a returned value to the `href` attribute, prefix the function call with the `void` operator:

```
<a href="javascript:void loadPages()">
```

If you don't want the `href` attribute to do anything (that is, you want to let the `onclick` event handler do all the work), assign a blank function after the operator:

```
<a href="javascript:void (0)">
```

Experienced programmers of many other languages recognize this operator as a way of indicating that no values are returned from a function or procedure. The operator has that precise functionality here, but in a nontraditional location.

Variable scope: Globals and locals

A variable can have two scopes in JavaScript. As you might expect, any variable initialized within the main flow of a script (not inside a function) is a *global variable*, in that any statement in the same document's script can access it by name. You can, however, also initialize variables inside a function (in a `var` statement) so the variable name applies only to statements inside that function; the scope is local to the function, so they are *local variables*. By limiting the scope of the variable to a single function, you can reuse the same variable name in multiple functions, thereby enabling the variables to carry

very different information in each function. Keep in mind that when you declare a variable inside of a function without the `var` keyword, you are creating a global variable and not a local variable. Listing 23-2 demonstrates the various possibilities.

LISTING 23-2

Variable Scope Workbench Page

HTML: jsb-23-02.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Variable scope</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-23-02.js"></script>
   </head>
   <body>
      <h1>Variable scope</h1>
      <h3>Charlie Brown has a global dog (Snoopy), a local dog (Gromit),
          a global toy (Gumby), and a local toy (Pokey).</h3>
      <div id="placeHolder"></div>
   </body>
</html>
```

JavaScript: jsb-23-02.js

```
// initialize when the page has loaded
addEvent(window, "load", testValues);

var newElem;
var newText;

var toyGlobal = "Gumby";
var aBoy = "Charlie Brown";
var hisDog = "Snoopy";

function showLocal()
{
   var toyLocal = "Pokey";
   return toyLocal;
}

function showGlobal()
{
   newElem = document.createElement("div");
   newElem.className = "objProperty";
   newText = document.createTextNode("Global version of hisDog is intact: "
             + hisDog);
      // just picked up a global variable value instead
      // of the local variable in the calling function
```

continued

LISTING 23-2 *(continued)*

```
    newElem.appendChild(newText);
    placeHolderElement.appendChild(newElem);
}

function testValues()
{
    // Dangerous ground here -- declaring a global variable in a function
    placeHolderElement = document.getElementById("placeHolder");

    // Now declare the local variable
    var hisDog = "Gromit";  // initializes local version of "hisDog"

        if (placeHolderElement)
        {
            newElem = document.createElement("div");
            newElem.className = "objProperty";
            newText = document.createTextNode("aBoy is: " + aBoy);
                // just picked up a global variable value
            newElem.appendChild(newText);
            placeHolderElement.appendChild(newElem);

            newElem = document.createElement("div");
            newElem.className = "objProperty";
            newText = document.createTextNode("His toyGlobal is " + toyGlobal);
            newElem.appendChild(newText);
                // just picked up another global variable value
            placeHolderElement.appendChild(newElem);

            // Do not bother with toyLocal here because it will throw undefined

            newElem = document.createElement("div");
            newElem.className = "objProperty";
            newText = document.createTextNode(
                      "toyLocal value returned from the showLocal function is: "
                      + showLocal() );
            newElem.appendChild(newText);
            placeHolderElement.appendChild(newElem);

            newElem = document.createElement("div");
            newElem.className = "objProperty";
            newText = document.createTextNode("Local version of hisDog is: " + hisDog);
            newElem.appendChild(newText);
                // just picked up another global variable value
            placeHolderElement.appendChild(newElem);

            // now call another function that does not set the variable hisDog
            // and display the value. we'll see that the global value is intact
            showGlobal();

        }
}
```

In this page, you define a number of variables — some global, others local — that are spread out in the JavaScript file. When you load this page, it runs the testValues() function, which accounts for the current values of all the variable names. The script then follows up with at least one value extraction that was masked in the function. The results of the JavaScript look like this:

```
aBoy is: Charlie Brown
His toyGlobal is Gumby
toyLocal value returned from the showLocal function is: Pokey
Local version of hisDog is: Gromit
Global version of hisDog is intact: Snoopy
```

Examine the variable initialization throughout the JavaScript file. In the beginning of the script there are several lines of code that are not contained within a function; this is the immediate execution section. In that section you define the first variable (toyGlobal) as a global style outside of any function definition. The var keyword for the global variable is optional but often helpful for enabling you to see at a glance where you initialize your variables. You also define two more global variables: aBoy and hisDog.

You then create two short functions. The showLocal() function defines a variable (toyLocal) that only statements in it can use. The showGlobal() function defines a function that simply displays the value of a variable (more on which variable in just a bit).

There is also a testValues() function that is the onload event handler. The first thing you'll notice is a variable (placeHolderElement) declared without the var keyword. Since placeHolderElement is declared within a function, it is a global variable. The testValues() function calls the showGlobal() function that uses the placeHolderElement variable. Why wasn't this variable declaration made in the immediate execution section of the script? The placeHolderElement variable is a reference to one of the elements on the HTML page that uses these functions. The placeHolderElement variable cannot successfully reference the element until the page is fully loaded. The only way to guarantee that the page is loaded before you declare the variable is to place the variable declaration within the onload event handler. Since the testValues() function is the onload event handler, the only way to make this variable available to other functions is to declare it here globally.

Also inside the testValues() function (for purposes of demonstration), you reuse the hisDog variable name. By initializing hisDog with the var statement inside the function, you tell JavaScript to create a separate local variable whose scope is only within the function. This initialization does not disturb the global variable of the same name. It can, however, make things confusing for you as the script author.

Statements in the testValues() function attempt to collect the values of variables scattered around the JavaScript file. Even from within this function, JavaScript has no problem extracting global variables directly, including the one defined in the immediate execution section. But JavaScript cannot get the local variable defined in the showLocal() function; that toyLocal variable is private to its own function. If you try to reference the showLocal() function's variable value from within the showGlobal() function, you will get an error message saying that the variable name is not defined. In the eyes of everyone else outside of the showLocal() function, that's true. If you really need that value, you can have the function return the value to a calling statement, as you do in the testValues() function.

At the beginning of the testValues() function, the script reads the aBoy global value without a hitch. But because you initialized a separate version of hisDog inside that function, only the localized version is available to the testValues() function. If you reassign a global variable name inside a function, you cannot access the global version from inside that function.

As proof that the global variable — whose name was reused inside the `testValues()` function — remains untouched, the `testValues()` function calls the `showGlobal()` function. The `showGlobal()` function displays the value of the `hisDog` variable. Since we're no longer inside the `testValues()` function, we see the value of the global variable `hisDog`. Charlie Brown and his dog, Snoopy, are united.

A benefit of this variable-scoping scheme is that you can reuse throwaway variable names in any function you like. For example, you can use the `i` loop counting variable in every function that employs loops. (In fact, you can reuse it in multiple `for` loops of the same function because the `for` loop reinitializes the value at the start of the loop.) If you pass parameters to a function, you can assign the same names to those parameter variables to aid in consistency. For example, a common practice is to pass an entire form object reference as a parameter to a function (using a `this.form` parameter in the event handler). For every function that catches one of these objects, you can use the variable name `form` in the parameter:

```
function doSomething(form)
{
   // statements
}
// ...
<input type="button" value="Do Something" onclick="doSomething(this.form)">
```

If five buttons on your page pass their form objects as parameters to five different functions, each function can assign `form` (or whatever you want to use) to that parameter value.

We recommend reusing variable names only for these throwaway variables. In this case, the variables are all local to functions, so the possibility of a mix-up with global variables does not exist. But the thought of reusing a global variable name as, say, a special case inside a function sends shivers up our spines. Such a tactic is doomed to cause confusion and error.

Caution

Reusing a global variable name locally is one of the most subtle and therefore difficult bugs to find in JavaScript code. The local variable ends up temporarily hiding the global variable without making any effort to let you know. Just do yourself a favor and make sure you don't reuse a global variable name as a local variable in a function. In the same vein, declaring a global variable within a function may also create bugs that are difficult to find in JavaScript code. ■

Some programmers devise naming conventions to avoid reusing global variables as local variables. A popular scheme puts a lowercase `g` in front of any global variable name. In the example from Listing 23-2, you could have named the global variables:

```
gToyGlobal
gABoy
gHisDog
gPlaceHolderElement
```

Then, if you define local variables, don't use the leading `g`. A similar scheme involves using an underscore character (_) global instead of a `g` in front of global variable names. In the example from Listing 23-2, you could have named the `local` variables:

```
_ToyLocal
_HisDog
```

Any scheme you employ to prevent the reuse of variable names in different scopes is fine, as long as it does the job. The same can be said of any scheme that clearly identifies global variables.

In a multiframe or multiwindow environment, your scripts can also access global variables from any other document currently loaded into the browser. For details about this level of access, see Chapter 27, "Window and Frame Objects."

Variable scoping rules apply equally to nested functions. Any variables defined in an outer function (including parameter variables) are exposed to all functions nested inside. But if you define a new local variable inside a nested function, that variable is not available to the outer function. Instead, you can return a value from the nested function to the statement in the outer function that invokes the nested function.

Parameter variables

When a function receives data in the form of parameters, remember that the values may be copies of the data (in the case of run-of-the-mill data values) or references to real objects (such as a form object). In the latter case, you can change the object's modifiable properties in the function when the function receives the object as a parameter, as shown in the following example:

```
function validateCountry(form)
{
   if (form.country.value == "")
   {
      form.country.value = "USA";
   }
}
```

Therefore, whenever you pass an object reference as a function parameter, be aware that the changes you make to an object you've passed into a function affect the real object.

As a matter of style, if our function needs to extract properties, or results of methods, from passed data (such as object properties or string substrings), we like to do that at the start of the function. We initialize as many variables as needed for each piece of data used later in the function. This task enables us to assign meaningful names to the data chunks, rather than rely on potentially long references within the working part of the function (such as using a variable like `inputStr` instead of `form.entry.value`). Today's machines are so incredibly fast that we don't really need to do this for machine speed; we're doing it for human speed — the code is now more readable and maintainable. Here's a quick example:

```
function updateContactInfo(form)
{
   var firstName = form.firstname.value;
   // or the preferred way:
   var lastName = document.getElementById("lastname").value;
   var address1 = document.getElementById("addr1").value;
   var address2 = document.getElementById("addr2").value;
   var phone = document.getElementById("phone").value;
   var email = document.getElementById("email").value;

   // Process contact info using local variables
}
```

Notice in this example how the form field information is first stored in local variables, which are then used to carry out the hypothetical updating of contact information. Throughout the remainder of the function you can use the local variables instead of the longer and less wieldy form fields.

Recursion in functions

In what may come as a strange surprise, it is possible for functions to call themselves — a process known as *recursion*. The classic example of programmed recursion is the calculation of the factorial (the factorial for a value of 4 is `4 * 3 * 2 * 1`), shown in Listing 23-3.

In the third line of this function, the statement calls itself, passing along a parameter of the next lower value of `n`. As this function executes, diving ever deeper into itself, JavaScript watches intermediate values and performs the final evaluations of the nested expressions. If designed properly, a recursive function eventually stops calling itself, and the program flow eventually returns back to the original function call.

Recursive functions are dangerous in the sense that they can easily fall into an infinite state (popularly called an *infinite loop*). For this reason, it is very important that you test them carefully. In particular, make sure that the recursion is finite: that a limit exists for the number of times it can recurse. In the case of Listing 23-3, that limit is the initial value of `n`. Failure to watch out for this limit may cause the recursion to overpower the limits of the browser's memory and even lead to a crash.

LISTING 23-3

A JavaScript Function Utilizing Recursion

```
function factorial(n)
{
   if (n > 0)
   {
      return n * (factorial(n-1));
   } else
   {
      return 1;
   }
}
```

Turning functions into libraries

As you start writing functions for your scripts, be on the lookout for ways to make functions generalizable (written so that you can reuse the function in other instances, regardless of the object structure of the page). The likeliest candidates for this kind of treatment are functions that perform specific kinds of validation checks (see examples in Chapter 46, "Data-Entry Validation," on the CD-ROM), data conversions, or iterative math problems.

To make a function generalizable, don't let it make any references to specific objects by name. Object names generally change from document to document. Instead, write the function so that it accepts a named object as a parameter. For example, if you write a function that accepts a `text` object as its parameter, the function can extract the object's data or invoke its methods without knowing anything about its enclosing form or name. Look again, for example, at the `factorial()` function, but now as part of an entire document in Listing 23-4.

LISTING 23-4

Calling a Generalizable Function

HTML: jsb-23-04.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Variable Scope Trials</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-23-04.js"></script>
   </head>
   <body>
      <h1>Variable Scope Trials</h1>
      <form id="theForm" action="calc-factorial.php" method="get">
         <p>
            <label for="visitorInput">Enter an input value:</label>
            <input type="text" id="input" name="input" value="0">

            <input type="submit" value="Calc Factorial">

            <label for="output">Results:</label>
            <input type="text" id="output" value="">
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb-23-04.js

```
// initialize when the page has loaded
addEvent(window, "load", initialize);

function initialize()
{
   // intercept form submission
   addEvent(document.getElementById("theForm"), "submit", calcFactorial);
}

function calcFactorial(evt)
{
   // consolidate event handling
   if (!evt) evt = window.event;

   // plug transformed input to output field
   var oInput = document.getElementById("input");
   var oOutput = document.getElementById("output");
```

continued

LISTING 23-4 *(continued)*

```
        // if they both exist
        if (oInput && oOutput)
        {
           oOutput.value = factorial(oInput.value);
        }

     // cancel form submission
        // W3C DOM method (hide from IE)
        if (evt.preventDefault) evt.preventDefault();
        // IE method
        return false;
}

function factorial(n)
{
        if (n > 0)
        {
           return n * (factorial(n - 1));
        }
        else
        {
           return 1;
        }
}
```

This function is designed to be generalizable, accepting only the input value (`n`) as a parameter. In the form, the `onsubmit` event handler sends only the input value from one of the form's fields to the `factorial()` function. The returned value is assigned to the output field of the form. The `factorial()` function is totally ignorant about forms, fields, or buttons in this document. If you need this function in another script, you can copy and paste it into that script knowing that it has been pre-tested. Any generalizable function may be part of your personal library of scripts — from which you can borrow — and save time in future scripting tasks.

You cannot always generalize a function. Somewhere along the line in your scripts, you will have to have references to JavaScript or custom objects. But if you find that you're frequently writing functions that perform the same kind of actions, see how you can generalize the code and put the results in your library of ready-made functions. You should also consider placing these reusable library functions in an external `.js` library file, as you've seen us do in this chapter and in others. You can also see Chapter 4 for details on this convenient way to share utility functions among many documents.

Making sense of closures

A topic that has confused many an aspiring scripter is closures, which may enter the picture when you declare a function within another function. At the core of JavaScript, *closures* refer to the fact that you can keep a local variable defined in a function alive even after the function has executed — which normally signals the end of life for a local variable. That's right, it's possible for a function to return

and its local variables to go on living like some kind of strange zombie data. How is this possible? Take a look at an example:

```
function countMe()
{
  var count = 1;
  var showCount = function() { alert(count); }
  count++;
  return showCount;
}
```

The unusual thing to note about this code is how the inner function assigned to the `showCount` variable is returned by the function. When you call the `countMe()` function, you receive a reference to the inner function that displays the `count` variable value. That wouldn't be a problem, except for the fact that the inner function acts on a variable (`count`) that is local to the `countMe()` function.

To see the closure come to life, take a look at this code that calls the `countMe()` function:

```
var countamatic = countMe();
countamatic();
```

The first line calls the `countMe()` function, which results in the local `count` variable being created, and a reference to the inner function being passed out and stored in the `countamatic` variable. The local variable `count` is also incremented within the `countMe()` function. Without knowing about closures, you would clearly be in some serious gray area at this point because the `countamatic()` function defined in the first line is now set to display the value of a variable that is clearly out of scope. But JavaScript works a miracle by keeping the `count` variable alive in a closure and still allowing the `countamatic()` function to access it. Thus, the second statement displays an alert with the number 2 in it.

If closures still seem a bit mysterious, just remember that a potential closure is created any time you specify a function within another function. You really only take advantage of a closure when you pass an inner function reference outside the scope of the function in which it is defined.

Okay, so closures reveal a sneaky way to manipulate scope in JavaScript, but what good are they? Closures are gaining a great deal of usage in Ajax applications because Ajax programming often uses them to work around inherent limitations in how you normally use the `this` keyword.

Cross-Reference

For more on Ajax, see Chapter 39, "Ajax, E4X, and XML." ■

Although we could just pawn everything closure-related off on Ajax, we can demonstrate a simple but practical application of how closures can help you carry out the seemingly impossible. Consider the scenario where you want to set a timer that calls a function after an interval of time has elapsed. You may be thinking: No problem — just create a function and pass its reference to the `setTimeout()` function. End of story. What we didn't mention is that you need to pass a couple of parameters to the function. See the problem?

Unless you design with anonymous functions, there is no mechanism for using parameters when you pass a function reference to another function, as in specifying a timer event handler when

calling the `setTimeout()` function. Now take a look at this code that uses closures to circumvent the problem:

```
function wakeupCaller(name, roomnum)
{
   return
   (
      function()
      {
         alert("Call " + name + " in room #" + roomnum + ".");
      }
   );
}
```

By placing a zero-param function within a parameterized function, you now have the ingredients for a timer handler that can accept parameters. The next step is to create an actual function reference that uses the closure:

```
var wakeWilson = wakeupCaller("Mr. Wilson", 515);
```

At this point, you've passed parameters to a function and received a zero-param function reference in return, which can then be passed along to the `setTimeout()` function:

```
setTimeout(wakeWilson, 600000);
```

Thanks to closures, Mr. Wilson will now get his wake up call!

Caution

Before you dive into closures and begin exploiting them in all of your code, let us caution you that they can result in some tricky bugs when used incorrectly. Extensive use of closures involving references to DOM objects can also cause memory leaks (gradual increase of memory used by the browser) if the objects are not disposed of (that is, set to `null`) when they are no longer needed. Definitely spend the time to explore closures in more detail before you get too wild with them. ■

Creating Your Own Objects with Object-Oriented JavaScript

In all the previous chapters of this book, you've seen how conveniently the browser document object models organize all the information about the browser window and its document. More specifically, you learned how to use standard objects as a means of accessing different aspects of the browser window and document. What may not be obvious from the scripting you've done so far is that JavaScript enables you to create your own objects in memory — objects with properties and methods that you define. These objects are not user-interface elements on the page, but rather the kinds of objects that may contain data and script functions (behaving as methods) whose results the user can see displayed in the browser window.

You actually had a preview of this power in the discussion about arrays (Chapter 18, "The Array Object"). An array, you recall, is an ordered collection of data. An object typically contains different kinds of data. It doesn't have to be an ordered collection of data — although your scripts can

use objects in constructions that strongly resemble arrays. Moreover, you can attach any number of custom functions as methods for that object. You are in total control of the object's structure, data, and behavior.

The practice of employing custom objects in your JavaScript code is known as *object-oriented programming*, or *OO programming* for short. OO has been around a long time and has been used to great success in other programming languages such as C++ and Java. However, the scripted nature of JavaScript has caused OO to catch on a bit more slowly in the JavaScript world. Even so, support for custom objects is a standard part of modern JavaScript-enabled browsers and is something you should consider taking advantage of whenever prudent.

Note

To split hairs, technically, we have to clarify that JavaScript isn't truly an object-oriented language in a strict sense. Instead, JavaScript is considered an *object-based* language. The difference between object-oriented and object-based is significant and has to do with how objects can be extended. Even so, conceptually, JavaScript's support of objects is enough akin to true OO languages that it's not unreasonable to discuss JavaScript in OO terms. You learn about some of the specific object features that allow JavaScript to approach OO languages later in the chapter. What's of further interest is that ECMAScript now supports the notions of classes, interfaces, etc., in terms that are closer to the traditional OO manner, which means that the next release(s) of JavaScript will start to support these notions as well. ■

There is no magic to knowing when to use a custom object instead of an array in your application. The more you work with and understand the way custom objects work, the more likely you will think about your data-carrying scripts in these terms — especially if an object can benefit from having one or more methods associated with it. This avenue is certainly not one for beginners, but we recommend that you give custom objects more than a casual perusal after you have gained some JavaScripting experience.

The nuts and bolts of objects

An *object* in JavaScript is really just a collection of properties. *Properties* can take on the form of data types, functions (methods), or even other objects. In fact, you might find it easier to think of a custom object as an array of values, each of which is mapped to a property (a data type, method, or object). Wait — a method can be a property of an object? We'll see how in just a bit; for now, take it on faith. A function contained in an object is known as a *method*. Methods are no different than other functions, except that they are intended to be used in the context of an object, and therefore are assumed to have access to properties of that object. This connection between properties and methods is one of the core concepts prevalent in OO.

Objects are created using a special function known as a *constructor*, which determines the name of the object — the constructor is given the same name as the object. Here's an example of a constructor function:

```
function Alien()
{
}
```

Although this function doesn't contain any code, it does nonetheless lay the groundwork for creating an `Alien` object. You can think of a constructor as a blueprint that is then used to create actual objects. A word about naming constructor functions: Conventionally, the constructor name is in

TitleCase, and each instance variable referencing the object is in camelCase. Here's an example of how you create an object using a constructor:

```
var myAlien = new Alien();
```

The `new` keyword is used, in conjunction with a constructor, to create JavaScript objects.

Creating properties for custom objects

Earlier we mentioned that properties are key to objects, so you might be wondering how you go about creating a property for a custom object. Custom object properties are created in the constructor with some help from the `this` keyword, as the following code reveals:

```
function Alien()
{
   this.name = "Clyde";
   this.aggressive = true;
}
```

The `this` keyword is used to reference the current object, which in this case is the object that is being created by the constructor. So, you use the `this` keyword to identify new properties for the object. The only problem with this example is that it results in all aliens that are created with the `Alien()` constructor having the same name and aggression. The fix is to pass in the property values to the constructor so that each alien can be customized upon creation:

```
function Alien(name, aggressive)
{
   this.name = name;
   this.aggressive = aggressive;
}
```

Now you can create different aliens that each have their own unique property values:

```
var alien1 = new Alien("Ernest", false);
var alien2 = new Alien("Wilhelm", true);
```

To get to the properties of the object (for reading or writing after the object has been created), use the same type of dot syntax you use with DOM objects. To change the `name` property of one of the objects, the statement would be:

```
alien1.name = "Julius";
```

Creating methods for custom objects

Properties are really only half of the JavaScript OO equation. The other half is methods, which are functions that you tie to objects so that they can access object properties. Following is an example of a method that you might use with the `alien` class:

```
function attack()
{
   if (this.aggressive)
   {
      // Do some attacking and return true to indicate that the attack
      // commenced
```

```
      return true;
   }
   else
   {
      // Don't attack and return false to indicate that the attack didn't
      // happen
      return false;
   }
}
```

Notice that the `attack()` method references the `this.aggressive` property to decide if the attack should take place. The only thing missing at this point is the connection between the `attack()` method and the `alien` object. Without this connection the `this` keyword would have no meaning because there would be no associated object. Here's how the connection is made:

```
function Alien(name, aggressive)
{
   // properties
   this.name = name;
   this.aggressive = aggressive;
   // methods
   this.attack = attack;
}
```

This code clearly illustrates how methods are really just properties: they are declared the same as properties, so they masquerade as properties. A new property named `attack` is created and assigned a reference to the `attack()` method. It's very important to note that the `attack()` method is specified by reference (without the parentheses). Here, then, is the creation of an `alien` object and the invocation of its `attack()` method:

```
var alien1 = new Alien("Ernest", false);
alien1.attack();
```

The way we have defined the attack method above for the alien object places it in the global namespace, which is not a good thing in terms of OO best practices (as you'll see later in this chapter when we discuss encapsulation). A better approach is to embed it in the constructor:

```
function Alien(name, aggressive)
{
   // properties
   this.name = name;
   this.aggressive = aggressive;
   // methods
   this.attack = function(name, aggressive)
   {
      if (this.aggressive)
      {
         // Do some attacking and return true to indicate that
         // the attack commenced
         return true;
      }
      else
      {
```

```
                // Don't attack and return false to indicate that
               // the attack didn't happen
                return false;
            }
        };
    }
```

You're now armed with enough of the basics of JavaScript objects to move on to a more complete example, which the next section provides. This example will be progressively improved over the rest of the sections in this chapter as you build your custom object skills in a step-wise fashion.

An OO example – planetary objects

Building on your familiarity with the planetary data array created in Chapter 18, "The Array Object," this chapter shows you how convenient it is to use the data when it is constructed in the form of an OO design that utilizes custom objects. The application goal for the extended example in this section is to present a drop-down list of the nine planets of the solar system and display the properties of the selected planet.

In this chapter, instead of building arrays to hold the data, you build objects — one object for each planet. The design of your planetary object has five properties and one method. The properties of each planet are name, diameter, distance from the sun, year length, and day length. To assign more intelligence to these objects, in Listing 23-5 you give each of them the capability to display their data below the drop-down list. You can conveniently define one function that knows how to behave with any of these planet objects, rather than having to define nine separate functions. When used within the context of an object, a function is actually referred to as a *method*.

                         "165 years", "15 hours, 48 minutes");
var pluto = new Planet("Pluto", "1500 miles", "3.67 billion miles",
                       "248 years", "6 days, 7 hours");

// invoke Planet object method corresponding to the
// index of the visitor's choice
function doDisplay(popup)
{
   i = popup.selectedIndex;
   eval(popup.options[i].text.toLowerCase() + ".showPlanet()");
}
```

The first task is to define the object constructor function, which performs several important jobs. For one, everything in this function establishes the structure of your custom object: the properties available for data storage and retrieval, and any methods that the object can invoke. The name of the function is the name you use later to create new instances of the object. Therefore, choosing a name that truly reflects the nature of the object is important. And, because you probably want to stuff some data into the function's properties to get one or more instances of the object loaded and ready for the page's user, the function definition includes parameters for each of the properties defined in this object definition.

Inside the object, you use the `this` keyword to assign data that comes in as parameters to labeled properties. For this example, we use the same names for both the incoming parameter variables and the properties. That's primarily for convenience (and is very common practice), but you can assign any parameter and property names you want and connect them any way you like. In the `Planet()` constructor function, five property slots are reserved for every instance of the object, whether or not any data actually is placed in every property (any unassigned slot has a value of `null`).

The last entry in the `Planet()` constructor function is the definition of the `showPlanet()` method. As you do in every JavaScript method you encounter, you must invoke a method by using a reference to the object, a period, and the method name, followed by a set of parentheses. You see that syntax in a minute.

The next long block of statements creates the individual objects according to the definition established in the `Planet()` constructor. Just like in an array, an assignment statement and the keyword `new` create an object. We assign names that are the real names of planets (the `mercury` object reference name refers to the Mercury planet object).

The act of creating a new object sets aside space in memory (associated with the current document) for this object and its properties. An object created in memory is known as an *instance*. In this script, you create nine object instances, each with a different set of properties. Note that no parameter is sent

(or expected by the function) that corresponds to the `showPlanet()` method. Omitting that parameter here is fine because the specification of that method in the object definition means that the script automatically attaches the method to every version (instance) of the planet object that it creates. This is important, because it links the function (method) to the object, thereby providing it access to the object's properties.

The last function definition, `doDisplay()`, is an event handler, invoked whenever the user makes a choice from the list of planets. The first statement extracts the index value of the selected item. Using that index value, the script extracts the text. But things get a little tricky because you need to use that text string as a variable name — the name of the planet — so that you can append to it the call to the `showPlanet()` method. To make the disparate data types come together, use the `eval()` function (see Chapter 24 for a complete discussion). Inside the parentheses, extract the string for the planet name, change it to lowercase, and concatenate a string that completes the reference to the object's `showPlanet()` method. The `eval()` function evaluates that string, which turns it into a valid method call. Therefore, if the user selects jupiter from the drop-down list, the method call becomes `jupiter.showPlanet()`.

Now it's time to look back to the `showPlanet()` method definition. When that method runs in response to a user selection of the planet Jupiter, the method's only scope is of the `jupiter` object. Therefore, all references to `this.propertyName` in `showPlanet()` refer just to `jupiter`. The only possibility for `this.name` in the `jupiter` object is the value assigned to the `name` property for `jupiter`. The same goes for the rest of the properties extracted in the method.

Further encapsulation

One of the benefits of using objects in scripting is that all the "wiring" inside the object — properties and methods — are defined within the local variable scope of the object. It's a concept called *encapsulation*. Thus, when you use the `this` keyword to create object properties and assign values to them inside a constructor function, the property names, and any code associated with them, are private to the object and never conflict with global variable or object names.

In large scripting projects, especially when multiple programmers are involved, it's fairly easy for global names to clash. For example, in Internet Explorer, all DOM object IDs become part of the global variable space because that browser allows scripts to reference an element object simply by its ID (unlike the W3C DOM, which uses the `document.getElementById()` method). As a project grows in size and complexity, it is increasingly important to avoid piling up more and more objects — including function definitions — in the global variable name space.

In Listing 23-5, for example, the `showPlanet()` method is defined in the local name space. It's a local method to the object because the method definition is defined within the `planet()` constructor function. If we were to define the `showPlanet()` method outside of the `Planet()` constructor function (as shown in an earlier example in this chapter), the `showPlanet()` method would be taking up a global object name that might be used elsewhere.

Creating an array of objects

In Listing 23-5, each of the planet objects is assigned to a global variable whose name is that of the planet. If the idea of custom objects is new to you, this idea probably doesn't sound so bad, because it's easy to visualize each variable representing an object. But, as shown in the `doDisplay()` function, accessing an object by name requires use of the `eval()` function to convert a string representation to a valid object reference. Although it's not too important in this simple example, the `eval()` function is not particularly efficient in JavaScript. If you find yourself using an `eval()` function, look

for ways to improve efficiency, such that you can reference an object directly. The way to accomplish that streamlining for this application is to place the objects in an array.

To assign the custom objects in Listing 23-5 to an array, first create an empty array and then assign the result of each object constructor call as an entry in the array. The modified code section would result in Listing 23-6. This partial listing of the code from the external JavaScript file shows just the change in the code. The HTML for Listings 23-5 and 23-6 are exactly the same, so only the code from the partial external JavaScript file is included here. Both files are complete on the CD-ROM.

LISTING 23-6

Array of Planet Objects

JavaScript: partial of jsb-23-06.js

```
// create new Planet objects, and store in an array of reference variables
// 'new' will create a new Planet instance and insert parameter data into object
var planets = new Array
(
   new Planet("Mercury","3100 miles", "36 million miles",
              "88 days", "59 days"),
   new Planet("Venus", "7700 miles", "67 million miles",
              "225 days", "244 days"),
   new Planet("Earth", "7920 miles", "93 million miles",
              "365.25 days","24 hours"),
   new Planet("Mars", "4200 miles", "141 million miles",
              "687 days", "24 hours, 24 minutes"),
   new Planet("Jupiter","88,640 miles","483 million miles",
              "11.9 years", "9 hours, 50 minutes"),
   new Planet("Saturn", "74,500 miles","886 million miles",
              "29.5 years", "10 hours, 39 minutes"),
   new Planet("Uranus", "32,000 miles","1.782 billion miles",
              "84 years", "23 hours"),
   new Planet("Neptune","31,000 miles","2.793 billion miles",
              "165 years", "15 hours, 48 minutes"),
   new Planet("Pluto", "1500 miles", "3.67 billion miles",
              "248 years", "6 days, 7 hours")
);
}
```

The supreme advantage to this approach comes in a modified `doDisplay()` function, which can use the index value from the `select` element's `selectedIndex` directly:

```
function doDisplay(popup)
{
   i = popup.selectedIndex;
   planets[i].showPlanet();
}
```

The presence of so many similar objects cries out for their storage as an array. Here, we are using the numeric value of the drop-down list's `selectedIndex` to locate the proper array element.

Taking advantage of embedded objects

One powerful technique for using custom objects is embedding an object within another object. When you place one object inside another object, the object being placed is known as an *embedded object* or *object property*. Let's extend the planet example to help you understand the implications of using a custom object property.

Say that you want to beef up the planet page with a photo of each planet. Each photo has a URL for the photo file; each photo also contains other information, such as the copyright notice and a reference number, which displays on the page for the user. One way to handle this additional information is to create a separate object definition for a photo database. Such a definition may look like this:

```
function Photo(name, URL, copyright, refNum)
{
   this.name = name;
   this.URL = URL;
   this.copyright = copyright;
   this.refNum = refNum;
}
```

You then need to create individual `photo` objects for each picture. One such definition may look like this:

```
mercuryPhoto = new Photo("Planet Mercury", "/images/merc44.gif",
                         "(c)1990 NASA", 28372);
```

Attaching a `photo` object to a `planet` object requires modifying the `planet` constructor function to accommodate one more property — an object property. The new `planet` constructor looks like this:

```
function Planet(name, diameter, distance, year, day, photo)
{
   this.name = name;
   this.diameter = diameter;
   this.distance = distance;
   this.year = year;
   this.day = day;
   this.showPlanet = showPlanet;
   this.photo = photo; // add photo property
}
```

When the `photo` objects are created, you can then create each `planet` object by passing one more parameter — a `photo` object you want associated with that object:

```
// create new planet objects, and store in a series of variables
Mercury = new Planet("Mercury", "3100 miles", "36 million miles",
                     "88 days", "59 days", mercuryPhoto);
```

To access a property of a `photo` object, your scripts then have to assemble a reference that works its way through the connection with the `planet` object:

```
copyrightData = Mercury.photo.copyright;
```

The potential of embedded objects of this type is enormous. For example, you can embed all the copy elements and image URLs for an online catalog in a single document. As the user selects items to

view (or cycles through them in sequence), a new JavaScript-written page displays the information in an instant. This requires only the image to be downloaded — unless the image was pre-cached, as described in the image object discussion in Chapter 29, “The Document and Body Objects.” In this case, everything works instantaneously — no waiting for page after page of catalog.

If, by now, you think you see a resemblance between this object-within-an-object construction and a relational database, give yourself a gold star. Nothing prevents multiple objects from having the same sub-object as their properties — like multiple business contacts having the same company object property.

The current way to create objects

For current browsers, you can also benefit from a shortcut literal syntax for creating a new object. You can set pairs of property names and their values inside a set of curly braces, and you can assign the whole construction to a variable that becomes the object name. The following script shows how to organize this kind of object constructor:

```
var Earth = {diameter:"7920 miles", distance:"93 million miles", year:"365.25",
             day:"24 hours", showPlanet:showPlanet};
```

Colons link name-value pairs, and commas separate multiple name-value pairs. The value portion of a name-value pair can even be an array (using the `[...]` constructor shortcut) or a nested object (using another pair of curly braces). In fact, you can nest arrays and objects to your heart’s content to create exceedingly complex objects. All in all, this is a very compact way to embed data in a page for script manipulation. If your CGI, XML, and database skills are up to the task, consider using a server program to convert XML data into this compact JavaScript version, with each XML record being its own JavaScript object. For multiple records, assign the curly-braced object definitions to an array entry. Then your scripts on the client can iterate through the data and generate HTML to display the data in a variety of forms, and sorted according to different criteria (thanks to the JavaScript array-sorting powers).

Defining object property getters and setters

The idea of creating getters and setters, generally known in JavaScript as *accessors*, for an object is introduced in Chapter 25, “Document Object Model Essentials,” where they are described in the context of W3C DOM objects. Here, we look at an example of using getters and setters in the context of custom objects.

The purpose of a setter is to assign a new value to a property in an object and at the same time check it for validity if necessary. A setter defines how a new value assigned to the property should apply the value to the object. We would define a getter for each property we wanted to read in the object. In our object, we would typically define a getter and setter for each property of the object. If you have a requirement for a read-only property, then you would define only a getter method.

As you can see in Listing 23-7, both getter and setter methods in the `TitleCaseName` object property are written in the form of methods, using the name of the corresponding property. Reading or writing an object’s property value can include sophisticated processing for either operation. This is called *object literal notation*. Firefox 2.0+, Safari 3.0+, Chrome+, and Opera 9.5+ support this. As of IE8, there is no support for getters and setters for custom objects. This partial listing of the code in the external JavaScript file shows just the change in the code for Listing 23-6. The HTML for

Listings 23-5 and 23-7 are exactly the same, so only the code from the partial external JavaScript file is included here. Both files are complete on the CD-ROM.

LISTING 23-7

Planet Object Constructor Using Getters and Setters

JavaScript: partial of jsb-23-07.js

```
// object property with accessors using object literal notation
// its property 'name', is a String value that is TitleCased when set
var TitleCaseName =
{
   _name: null,

   get name()
   {
     return this._name;
   },

   set name(value)
   {
     this._name = value.substring(0,1).toUpperCase() + value.substring(1);
   }
};

// definition of Planet object constructor
function Planet(name, diameter, distance, year, day)
{
   // properties
   TitleCaseName.name = name;
   this.name = TitleCaseName.name;
   this.diameter = diameter;
   this.distance = distance;
   this.year = year;
   this.day = day;
   // methods
   this.showPlanet = function()
   {
      // . . .
   };
}
```

In our continuing planet scenario, we want to make sure that when a `Planet` object is created, its `name` property is in TitleCase, regardless of how the developer programs the code. This is the perfect opportunity for a setter: we want to take the current value of the `name` property, convert its case, and then apply the new value to the `name` property.

The first thing in the listing is the definition of the getter and setter methods that will be used in the `TitleCaseName` object. You'll notice that the `function` keyword is not used. Once we've defined

our local properties, we define the getters and/or setters. To define each getter, we only need the `get` keyword, followed by the property name we want to read. Typically, we would return the value of the corresponding property. In our case, we're only defining a getter that simply reads the current value of the object's `_name` property and returns it. We use the underscore prefix in `_name` to indicate that this property is strictly internal and should not be referenced outside its containing object.

Similarly, we use the `set` keyword to define each setter. In this case, our setter converts the `value` parameter to TitleCase, and then assigns it to the `_name` property.

The final piece is in the `Planet` object's constructor function. Notice the first two properties in this function. In our case, the value supplied at object instantiation for the `name` property of a planet will "call" the `TitleCaseName` getter and setter function. In the first of these two lines, we assign the name to `TitleCaseName`. This invokes the setter, converting the value to `TitleCase`. In the second line, the getter is invoked, assigning the `TitleCased` name to `Planet` name.

Object-Oriented Concepts

As mentioned previously, JavaScript is object-based rather than object-oriented. This means that instead of adhering to the class, subclass, and inheritance schemes of object-oriented languages such as Java, JavaScript uses what is called *prototype inheritance*. This scheme works not only for native and DOM objects but also for custom objects.

Adding a prototype

A custom object is frequently defined by a constructor function, which typically parcels out initial values to properties of the object, as in the following example:

```
function Car(plate, model, color)
{
   this.plate = plate;
   this.model = model;
   this.color = color;
}
var car1 = new Car("AB 123", "Ford", "blue");
```

Current browsers offer a handy shortcut to stuff default values into properties if none are provided (the supplied value is `null`, `0`, or an empty string). The `OR` operator (`||`) can let the property assignment statement apply the passed value, if present, or a default value you hard-wire into the constructor. Therefore, you can modify the preceding function to offer default values for the properties:

```
function Car(plate, model, color)
{
   this.plate = plate || "missing";
   this.model = model || "unknown";
   this.color = color || "unknown";
}
var car1 = new Car("AB 123", "Ford", "");
```

After the preceding statements run, the `car1` object has the following properties:

```
car1.plate    // value = "AB 123"
car1.model    // value = "Ford"
car1.color    // value = "unknown"
```

You can then add a new property to the constructor's `prototype` property, as in

```
Car.prototype.companyOwned = true;
```

Any `Car` object you already created, or are about to create, automatically inherits the new `companyOwned` property and its value. You can still override the value of the `companyOwned` property for any individual `Car` object. But if you don't override the property for instances of the `Car` object, the `Car` objects whose `companyOwned` property is not overridden automatically inherit any change to the `prototype.companyOwned` value. This has to do with the way JavaScript looks for `prototype` property values. In a similar fashion, we use prototypes in Listing 23-8 in our ongoing improvements to our `Planet` object. This partial listing of the code in the external JavaScript file shows just the change in the code for Listing 23-7. The HTML for Listings 23-5 and 23-8 are exactly the same, so only the code from the partial external JavaScript file is included here. Both files are complete on the CD-ROM.

LISTING 23-8

Planet Object Constructor Using Prototype

JavaScript: partial of jsb-23-08.js

```
// definition of Planet object constructor
function Planet(name, diameter, distance, year, day)
{
   // properties
   TitleCaseName.name = name;
   this.name = TitleCaseName.name;
   this.diameter = diameter;
   this.distance = distance;
   this.year = year;
   this.day = day;
}

Planet.prototype =
{
   constructor : Planet,
   // methods
   showPlanet : function()
   {
      // . . .
   }
};
```

Prototype inheritance

Each time your script attempts to read or write a property of an object, JavaScript follows a specific sequence in search of a match for the property name. The sequence is as follows:

1. If the property has a local value assigned to the current object, this is the value to use.
2. If there is no local value, check the value of the property's prototype of the object's constructor.

3. Continue up the prototype chain until either a match of the property is found (with a value assigned to it) or the search reaches the native `Object` object.

Therefore, if you change the value of a constructor's `prototype` property and you do not override the property value in an instance of that constructor, JavaScript returns the current value of the constructor's `prototype` property.

Nested objects and prototype inheritance

When you begin nesting objects, especially when one object invokes the constructor of another, there is an added wrinkle to the prototype inheritance chain. Let's continue with the `Car` object defined earlier. In this scenario, consider the `Car` object to be akin to a root object that has properties shared among two other types of objects. One of the object types is a company fleet vehicle, which needs the properties of the root `Car` object (`plate`, `model`, `color`) but also adds some properties of its own. The other object that shares the `Car` object is an object representing a car parked in the company garage — an object that has additional properties regarding the parking of the vehicle. This explains why the `Car` object is defined on its own.

Now look at the constructor function for the parking record, along with the constructor for the basic `Car` object:

```
function Car(plate, model, color)
{
   this.plate = plate || "missing";
   this.model = model || "unknown";
   this.color = color || "unknown";
}
function CarInLot(plate, model, color, timeIn, spaceNum)
{
   this.timeIn = timeIn;
   this.spaceNum = spaceNum;
   this.carInfo = car;
   this.carInfo(plate, model, color);
}
```

The `CarInLot` constructor not only assigns values to its unique properties (`timeIn` and `spaceNum`) but it also includes a reference to the `Car` constructor, arbitrarily assigned to a property called `carInfo`. This property assignment is merely a conduit that allows property values intended for the `Car` constructor to be passed within the `CarInLot` constructor function. To create a `CarInLot` object, use a statement like the following:

```
var car1 = new CarInLot("AA 123", "Ford", "blue", "10:02AM", "31");
```

After this statement, the `car1` object has the following properties and values:

```
car1.timeIn      // value = "10:02AM"
car1.spaceNum    // value = "31"
car1.carInfo     // value = reference to car object constructor function
car1.plate       // value = "AA 123"
car1.model       // value = "Ford"
car1.color       // value = "blue"
```

Let's say that five `CarInLot` objects are created in the script (`car1` through `car5`). The prototype wrinkle comes into play if, for example, you assign a new property to the `Car` constructor prototype:

```
Car.prototype.companyOwned = true;
```

Even though the `CarInLot` objects use the `Car` constructor, the instances of `CarInLot` objects do not have a prototype chain back to the `Car` object. As the preceding code stands, even though you've added a `companyOwned` property to the `Car` constructor, no `CarInLot` object inherits that property (even if you were to create a new `CarInLot` object after defining the new `prototype` property for `Car`). To get the `CarInLot` instances to inherit the `prototype.companyOwned` property, you must explicitly connect the prototype of the `CarInLot` constructor to the `Car` constructor prior to creating instances of `CarInLot` objects:

```
CarInLot.prototype = new Car();
```

The complete sequence, then, is as follows:

```
function Car(plate, model, color)
{
   this.plate = plate || "missing";
   this.model = model || "unknown";
   this.color = color || "unknown";
}
function CarsInLot(plate, model, color, timeIn, spaceNum)
{
   this.timeIn = timeIn;
   this.spaceNum = spaceNum;
   this.carInfo = car;
   this.carInfo(plate, model, color);
}
CarsInLot.prototype = new Car();
var car1 = new CarsInLot("123ABC", "Ford","blue","10:02AM", "32");
Car.prototype.companyOwned = true;
```

After this stretch of code runs, the `car1` object has the following properties and values:

```
car1.timeIn            // value = "10:02AM"
car1.spaceNum          // value = "31"
car1.carInfo           // value = reference to car object constructor function
car1.plate             // value = "AA 123"
car1.model             // value = "Ford"
car1.color             // value = "blue"
car1.companyOwned      // value = true
```

NN4+/Moz provides one extra, and proprietary, bit of syntax in this prototype world. The `__proto__` property (that's with double underscores before and after the word *proto*) returns a reference to the object that is next up the prototype chain. For example, if you inspect the properties of `car1.__proto__` after the preceding code runs, you see that the properties of the object next up the prototype chain are as follows:

```
car1.__proto__.plate           // value = "AA 123"
car1.__proto__.model           // value = "Ford"
```

```
car1.__proto__.color          // value = "blue"
car1.__proto__.companyOwned   // value = true
```

This property can be helpful in debugging custom objects and prototype inheritance chain challenges, but the property is not part of the ECMA standard. Therefore, we discourage you from using the property in your production scripts, since it isn't available in non-Mozilla-based browsers.

Object Object

Properties	Methods
constructor	hasOwnProperty()
prototype	isPrototypeOf()
	propertyIsEnumerable()
	toSource()
	toString()
	unwatch()
	valueOf()
	watch()

Syntax

Creating an `Object` object:

```
function constructorName([arg1,...[,argN]])
{
    statement(s)
}
var objName = new constructorName(["argName1",...[,"argNameN"]);
var objName = new Object();
var objName = {propName1:propVal1[, propName2:propVal2[,...N]]}
```

Accessing an `Object` object properties and methods:

```
objectReference.property | method([parameters])
```

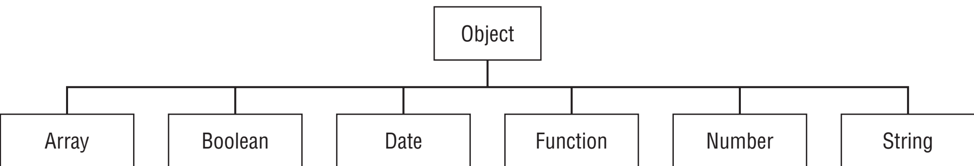
Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Chrome+

About this object

Although it might sound redundant, the `Object` object is a vital native object in the JavaScript environment. It is the root object on which all other native objects — such as `Date`, `Array`, `String`, and the like — are based (see Figure 23-1). This object also provides the foundation for creating custom objects, as described earlier in this chapter.

FIGURE 23-1

The `Object` object hierarchy.



By and large, your scripts do not access the properties of the native `Object` object. The same is true for many of its methods, such as `toString()` and `valueOf()`, which internally allow debugging alert dialog boxes (and The Evaluator) to display something when referring to an object or its constructor. In the case of methods like `toString()` and `valueOf()`, you will typically override these in the child. Similarly, the `toSource()` method returns a string representation of the source code for an object, which is not something you would typically need to use in a script.

A little more practical are the `watch()` and `unwatch()` methods of the `Object` object, which provide a mechanism for taking action when a property value changes. You can call the `watch()` method and assign a function that is called when a certain property changes. This enables you to handle an internal property change as an event. When you're finished watching a property, the `unwatch()` method is used to stop the watchpoint.

Listing 23-9 contains an example of how the `watch()` and `unwatch()` methods can be used to track the value of a property.

LISTING 23-9

Watching an Object Property

HTML: jsb-23-09.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Object Watching</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-23-09.js"></script>
   </head>
   <body>
      <h1>Watching Over You</h1>
      <form id="theForm" action="validate.php" method="get">
         <div>
         <label for="theText">Enter text here: </label>
         <input id="theText" type="text" name="entry" size="50"
                value="Default Value">
         <p><input id="fourScoreButton" type="button" value="Set to Phrase I"
                   onclick="setIt('Four score and seven years ago...')"></p>
         <p><input id="whenInButton" type="button" value="Set to Phrase 2"
                   onclick="setIt('When in the course of human events...')"></p>
```

continued

LISTING 23-9 *(continued)*

```
          <p><input id="resetButton" type="reset"
                    onclick="setIt('Default value')"></p>
          <p><input id="watchButton" type="button" value="Watch It"
                    onclick="watchIt(true)">
             <input id="unWatchButton" type="button" value="Don't Watch It"
                    onclick="watchIt(false)"></p>
          </div>
       </form>
    </body>
</html>
```

JavaScript: jsb-23-09.js

```
function setIt(msg)
{
   document.forms[0].entry.value = msg;
}

function watchIt(on)
{
   var obj = document.forms[0].entry;
      if (on)
      {
         obj.watch("value",report);
      } else
      {
         obj.unwatch("value");
      }
}

function report(id, oldval, newval)
{
   alert("The field's " + id + " property on its way from \n'" +
         oldval + "'\n to \n'" + newval + "'.");
   return newval;
}
```

You can use a trio of methods (`hasOwnProperty()`, `isPrototypeOf()`, and `propertyIsEnumerable()`) to perform some inspection of the prototype environment of an object instance. They are of interest primarily to advanced scripters who are building extensive, simulated, object-oriented applications.

Properties

constructor

Value: Object type Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Chrome+

This is the property that is inherited by any custom, `Array`, `String`, or other objects, when one of those objects is instantiated. It is a reference to the constructor function that was used to create the object. Be aware, though, that if a prototype were used, this property might not contain a valid value. Using the earlier car example, if you were to create a car with the `Car` constructor, then the constructor property would refer to `Car`:

```
var car1 = new Car("AA 123", "Ford", "blue");
   if (car1.constructor == Car)    // would evaluate to true
   {
      // statements dealing with the car object
   }
```

Methods

hasOwnProperty("*propName*")

Returns: Boolean.

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari-, Chrome+

The `hasOwnProperty()` method returns `true` if the current object instance has the property defined in its constructor or in a related constructor function. But if this property is defined externally, as through assignment to the object's `prototype` property, the method returns `false`.

Using the example of the `Car` and `CarInLot` objects from earlier in this chapter, the following expressions evaluate to `true`:

```
car1.hasOwnProperty("spaceNum");
car1.hasOwnProperty("model");
```

Even though the `model` property is defined in a constructor that is invoked by another constructor, the property belongs to the `car1` object. The following statement, however, evaluates to `false`:

```
car1.hasOwnProperty("companyOwned");
```

This property is defined by way of the prototype of one of the constructor functions and is not a built-in property for the object instance.

isPrototypeOf(*objRef*)

Returns: Boolean

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari-, Chrome+

The `isPrototypeOf()` method is intended to reveal whether or not the current object has a prototype relation with an object passed as a parameter. In practice, the IE and NN/Moz versions of this method operate differently and return different results.

propertyIsEnumerable("*propName*")

Returns: Boolean

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari-, Chrome+

In the terminology of the ECMA-262 language specification, a value is enumerable if constructions such as the `for...in` property inspection loop (see Chapter 21, "Control Structures and Exception

Handling”) can inspect it. Enumerable properties include values such as arrays, strings, and virtually every kind of object. According to the ECMA specification, this method is not supposed to work its way up the prototype chain.

toSource()

Returns: String

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari-, Chrome+

The `toSource()` method obtains a string representation of the source code for an object. Unlike the `toString()` method, which returns a string equivalent of the value of an object, the `toSource()` method returns the underlying code for the object as a string. Seeing as how this is a very specialized, low-level feature, the method is typically only used internally by JavaScript, and potentially in some debugging scenarios.

toString()

Returns: String

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari-, Chrome+

The `toString()` method is used to obtain a string representation of the value of an object. It is fairly common to take advantage of this method in situations where an object needs to be examined as raw text. When creating custom objects, you have the ability to create your own `toString()` method that reveals whatever information about the object you desire to be seen.

unwatch("*propName*")

Returns: Boolean

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Chrome+

As the counterpart to the `watch()` method, the `unwatch()` method terminates a watchpoint that has been set for a particular property.

valueOf()

Returns: Object

Compatibility: WinIE5.5+, MacIE-, NN6+, Moz+, Safari-, Chrome+

The `valueOf()` method is used to resolve an object to a primitive data type. This may not always be possible, in which case the method simply returns the object itself. Otherwise, the method returns a primitive value that represents the object.

watch("*propName*")

Returns: Boolean

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Chrome+

The `watch()` method is the key to a handy little JavaScript debugging feature known as watchpoints. A watchpoint enables you to specify a function that is called whenever the value of a property is set. You can then carefully track the state of properties and take action when an important property value changes.

You set a watchpoint by calling the `watch()` method and passing the name of the property that you want to watch, like this:

```
obj.watch("count",
   function(prop, oldval, newval)
   {
      document.writeln(prop + " changed from " + oldval + " to " + newval);
      return newval;
   }
);
```

In this example, a function is created to output a property change notification and then return the new property value. Every watchpoint handler must follow this same convention of using three arguments that specify the property, old value, and new value, respectively.

CHAPTER 24

Global Functions and Statements

IN THIS CHAPTER

Converting strings into object references

Creating URL-friendly strings

Adding comments to scripts

In addition to all the objects and other language constructs described in the preceding chapters of this reference part of the book, several language items need to be treated on a global scale. These items do not apply to any particular objects (or, in fact, to any object), and you can use them anywhere in a script. If you read earlier chapters, you were introduced to many of these functions and statements. This chapter serves as a convenient place to highlight these all-important items that are otherwise easily forgotten. At the end of the chapter, note the brief introduction to several objects that are built into the Windows-only versions of Internet Explorer.

This chapter begins with coverage of the following global functions and statements that are part of the core JavaScript language:

Functions	Statements
`decodeURI()`	`// and /*...*/` (*comment*)
`decodeURIComponent()`	`const`
`encodeURI()`	`var`
`encodeURIComponent()`	
`escape()`	
`eval()`	
`isFinite()`	
`isNaN()`	
`Number()`	
`parseFloat()`	
`parseInt()`	

Functions	Statements
toString()	
unescape()	
unwatch()	
watch()	

Global functions are not tied to the document object model. Instead, they typically enable you to convert data from one type to another. The list of global statements is short, but a couple of them appear extensively in your scripting.

Functions

decodeURI("*encodedURI*")
decodeURIComponent("*encodedURIComponent*")
encodeURI("*URIString*")
encodeURIComponent("*URIComponentString*")

Returns: String

Compatibility: WinIE5.5+, MacIE–, NN6+, Moz+, Safari+, Opera+, Chrome+

The ECMA-262 standard, as implemented in IE5.5+, NN6+, and Mozilla-based browsers, provides utility functions that perform a more rigorous conversion of strings to valid URI strings, and vice versa, than was achieved earlier via the `escape()` and `unescape()` functions (described later in this chapter). In fact, the modern `encodeURI()`, `encodeURIComponent()`, `decodeURI()`, and `decodeURIComponent()` functions serve as replacements to the now deprecated `escape()` and `unescape()` functions.

The purpose of the encoding functions is to convert any string to a version that you can use as a Uniform Resource Identifier, such as a web page address or an invocation of a server CGI script. Whereas Latin alphanumeric characters pass through the encoding process untouched, you must use the encoding functions to convert some symbols and other Unicode characters into a form (hexadecimal representations of the character numbers) that the Internet can pass from place to place. The space character, for example, must be encoded to its hex version: `%20`.

Perhaps the biggest difference between the `encodeURI()` and `escape()` functions (and their `decodeURI()` and `unescape()` counterparts) is that the more modern versions do not encode a wide range of symbols that are perfectly acceptable as URI characters according to the syntax recommended in RFC2396 (`http://www.ietf.org/rfc/rfc2396.txt`). Thus, the following characters are not encoded via the `encodeURI()` function:

```
; / ? : @ & = + $ , - _ . ! ~ * ' ( ) #
```

Use the `encodeURI()` and `decodeURI()` functions only on complete URIs. Applicable URIs can be relative or absolute, but these two functions are wired especially so that symbols that are part of the protocol (`://`), search string (`?` and `=`, for instance), and directory-level delimiters (`/`) are not encoded. The `decodeURI()` function should work with URIs that arrive from servers as page

locations, but be aware that some server CGIs encode spaces into plus symbols (+) that are not decoded back into spaces by the JavaScript function. If the URIs your script needs to decode contain plus symbols in place of spaces, you need to run your decoded URI through a string replacement method to finish the job (regular expressions come in handy here). If you are decoding URI strings that your scripts encoded, use the decode functions only on URIs that were encoded via the corresponding encode function. Do not attempt to decode a URI that was created via the old `escape()` function, because the conversion processes work according to different rules.

The difference between a URI and a URI component is that a *component* is a single piece of a URI, generally not containing delimiter characters. For example, if you use the `encodeURIComponent()` function on a complete URI, almost all of the symbols (other than things such as periods) are encoded into hexadecimal versions — including directory delimiters. Therefore, you should use the component-level conversion functions only on quite granular pieces of a URI. For example, if you assemble a search string that has a name-value pair, you can use the `encodeURIComponent()` function separately on the name and on the value. But if you use that function on the pair that is already in the form `name=value`, the function encodes the equal symbol to a hexadecimal equivalent.

Since the `escape()` and `unescape()` functions were sometimes used on strings that weren't necessarily URL (URI) strings, you will generally use the `encodeURIComponent()` and `decodeURIComponent()` functions when modernizing code that utilizes `escape()` and `unescape()`.

Example

Use The Evaluator (see Chapter 4, "JavaScript Essentials") to experiment with the differences between encoding a full URI and a component, and encoding and escaping a URI string. For example, compare the results of the following three statements:

```
escape("http://www.giantco.com/index.htm?code=42")
encodeURI("http://www.giantco.com/index.htm?code=42")
encodeURIComponent("http://www.giantco.com/index.htm?code=42")
```

Because the sample URI string is valid as is, the `encodeURI()` version makes no changes. Experiment further by making the search string value into a string with a space, and see how each function treats that character.

escape("*URIString*" [,1])
unescape("*escapedURIString*")

Returns: String

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

If you watch the content of the Location field in your browser, you may occasionally see URLs that include a lot of % symbols, plus some numbers. The format you see is *URL encoding* (more accurately called *URI encoding* — Uniform Resource Identifier rather than Uniform Resource Locator). This format allows even multiple word strings and nonalphanumeric characters to be sent as one contiguous string of a very low, common denominator character set. This encoding turns a character, such as a space, into its hexadecimal equivalent value, preceded by a percent symbol. For example, the space character (ASCII value 32) is hexadecimal 20, so the encoded version of a space is `%20`.

All characters, including tabs and carriage returns, can be encoded in this way and sent as a simple string that can be decoded on the receiving end for reconstruction. You can also use this encoding

to preprocess multiple lines of text that must be stored as a character string in databases. To convert a plain-language string to its encoded version, use the `escape()` method. This function returns a string consisting of the encoded version. For example:

```
var theCode = escape("Hello there");
    // result: Hello%20there
```

Most, but not all, non-alphanumeric characters are converted to escaped versions with the `escape()` function. One exception is the plus sign, which URLs use to separate components of search strings. If you must encode the plus symbol, too, then add the optional second parameter to the function to make the plus symbol convert to its hexadecimal equivalent (2B):

```
var a = escape("Adding 2+2");
    // result: Adding%202+2
var a = escape("Adding 2+2",1);
    // result: Adding%202%2B2
```

Note that browser support is not consistent in the treatment of the optional second parameter; the same result could be returned whether or not the second argument is included.

The `unescape()` function was used to convert an escaped string back into plain language. We say "was" because the function is now deprecated thanks to `decodeURI()` and `decodeURIComponent()` and shouldn't be used.

The `escape()` function operates in a way that is approximately midway between the newer functions `encodeURI()` and `encodeComponentURI()`. However, the function is now deprecated in lieu of the newer functions and shouldn't be used.

eval("*string*")

Returns: Object reference

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Expression evaluation, as you probably are well aware by now, is an important concept to grasp for scripting with JavaScript (and for programming in general). An expression evaluates to some value. But occasionally, you need to force an additional evaluation on an expression to receive the desired results. The `eval()` function acts on a string value to force an evaluation of that string expression. Perhaps the most common application of the `eval()` function is to convert a string version of an object reference to a genuine object reference.

Example

The `eval()` function can evaluate any JavaScript statement or expression stored as a string. This includes string equivalents of arithmetic expressions, object value assignments, and object method invocation. We do not recommend that you rely on the `eval()` function, however, because this function is inherently inefficient (from the standpoint of performance). Fortunately, you may not need the `eval()` function to get from a string version of an object's name to a valid object reference. For example, if your script loops through a series of objects whose names include serial numbers, you can use the object names as array indexes rather than use `eval()` to assemble the object references. The inefficient way to set the value of a series of fields named `data0`, `data1`, and so on, is as follows:

```
function fillFields()
{
   var theObj;
```

```
        for (var i = 0; i < 10; i++)
        {
            theObj = eval("document.forms[0].data" + i);
            theObj.value = i;
        }
    }
```

A more efficient way is to perform the concatenation within the index brackets for the object reference:

```
function fillFields()
{
    for (var i = 0; i < 10; i++)
    {
        document.getElementById("myForm").elements["data" + i].value = i;
    }
}
```

Tip

Whenever you are about to use an `eval()` function, look for ways to use string index values of arrays of objects instead. The W3C DOM makes it even easier with the help of the `document.getElementById()` method, which takes a string as a parameter and returns a reference to the named object. ■

`isFinite(`*`number`*`)`

Returns: Boolean

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

It is rare that you will ever need the `isFinite()` function, but its purpose is to advise whether a number is beyond the absolute minimum or maximum values that JavaScript can handle. If a number is outside of that range, the function returns `false`. The parameter to the function must be a number data type.

`isNaN(`*`expression`*`)`

Returns: Boolean

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

For those instances in which a calculation relies on data coming from a text field or other string-oriented source, you frequently need to check whether the value is a number. If the value is not a number, the calculation may result in a script error.

Example

Use the `isNaN()` function to test whether a value is a number, prior to passing the value onto a calculation. The most common use of this function is to test the result of a `parseInt()` or `parseFloat()` function. If the strings submitted for conversion to those functions cannot be converted to a number, the resulting value is `NaN` (a special symbol indicating "not a number"). The `isNaN()` function returns `true` if the value is not a number.

A convenient way to use this function is to intercept improper data before it can do damage, as follows:

```
function calc(form)
{
   var inputValue = parseInt(form.entry.value);
      if (isNaN(inputValue))
      {
         alert("You must enter a number to continue.");
      }
      else
      {
         // statements for calculation
      }
}
```

Probably the biggest mistake scripters make with this function is failing to observe the case of all the letters in the function name. The trailing uppercase "N" is easy to miss.

Number("*string*")
parseFloat("*string*")
parseInt("*string*" [,*radix*])

Returns: Number

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

All three of these functions convert a string value into a numeric value. The `parseInt()` and `parseFloat()` functions are compatible across all versions of all browsers, including very old browsers; the `Number()` function was introduced in version 4 browsers.

Use the `Number()` function when your script is not concerned with the precision of the value, and prefers to let the source string govern whether the returned value is a floating-point number or an integer. The function takes a single parameter — a string to convert to a number value.

The `parseFloat()` function also lets the string source value determine whether the returned value is a floating-point number or an integer. If the source string includes any non-zero value to the right of the decimal, the result is a floating-point number. But if the string value were, say, `"3.00"`, the returned value would be an integer value.

An extra, optional parameter for `parseInt()` enables you to define the number base for use in the conversion. If you don't specify a radix parameter, JavaScript tries to look out for you; but in doing so, JavaScript may cause some difficulty for you. The primary problem arises when the string parameter for `parseInt()` starts with a zero, which a text box entry or database field might do. In JavaScript, numbers starting with zero are treated as octal (base-8) numbers. Therefore, `parseInt("010")` yields the decimal value 8.

When you apply the `parseInt()` function, always specify the radix of 10 if you are working in base-10 numbers. You can, however, specify any radix value from 2 through 36. For example, to convert a binary number string to its decimal equivalent, assign a radix of 2 as follows:

```
var n = parseInt("011",2);
   // result: 3
```

Similarly, you can convert a hexadecimal string to its decimal equivalent by specifying a radix of 16:

```
var n = parseInt("4F",16);
    // result: 79
```

Example

Both parseInt() and parseFloat() exhibit a very useful behavior: If the string passed as a parameter starts with at least one number followed by, say, letters, the functions do their jobs on the numeric part of the string and ignore the rest. This is why you can use parseFloat() on the navigator.appVersion string to extract just the reported version number without having to parse the rest of the string. For example, Firefox 1.0 for Windows reports a navigator.appVersion value as

```
5.0 (Windows; en-US)
```

But you can get just the numeric part of the string via parseFloat():

```
var ver = parseFloat(navigator.appVersion);
```

Note

The number stored in the navigator.appVersion property refers to the version number of the underlying browser engine, which helps explain why the reported version in this case is 5.0, even though the Firefox browser application is considered version 1.0. ■

Because the result is a number, you can perform numeric comparisons to see, for instance, whether the version is greater than or equal to 4.

toString([*radix*])

Returns: String

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Every JavaScript core language object and every DOM document object has a toString() method associated with it. This method is designed to render the contents of the object as a string of text that is as meaningful as possible. Table 24-1 shows the result of applying the toString() method on each of the convertible core language object types.

TABLE 24-1

toString() Method Results for Object Types

Object Type	Result
String	The same string
Number	String equivalent (but numeric literals cannot be converted)
Boolean	true or false
Array	Comma-delimited list of array contents (with no spaces after commas)
Function	Decompiled string version of the function definition

toString()

Many DOM objects can be converted to a string. For example, a `location` object returns its URL. But when an object has nothing suitable to return for its content as a string, it usually returns a string in the following format:

```
[object objectType]
```

Example

The `toString()` method is available on all versions of all browsers. By setting the optional `radix` parameter between 2 and 16, you can convert numbers to string equivalents in different number bases. Listing 24-1 calculates and draws a conversion table for decimal, hexadecimal, octal, and binary numbers between 0 and 20. In this case, the source of each value is the value of the index counter variable, each time the `for` loop's statements execute.

Note

The function to assign event handlers throughout the code in this chapter and much of the book is `addEvent()`, a cross-browser event handler explained in detail in Chapter 32, "Event Objects."

The `addEvent()` function is part of the script file `jsb-global.js` located on the accompanying CD-ROM in the `Content/` folder, where it is accessible to all chapters' scripts. ■

LISTING 24-1

Using toString() with Radix Values

HTML: jsp-24-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Using toString() to convert to other number bases:</title>
      <link rel="stylesheet" type="text/css" href="jsp-24-01.css">
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-24-01.js"></script>
   </head>
   <body>
      <h1>Using toString() to convert to other number bases:</h1>
      <table id="numberConversions">
         <tr>
            <th>Decimal</th>
            <th>Hexadecimal</th>
            <th>Octal</th>
            <th>Binary</th>
         </tr>
      </table>
   </body>
</html>
```

CSS: jsp-24-01.css

```
th, td
{
   border: 5px groove black;
```

```
   text-align: center;
   padding-left: 2px;
   padding-right: 2px;
}

th
{
   font-weight: bold;
}
```

JavaScript: jsb-24-01.js

```
// initialize when the page has loaded
addEvent(window, "load", initialize);

function initialize()
{
   var theTable = document.getElementById("numberConversions");

      if (theTable)
      {
         var newRowElem;
         var newCellElem;
         var newText;
         // Insert the rows after the existing row
         var newRowPosition = 1;

         // put the converted number data into the table
         for (var i = 0; i <= 20; i++)
         {

            // create a new row
            newRowElem = theTable.insertRow(newRowPosition);

            // create the 1st new cell in the new row and its text
            newCellElem = newRowElem.insertCell(0);
            newText = document.createTextNode(i.toString(10));
            newCellElem.appendChild(newText);

            // create the next new cell in the new row and its text
            newCellElem = newRowElem.insertCell(1);
            newText = document.createTextNode(i.toString(8));
            newCellElem.appendChild(newText);

            // create the next new cell in the new row and its text
            newCellElem = newRowElem.insertCell(1);
            newText = document.createTextNode(i.toString(16));
            newCellElem.appendChild(newText);

            // create the next new cell in the new row and its text
            newCellElem = newRowElem.insertCell(2);
            newText = document.createTextNode(i.toString(2));
```

continued

LISTING 24-1 *(continued)*

```
              newCellElem.appendChild(newText);

              newRowPosition += 1;

           }
        }
}
```

The `toString()` method of user-defined objects does not convert the object into a meaningful string, but you can create your own method to do just that. For example, if you want to make your custom object's `toString()` method behave like an array's method, define the action of the method and assign that function to a property of the object (as shown in Listing 24-2).

LISTING 24-2

Creating a Custom toString() Method

HTML: jsp-24-02.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>A custom object defined toString() result:</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-24-02.js"></script>
   </head>
   <body>
      <h1>A custom object defined toString() result:</h1>
      <!-- Hard code what's in the object so we can validate
           the JavaScript visually on the page. -->
      <h3>The custom object is book and its properties are</h3>
      <h4>title:"The Aeneid", author:"Virgil", pageCount:543</h4>
      <h3>Now let's look at the results of the custom object's toString() in
          the JavaScript:</h3>
      <div id="placeHolder"></div>
   </body>
</html>
```

JavaScript: jsb-24-02.js

```
// initialize when the page has loaded
addEvent(window, "load", initialize);

var newElem;
var newText;
```

```
// define the function that will be the method for the custom object
function customToString()
{
   var dataArray = new Array();
   var count = 0;
   for (var i in this)
   {
      dataArray[count++] = this[i];
         if (count > 2)
         {
            break;
         }
   }
   return dataArray.join(",");
}

// define a custom object
var book = { title:"The Aeneid", author:"Virgil", pageCount:543 };

// declare a method for the custom object
book.toString = customToString;

// the onload event we identified earlier
function initialize()
{

   var placeHolderElement = document.getElementById("placeHolder");

      if (placeHolderElement)
      {
         //book.toString();

         newElem = document.createElement("h4");
         newText = document.createTextNode(book.toString());
         // insert the text into the new h4
         newElem.appendChild(newText);
         // insert the completed h4 into placeholder
         placeHolderElement.appendChild(newElem);

      }

}
```

When you run Listing 24-2, you can see how the `custom` object's `toString()` handler extracts the values of all elements of the object. You can customize how the data should be labeled and/or formatted.

Keep in mind that you can provide a custom `toString()` method to any object that you create, not just arrays. This is a handy way to provide a glimpse at the contents of an object for debugging purposes. For example, you could craft a `toString()` method that carefully formats all of the properties of an object into an easily readable string of text. Then, use an alert box or browser debugging console to view the contents of the object if a problem arises.

```
unwatch(property)
watch(property, handler)
```

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN4+, Moz-, Safari-, Opera-, Chrome-

To supply the right kind of information to external debuggers, JavaScript in NN4+ implements two global functions that belong to every object — including user-defined objects. The `watch()` function keeps an eye on a desired object and property. If that property is set by assignment, the function invokes another user-defined function that receives information about the property name, its old value, and its new value. The `unwatch()` function turns off the watch functionality for a particular property.

Statements

//
/*...*/

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Comments are statements that the JavaScript interpreter (or server-side compiler) ignores. However, these statements enable authors to leave notes about how things work in their scripts. Although lavish comments are useful to authors during a script's creation and maintenance, the full content of a client-side comment is downloaded with the document. Every byte of non-operational content of the page takes a bit more time to download. Still, we recommend lots of comments — particularly as you create a script.

JavaScript offers two styles of comments. One style consists of two forward slashes (no spaces between them), and is useful for creating a comment on a single line. JavaScript ignores any characters to the right of those slashes on the same line, even if they appear in the middle of a line. You can stack as many lines of these single-line comments as is necessary to convey your thoughts. We typically place a space between the second slash and the beginning of the comment. The following are examples of valid, one-line comment formats:

```
// this is a comment line usually about what's to come
var a = "Fred";  // a comment about this line
// You may want to capitalize the first word of a comment
// sentence if it runs across multiple lines.
//
// And you can leave a completely blank line, like the one above.
```

For longer comments, it is usually more convenient to enclose the section in the other style of comment, which is fully capable of spanning multiple lines. The following comment opens with a forward slash and asterisk (`/*`) and ends with an asterisk and forward slash (`*/`). JavaScript ignores all statements in between — including multiple lines. If you want to temporarily comment out a large segment of your script for debugging purposes, it is easiest to enclose the segment with these comment symbols. To make comment blocks easier to find, we generally place the symbols on their own lines as follows:

```
/*
some
  commented-out
    statements
*/
```

If you are developing rather complex scripts, you might find using comments a convenient way to help you organize segments of your scripts and make each segment easier to find. For example, you can define a comment block above each function and describe what the function is about, as in the following example.

```
/*-----------------------------------------------
   calculate()
   Performs a mortgage calculation based on
   parameters blah, blah, blah.  Called by blah
   blah blah.
-----------------------------------------------*/
function calculate(form)
{
   // statements
}
```

const

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `const` keyword initializes a constant. Unlike a variable, whose data is subject to change while a page loads, a constant's value cannot be modified once it is assigned. It is common practice in many programming languages to define constant identifiers with all uppercase letters, usually with underscore characters to delimit multiple words. This style makes it easier to quickly find constants in your code and reminds you that their values are fixed.

Example

Listing 24-3 shows how you can use a constant in any browser other than IE. The page conveys temperature data for several cities. (Presumably, this data is updated on the server and fashioned into an array of data when the user requests the page.) For temperatures below freezing, the temperature is shown in a distinctive text style. Because the freezing temperature is a constant reference point, it is assigned as a constant.

LISTING 24-3

Using the const Keyword

HTML: jsp-24-03.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>The const keyword</title>
```

continued

LISTING 24-3 *(continued)*

```
      <link rel="stylesheet" type="text/css" href="jsp-24-03.css">
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb-24-03.js"></script>
   </head>
   <body>
      <h1>The const keyword</h1>
      <table id="temps">
         <tr>
            <th>City</th>
            <th><div>Temperature</div><div>(Fahrenheit)</div></th>
         </tr>
      </table>
   </body>
</html>
```

CSS: jsp-24-03.css

```
.cold
{
   font-weight: bold;
   color: blue;
}

td
{
   text-align: center;
}
```

JavaScript: jsb-24-03.js

```
// initialize when the page has loaded
addEvent(window, "load", showData);

const FREEZING_F = 32;

var cities = ["London", "Moscow", "New York", "Tokyo", "Sydney"];

var cityTempsF = [33, 12, 20, 40, 75];

function showData()
{
   var theTable = document.getElementById("temps");

      if (theTable)
      {
         var newRowElem;
         var newCellElem;
         var newText;
         // Insert the rows after the existing row
         var newRowPosition = 1;
```

```
      // put the city temperature data in the table
      for (var i = 0; i < cities.length; i++)
      {
         // create a new row
         newRowElem = theTable.insertRow(newRowPosition);

         // create the new city cell in the new row and its text
         newCellElem = newRowElem.insertCell(0);
         newText = document.createTextNode(cities[i]);
         newCellElem.appendChild(newText);

         // create the new temp cell in the new row and its text
         newCellElem = newRowElem.insertCell(1);
         newText = document.createTextNode(cityTempsF[i]);
         newCellElem.appendChild(newText);

         // style the cells with cold data
            if (cityTempsF[i] < FREEZING_F)
            {
               newCellElem.className = "cold";
            }
         newRowPosition += 1;
      }
   }
}
```

The `const` keyword likely will be adopted in the next version of the ECMA-262 standard and will become an official part of the JavaScript vernacular in future browsers. In the meantime, it enjoys full support in Mozilla-based browsers.

var

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Before using any variable, you should declare it (and optionally, initialize it with a value) via the `var` statement. If you omit the `var` keyword, the variable is automatically assigned as a global variable within the current document. To keep a variable local to a function, you must declare or initialize the variable with the `var` keyword inside the function's braces.

If you do not assign a value to a variable, it evaluates to `null`. Because a JavaScript variable is not limited to one variable type during its lifetime, you don't need to initialize a variable to an empty string or zero unless that initial value helps your scripting. (For example, if you initialize a variable as an empty string, you can then use the add-by-value operator (+=) to append string values to that variable in a future statement in the document.)

To save statement lines, you can declare, and/or initialize, multiple variables with a single `var` statement. Separate each `varName=value` pair with a comma, as in

```
var name, age, height;  // declare as null
var color = "green", temperature = 85.6; // initialize
```

Variable names (also known as identifiers) must be one contiguous string of characters, and the first character must be a letter. Many punctuation symbols are banned, but the underscore character is

valid and is often used to separate multiple words in a long variable name. All variable names (like most identifiers in JavaScript) are case-sensitive, so you must name a particular variable identically throughout the variable's scope.

By convention, variable names are written in camelCase, as in

```
var colorCode = "green";
```

WinIE Objects

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

For better or worse, Microsoft prides itself on the integration between web browser functionality and the Windows operating system. The linkage between browser and OS is most apparent in IE's facilities for accessing ActiveX objects. Microsoft has fashioned several such objects for access to scripters — again, provided the deployment is intended only for Windows versions of Internet Explorer. Some objects also exist as a way to expose some Visual Basic Script (VBScript) functionality to JavaScript. Because these objects are more within the realm of Windows and ActiveX programming, the details and quirks of working with them from WinIE is best left to other venues. But in case you are not familiar with these facilities, the following discussions introduce the basic set of WinIE objects. You can find more details at the Microsoft Developer Network (MSDN) web site at `http://msdn.microsoft.com/`.

The objects mentioned here are the `ActiveXObject`, `Dictionary`, `Enumerator`, and `VBArray` objects. Microsoft documents these objects as if they were part of the native JScript language. However, you can be sure that they will remain proprietary to Internet Explorer, if not exclusively for Windows-only versions.

Note

JScript is Microsoft's proprietary take on JavaScript, supported by Internet Explorer. JScript is essentially the same as JavaScript with a few Windows-specific extras thrown in, such as support for ActiveX objects. ■

ActiveXObject

`ActiveXObject` is a generic object that allows your script to open and access what Microsoft sometimes calls *automation objects*. An automation object is an executable program that might run on the client or be served from a server. This can include local applications, such as applications from the Microsoft Office suite, executable DLLs (dynamic-link libraries), and so on.

Use the constructor for the `ActiveXObject` to obtain a reference to the object according to the following syntax:

```
var objRef = new ActiveXObject(appName.className[, remoteServerName]);
```

This JScript syntax is the equivalent of the VBScript `CreateObject()` method. You need to know a bit about Windows programming to determine the application name and the classes or types available for that application. For example, to obtain a reference to an Excel worksheet, use this constructor:

```
var mySheet = new ActiveXObject("Excel.Sheet");
```

Once you have a reference to the desired object, you must also know the names of the properties and methods of the object you'll be addressing. You can access much of this information via Microsoft's developer tools, such as Visual Studio .NET, or the tools that come with Visual Basic .NET. These

tools enable you to query an object to discover its properties and methods. Unfortunately, an `ActiveXObject`'s properties are not enumerable through a typical JavaScript `for...in` property inspector.

Accessing an `ActiveXObject`, especially one on the client, involves some serious security considerations. The typical security setup for an IE client prevents scripts from accessing client applications, at least not without asking the user if it's okay to do so. While it's foolhardy to state categorically that one cannot perform surreptitious inspection or damage to a client without the user's knowledge (hackers find holes from time to time), it is highly unlikely. In a corporate environment, where some level of access to all clients is desirable, the client may be set up to accept instructions to work with ActiveX objects when they come from trusted sources. The bottom line is that unless you are well versed in Windows programming, don't expect the `ActiveXObject` to become some kind of magic portal that enables you to invade the privacy or security of unsuspecting users.

Dictionary

Although the `Dictionary` object is very helpful to VBScript authors, JavaScript already provides the equivalent functionality natively. A `Dictionary` object behaves very much like a JavaScript array that has string index values (similar to a Java hash table), although numeric index values are also acceptable in the `Dictionary`. Indexes are called *keys* in this environment. VBScript arrays do not have this facility natively, so the `Dictionary` object supplements the language for the sake of convenience. Unlike a JavaScript array, however, you must use the various properties and methods of the `Dictionary` object to add, access, or remove items from it.

You create a `Dictionary` object via the `ActiveXObject` as follows:

```
var dict = new ActiveXObject("Scripting.Dictionary");
```

You must create a separate `Dictionary` object for each array. Table 24-2 lists the properties and methods of the `Dictionary` object. After you create a blank `Dictionary` object, populate it via the `Add()` method for each entry. For example, the following statements create a `Dictionary` object to store U.S. state capitals:

```
var stateCaps = new ActiveXObject("Scripting.Dictionary");
stateCaps.Add("Illinois", "Springfield");
```

You can then access an individual item via the `Key` property (which, thanks to its VBScript heritage, looks more like a JavaScript method). One convenience of the `Dictionary` object is the `Keys()` method, which returns an array of all the keys in the dictionary — something that a string-indexed JavaScript array could use.

Enumerator

An `Enumerator` object provides JavaScript with access to collections that otherwise do not allow direct access to their items, via index number or name. This object isn't necessary when working with DOM collections, such as `document.all`, because you can use the `item()` method to obtain a reference to any member of the collection. But if you are scripting ActiveX objects, some of these objects' methods or properties may return collections that cannot be accessed through this mechanism or the JavaScript `for...in` property inspection technique. Instead, you must wrap the collection inside an `Enumerator` object.

To wrap a collection in an `Enumerator`, invoke the constructor for the object, passing the collection as the parameter:

```
var myEnum = new Enumerator(someCollection);
```

TABLE 24-2

Dictionary Object Properties and Methods

Property	Description
`Count`	Integer number of entries in the dictionary (read-only)
`Item("key")`	Reads or writes a value for an entry whose name is `key`
`Key("key")`	Assigns a new key name to an entry
Method	**Description**
`Add("key", value)`	Adds a value associated with a unique key name
`Exists("key")`	Returns Boolean `true` if `key` exists in dictionary
`Items()`	Returns `VBArray` of values in dictionary
`Keys()`	Returns `VBArray` of keys in dictionary
`Remove("key")`	Removes `key` and its value
`RemoveAll()`	Removes all entries

This enumerator instance must be accessed, via one of its four methods, to position a "pointer" to a particular item and then extract a copy of that item. In other words, you don't access a member directly (that is, by diving into the collection with an item number to retrieve). Instead, you move the pointer to the desired position and then read the item value. As you can see from the list of methods in Table 24-3, this object is truly intended for looping through the collection. Pointer control is limited to positioning it at the start of the collection and incrementing its position along the collection by one:

```
var val;
myEnum.moveFirst();
for (; !myEnum.atEnd(); myEnum.moveNext())
{
   val = myEnum.item();
   // more statements that work on value
}
```

VBArray

The `VBArray` object provides JavaScript access to Visual Basic *safe arrays*. Such an array is read-only and is commonly returned by ActiveX objects. Such arrays can be composed in VBScript sections of client-side scripts. Visual Basic arrays, by their very nature, can have multiple dimensions. For example, the following code creates a three-by-two VB array:

```
<script type="text/vbscript">
   Dim myArray(2, 1)
   myArray(0, 0) = "A"
   myArray(0, 1) = "a"
```

```
   myArray(1, 0) = "B"
   myArray(1, 1) = "b"
   myArray(2, 1) = "C"
   myArray(2, 2) = "c"
</script>
```

TABLE 24-3

Enumerator Object Methods

Method	Description
`atEnd()`	Returns `true` if pointer is at end of collection
`item()`	Returns value at current pointer position
`moveFirst()`	Moves pointer to first position in collection
`moveNext()`	Moves pointer to next position in collection

Once you have a valid VB array, you can convert it to an object that the JScript interpreter can't choke on:

```
<script type="text/javascript">
   var theVBArray = new VBArray(myArray);
</script>
```

Global variables from one script language block can be accessed by another block, even in a different language. But at this point, the array is not yet in the form of a JavaScript array. You can either convert it to such via the `VBArray.toArray()` method, or access information about the `VBArray` object through its other methods (described briefly in Table 24-4). Once you convert a `VBArray` to a JavaScript array, you can then iterate through the values, as with any JavaScript array.

TABLE 24-4

VBArray Object Methods

Method	Description
`dimensions()`	Returns number of dimensions of the original array
`getItem(dim1[, dim2[,...dimN]])`	Returns value at array location defined by dimension addresses
`ibound(dim)`	Returns lowest index value for a given dimension
`toArray()`	Returns JavaScript array version of `VBArray`
`ubound(dim)`	Returns highest index value for a given dimension

When you use the `toArray()` method, and the source array has multiple dimensions, values from dimensions after the first "row" are simply appended to the JavaScript array with no nesting structures.

Object models versus browser versions

Proprietary model extensions

Structure of the W3C DOM

Scripting trends

Without question, the biggest challenge facing client-side web scripters is the sometimes-baffling array of document object models (DOMs) that have competed for our attention throughout the short history of scriptable browsers. Netscape got the ball rolling in Navigator 2 with the first object model. By the time version 4 browsers came around, the original object model had gained not only some useful cross-browser features, but also a host of features that were unique to Navigator or Internet Explorer. The object models were diverging, causing no end of headaches for page authors whose scripts had to run on as many browsers as possible. A ray of hope emerged from the standards process of the World Wide Web Consortium (W3C) in the form of a DOM recommendation. The DOM brought forward much of the original object model, plus new ways of consistently addressing every object in a document. The goal of this chapter is to put each of the object models into perspective and help you understand how modern browsers have alleviated most of the object model compatibility problems. But before we get to those specifics, let's examine the role of the object model in designing scripted applications.

The Object Model Hierarchy

The tutorial chapters of Part II introduced the fundamental ideas behind a document object hierarchy in scriptable browsers. In other object-oriented environments, object hierarchy plays a much greater role than it does in JavaScript-able browsers. (In JavaScript, you don't have to worry about related terms, such as classes, inheritance, and instances.) Even so, you cannot ignore the hierarchy concept because some of your code relies on your ability to write references to objects that depend on their positions within the hierarchy.

Calling these objects *JavaScript objects* is not correct. They are really browser document objects: You just happen to use the JavaScript language to bring them to life. Some scripters of Microsoft Internet Explorer use the VBScript language to script the very same document objects. Technically speaking, JavaScript objects apply to data types and other core language objects separate from the document.

Hierarchy as road map

For the programmer, the primary role of the document object hierarchy is to provide a way for scripts to reference a particular object among all the objects that a browser window can contain. The hierarchy acts as a road map that the script can use to know precisely which object to address.

Consider, for a moment, a scene in which you and your friend Tony are in a high-school classroom. It's getting hot and stuffy as the afternoon sun pours in through the wall of windows on the west side of the room. You ask Tony, "Would you please open a window?" and motion your head toward a particular window in the room. In programming terms, you've issued a command to an object (whether or not Tony appreciates the comparison). This human interaction has many advantages over anything you can do in programming. First, by making eye contact with Tony before you speak, he knows that he is the intended recipient of the command. Second, your body language passes along some parameters with that command, pointing ever so subtly to a particular window on a particular wall.

If, instead, you are in the principal's office using the public address system, and you broadcast the same command ("Would you please open a window?"), no one knows what you mean. Issuing a command without directing it to an object is a waste of time, because every object thinks, "That can't be meant for me." To accomplish the same goal as your one-on-one command, the broadcast command has to be something like "Would Tony Jeffries in Room 312 please open the middle window on the west wall?"

Let's convert this last command to JavaScript *dot syntax* form (see Chapter 6, "Browser and Document Objects"). Recall from the tutorial that a reference to an object starts with the most global point of view and narrows to the most specific point of view. From the point of view of the principal's office, the location hierarchy of the target object is

```
room312.Jeffries.Tony
```

You can also say that Tony's knowledge about how to open a window is one of Tony's methods. The complete reference to Tony and his method then becomes

```
room312.Jeffries.Tony.openWindow()
```

Your job isn't complete yet. The method requires a parameter detailing which window to open. In this case, the window you want is the middle window of the west wall of Room 312. Or, from the hierarchical point of view of the principal's office, it becomes

```
room312.westWall.middleWindow
```

This object road map is the parameter for Tony's `openWindow()` method. Therefore, the entire command that comes over the PA system is

```
room312.Jeffries.Tony.openWindow(room312.westWall.middleWindow)
```

If, instead of barking out orders while sitting in the principal's office, you attempt the same task through radio from an orbiting space shuttle to all the inhabitants on Earth, imagine how laborious your object hierarchy would be. The complete reference to Tony's `openWindow()` method and the window that you want opened wolud have to be mighty long to distinguish the desired objects from the billions of objects within the space shuttle's view.

The point is that the smaller the scope of the object-oriented world you're programming, the more you can assume about the location of objects. For client-side JavaScript, the scope is no wider than

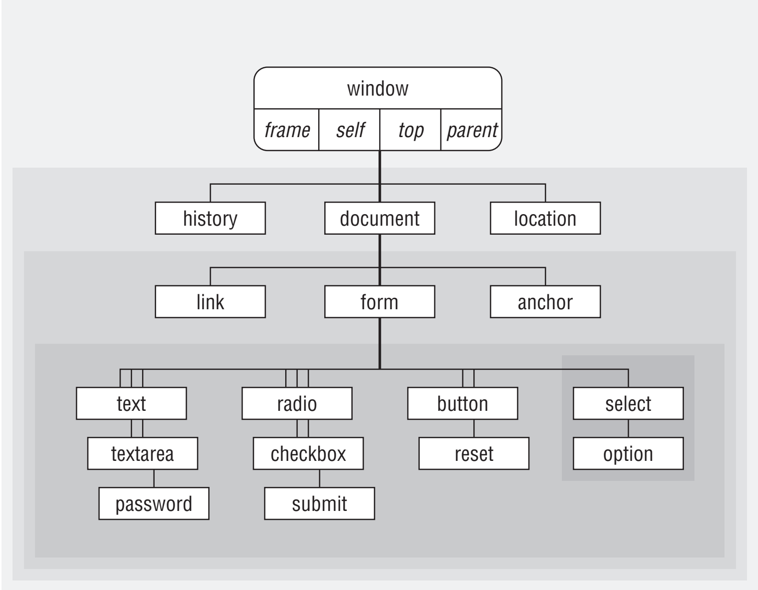
the browser itself. In other words, every object that a JavaScript script can work with resides within the browser application. With few exceptions, a script does not access anything about your computer hardware, operating system, other applications, desktop, or any other stuff beyond the browser program.

The first browser document object road map

Figure 25-1 shows the lowest-common-denominator document object hierarchy that is implemented in all scriptable browsers, including scriptable legacy browsers such as IE3 and NN2. Notice that the `window` object is the topmost object in the entire scheme. Everything you script in JavaScript is in the browser's window.

FIGURE 25-1

The lowest-common-denominator browser document object hierarchy.



Pay attention to the shading of the concentric rectangles. Every object in the same shaded area is at the same level relative to the `window` object. When a line from an object extends to the next-darker shaded rectangle, that object contains all the objects in darker areas. At most, one of these lines exists between levels. The `window` object contains the `document` object; the `document` object contains a form object; a form object contains many different kinds of form control elements.

How Document Objects Are Born

Most of the objects that a browser creates for you are established when an HTML document loads into the browser. The same kind of HTML code you use to create links, anchors, and input elements tells a JavaScript-enhanced browser to create those objects in memory. The objects are there whether or not your scripts call them into action.

The only visible differences to the HTML code for defining those objects are the one or more optional attributes specifically dedicated to JavaScript. By and large, these attributes specify the event you want the user interface element to react to and what JavaScript should do when the user takes that action. By relying on the document's HTML code to perform the object generation, you can spend more time figuring out how to do things with those objects, or how to have them do things for you.

Bear in mind that objects are created in their load order. If you create a multiframe environment, a script in one frame cannot communicate with another frame's objects until both frames load. This trips up a lot of scripters who create multiframe and multiwindow sites (for more information, see Chapter 27, "Window and Frame Objects").

But interestingly enough, you are not confined to just those objects that the document's HTML code generates. As you'll see later in this chapter, the W3C DOM allows you to add and delete objects from the object hierarchy. In fact, if you want to create HTML code that contains no JavaScript, you'll see how you can do that as well.

Object Properties

A property generally defines a particular current setting of an object. The setting may reflect a visible attribute of an object, such as the state of a checkbox (selected or not); it may also contain information that is not so obvious, such as the action and method of a submitted form.

Document objects have most of their initial properties assigned by the attribute settings of the HTML tags that generate the objects. Thus, a property may be a word (for example, a name) or a number (for example, a size). A property can also be an array, such as an array of images contained by a document. If the HTML does not include all attributes, the browser usually fills in a default value for both the attribute and the corresponding JavaScript property.

A Note to Experienced Object-Oriented Programmers

Although the basic object model hierarchy appears to have a class/subclass relationship, many of the traditional aspects of a true object-oriented environment don't apply to the model. The original JavaScript document object hierarchy is a *containment hierarchy,* not an *inheritance hierarchy.* No object inherits properties or methods of an object higher up the chain. Neither is there any automatic message passing from object to object in any direction. Therefore, you cannot invoke a window's method by sending a message to it through the `document` or a form object. All object references must be explicit.

Predefined document objects are generated only when the HTML code containing their definitions loads into the browser. In Chapter 23, ''Function Objects and Custom Objects,'' you learned how to create your own objects, but those objects do not present new visual elements on the page that go beyond what HTML, Java applets, and plug-ins can portray.

Inheritance *does* play a role, as you will see later in this chapter, in the object model defined by the W3C. This newer hierarchy is of a more general nature to accommodate requirements of XML as well as HTML. But the containment hierarchy for HTML objects, as described in this section, is still valid in W3C DOM–compatible browsers.

Property values may be changed in scripts, regardless of the DOM you are using; the difference is the code you write. Later in this chapter, we'll give you specifics for the examples you'll see now. Where applicable, we'll show the examples in DOM0 as well as the W3C DOM.

When used in script statements, property names are case-sensitive. Therefore, if you see a property name listed as `bgColor`, you must use it in a script statement with that exact combination of lowercase and uppercase letters. But when you set an initial value of a property by way of an HTML attribute, the attribute name (like all of HTML) is not case sensitive. Thus, `<BODY BGCOLOR="white">` and `<body bgcolor="white">` both set the same `bgColor` property value. Although XHTML won't validate correctly if you use anything but lowercase letters for tag and attribute names, most browsers will load the page anyway because they continue to be case insensitive for markup, regardless of the HTML or XHTML version you specify for the page's `DOCTYPE`. The case for property names is not influenced by the case of the markup attribute name. You can validate your HTML at `http://validator.w3.org/`.

Each property determines its own read/write status. Some properties are read-only, whereas you can change others on the fly by assigning a new value to them. For example, to put some new text into a text box object, you assign a string to the object's `value` property:

```
document.forms[0].phone.value = "555-1212";
```

or

```
document.getElementById("myPhoneTextBox").value = "555-1212";
```

When an object contained by the document exists (that is, its HTML is loaded into the document), you can also add one or more custom properties to that object. This can be helpful if you want to associate some additional data with an object for later retrieval. To add such a property, you may simply specify it in the same way that you assign a value to it:

```
document.forms[0].phone.delimiter = "-";
```

or

```
document.getElementById("myPhoneTextBox").value = "-";
```

You'll see later in the chapter that there are other ways to add properties to an object. Any property you set survives as long as the document remains loaded in the window and scripts do not overwrite the object. Be aware, however, that reloading the page usually destroys custom properties.

Object Methods

An object's *method* is a command that a script can give to that object. Some methods return values, but that is not a prerequisite for a method. Also, not every object has methods defined for it. In a majority of cases, invoking a method from a script causes some action to take place. The resulting action may be obvious (such as resizing a window) or something more subtle (such as sorting an array in memory).

All methods have parentheses after them, and methods always appear at the end of an object's reference. When a method accepts or requires parameters, the parameter values go inside the parentheses (with multiple parameters separated by commas).

Although an object has its methods predefined by the object model, you can also assign one or more additional methods to an object that already exists (that is, after its HTML is loaded into the document). To do this, a script in the document (or in another window or frame accessible by the document) must define a JavaScript function and then assign that function to a new property name

of the object. In the following example, written to take advantage of modern browser features, the `fullScreen()` function invokes two `window` object methods. By assigning the function reference to the new `window.maximize` property, we define a `maximize()` method for the `window` object. Thus, a button's event handler can call that method directly.

```
// define the function
function fullScreen()
{
   this.moveTo(0,0);
   this.resizeTo(screen.availWidth, screen.availHeight);
}
// assign the function to a custom property
window.maximize = fullScreen;
...
<!-- invoke the custom method -->
<input type="button" value="Maximize Window" onclick="window.maximize()" />
```

In this last example, DOM0 is used. Using the W3C DOM, the function and its assignment to a custom property will be coded exactly the same. The difference is how the `onclick` event handler is identified. In DOM0, the event is defined directly as an attribute of the object in the HTML: on the `input` tag in the case above. In the W3C DOM the event may be defined within the script, rather than on the HTML element itself:

```
// initialize when the page has loaded
addEvent(window, "load", initialize);

function initialize()
{
   // add an event to the button
   addEvent(document.getElementById("theButton"), click);
}
```

Note

The function to assign event handlers throughout the code in this chapter and much of the book is `addEvent()`, a cross-browser event handler explained in detail in Chapter 32.

The `addEvent()` function is part of the script file `jsb-global.js`, which is located on the accompanying CD-ROM in the `Content/` folder, where it is accessible to all chapters' scripts. ■

Object Event Handlers

An *event handler* specifies how an object reacts to an event that is triggered by a user action (for example, a button click) or a browser action (for example, the completion of a document load). Going back to the earliest JavaScript-enabled browser, event handlers were defined inside HTML tags as extra attributes. They included the name of the attribute, followed by an equal sign (working as an assignment operator) and a string containing the script statement(s) or function(s) to execute when the event occured (see Chapter 7, "Scripts and HTML Documents").

Although event handlers are commonly defined in an object's HTML tag, you also have the power to assign or change an event handler just as you assign or change the property of an object. The value of an event handler property looks like a function definition. For example, given this HTML definition

```
<input type="text" name="entry" onfocus="doIt()" />
```

the value of the object's `onfocus` (all lowercase) property is

```
function onfocus()
{
   doIt();
}
```

You can, however, assign an entirely different function to an event handler by assigning a function reference to the property. Such references don't include the parentheses that are part of the function's definition. (You see this again in Chapter 23 when you assign functions to object properties.)

Using the same text field definition you just looked at, you can assign a different function to the event handler, because, based on user input elsewhere in the document, you want the field to behave differently when it receives the focus. If you define a function like this

```
function doSomethingElse()
{
   //statements
}
```

You can then assign the function to the field with either:

```
document.formName.entry.onfocus = doSomethingElse;
```

or

```
document.getElementById("theEntryID").onfocus = doSomethingElse;
```

Because the new function reference is written in JavaScript, you must observe case for the function name. Additionally, you are best served across all browsers by sticking with all-lowercase event handler names as properties.

If your scripts create new element objects dynamically, you can assign event handlers to these objects by way of event handler properties. For example, the following code uses W3C DOM syntax to create a new button input element and assign an `onclick` event handler that invokes a function defined elsewhere in the script:

```
var newElem = document.createElement("input");
newElem.type = "button";
newElem.value = "Click Here";
newElem.onclick = doIt;
document.getElementById("theFormId").appendChild(newElem);
```

Object Model Smorgasbord

A survey of the entire evolution of scriptable browsers since NN2 and IE3 reveals six distinct DOM families. Even if your job entails developing content for just one current browser version, you may be surprised that family members from more than one DOM inhabit your authoring space.

Studying the evolution of the object model is extremely valuable for newcomers to scripting. It is too easy to learn the latest object model gadgets in your current browser, only to discover that your heroic scripting efforts are lost on earlier browsers accessing your pages. Even if you plan on supporting only modern browsers, a cursory knowledge of object model history is a useful part of your JavaScript knowledge base. Therefore, take a look at the six major object model types and how they came into

being. Table 25-1 lists the object model families and the browser versions that support them. Note that a release number is only listed when the level of support for an object model type leaps forward (for example, going from “limited” support to “most” support). Later in this chapter are some guidelines you can follow to help you choose the object model(s) that best suit your users’ appetites.

TABLE 25-1

Object Model Families

Model	Browser Support
Basic Object Model	NN2+, IE3+, Moz1+, FF2+, Safari1+, Opera+, Chrome+
Basic Plus Images	NN3+, MacIE3.01+, IE4+, Moz1+, FF2+, Safari1+, -, Opera+, Chrome+
NN4 Extensions	NN4
IE4 Extensions	IE4+ (some features in all versions require Win32 OS)
IE5 Extensions	IE5+ (some features in all versions require Win32 OS), Opera 9.62+ (very limited)
W3C DOM (I and II)	IE5+ (partial), Moz1 (most), FF2+ (most), Safari1 (partial), Safari1.3+ (most), Opera9.62+ (most), Chrome1+ (most)

It’s important to realize that even though browsers have come a long way toward providing unified support for web standards, we’re not quite there yet. As of this writing, no current browser fully and accurately supports Levels I and II of the W3C DOM. Firefox 2, Safari 1.3/2, Opera 9, and Chrome 1 have all closed the compatibility gap considerably, but some issues, not severely impacting HTML authoring, remain.

Basic Object Model

The first scriptable browser, Netscape Navigator 2, implemented a very basic DOM. Figure 25-1, which you saw earlier in the chapter, provides a visual guide to the objects that were exposed to scripting. The hierarchical structure starts with the window and drills inward toward the document, forms, and form control elements. A document is a largely immutable page on the screen. Only elements that are by nature interactive — links and form elements, such as text fields and buttons — are treated as objects with properties, methods, and event handlers.

The heavy emphasis on form controls opened numerous possibilities that were radical ideas at the time. Because a script could inspect the values of form controls, forms could be prevalidated on the client. If the page included a script that performed some calculations, data entry and calculated results were displayed via editable text fields.

Additional objects that exist outside the document — `window`, `history`, and `location` objects — provide scriptable access to simple yet practical properties of the browser that loads the page. The most global view of the environment is the `navigator` object, which includes properties about the browser brand and version.

When Internet Explorer 3 arrived on the scene, the short life of Navigator 2 was nearing its end. Even though NN3 was already widely available in prerelease form, Internet Explorer 3 implemented the basic object model from NN2 (plus one `window` object property from NN3). Therefore, despite the browser version number discrepancy, NN2 and IE3 were essentially the same with respect to their DOMs. For a brief moment in Internet Time, there was nearly complete harmony between Microsoft and Netscape DOMs — albeit at a very simple level.

Basic Object Model Plus Images

A very short time after Internet Explorer 3 was released, Netscape released Navigator 3 with an object model that built upon the original version. A handful of existing objects — especially the `window` object — gained new properties, methods, and/or event handlers. Scripts could also communicate with Java applets as objects. But the biggest new object on the scene was the `Image` object, along with the array of image objects exposed to the `document` object.

Most of the properties for a Navigator 3 image object gave read-only access to values typically assigned to attributes in the `<img>` tag. But you could modify one property — the `src` property — after the page loaded. Scripts could swap out images within the fixed image rectangle. Although these new image objects didn't have mouse-related event handlers, nesting an image inside a link (which had `onmouseover` and new `onmouseout` event handlers) let scripters implement image rollovers to liven up a page.

As more new scripters investigated the possibilities of adding JavaScript to their pages, frustration ensued when the image swapping they implemented for Navigator 3 failed to work in Internet Explorer 3. Although you could easily script around the lack of an image object to prevent script errors in Internet Explorer 3, the lack of this cool page feature disappointed many. Had they also taken into account the installed base of Navigator 2 in the world, they would have been disappointed there, too. To confuse matters even more, the Macintosh version of Internet Explorer 3.01 (the second release of the Internet Explorer for Mac browser) implemented scriptable image objects.

Despite these rumblings of compatibility problems to come, the object model implemented in Navigator 3 eventually became the baseline reference for future DOMs. With few exceptions, code written for this object model runs on all browsers from Navigator 3 and Internet Explorer 4, on through the latest versions of both brands and other modern browsers.

Navigator 4–Only Extensions

The next browser released to the world was Netscape Navigator 4. Numerous additions to the existing objects put more power into the hands of scripters. You could move and resize browser windows within the context of script-detectable `screen` object properties (for example, how big the user's screen was). Two concepts that represented new thinking about the object model were an enhanced event model and the layer object.

Event capture model

Navigator 4 added many new events to the repertoire. Keyboard events and more mouse events (`onmousedown` and `onmouseup`) allowed scripts to react to more user actions on form control elements and links. All of these events worked as they did in previous object models in which event

handlers were typically assigned as attributes to an element's tag (although you could also assign event handlers as properties in script statements). To facilitate some of the Dynamic HTML (DHTML) potential in the rest of the Navigator 4 object model, the event model was substantially enhanced.

At the root of the system is the idea that when a user performs some physical action on an event-aware object (for example, clicking a form button), the event reaches that button from the top down, through the document object hierarchy. If you have multiple objects that share an event handler, it may be more convenient to capture that event in just one place — the `window` or `document` object level — rather than assigning the same event handler to all the elements. The default behavior of Navigator 4 allowed the event to reach the target object, just as it had in earlier browsers. But you could also turn on *event capture* in the `window`, `document`, or layer object. When captured, the event could be handled at the upper level, preprocessed before being passed onto its original target, or redirected to another object altogether.

Whether or not you capture events, the Navigator 4 event model produces an `event` object (with a lowercase `e` to distinguish it from the static `Event` object) for each event. That object contains properties that reveal more information about the specific event, such as the keyboard character pressed for a keyboard event or the position of a click event on the page. Any event handler can inspect `event` object properties to learn more about the event, and then process the event accordingly.

Layers

Perhaps the most radical addition to the Navigator 4 object model was a new object that reflected an entirely new HTML element: the `layer` element. A *layer* is a container that is capable of holding its own HTML document, yet it exists in a plane in front of the main document. You can move, size, and hide a layer under script control. This new element allowed, for the first time, overlapping elements in an HTML page.

To accommodate the layer object in the document object hierarchy, Netscape defined a nesting hierarchy such that a layer was contained by a document. As a result, the `document` object acquired a property (`document.layers`) that was an array of layer objects in the document. This array exposed only the first level of layer(s) in the current `document` object.

Each layer had its own `document` object because each layer could load an external HTML document if desired. As a positionable element, a layer object had numerous properties and methods that allowed scripts to move, hide, show, and change its stacking order.

Unfortunately for Netscape, the W3C did not agree to make the `<layer>` tag part of the HTML 4 specification. As such, it is an orphan element that exists only in Navigator 4 (not implemented in Moz1 or later). The same goes for the scripting of the layer object and its nested references.

Internet Explorer 4+ Extensions

Microsoft broke important new ground with the release of Internet Explorer 4, which came several months after the release of Navigator 4. The main improvements were in the exposure of all HTML elements, scripted support of Cascading Style Sheets (CSS), and a new event model. Some other additions were available only on Windows 32-bit operating system platforms.

HTML element objects

The biggest change to the object model world was that every HTML element became a scriptable object, while still supporting the original object model. Microsoft invented the `document.all` array

(also called a *collection*). This array contains references to every element in the document, regardless of element nesting. If you assign a unique identifier (name) to the `id` attribute of an element, you can reference the element by the following syntax:

```
document.all.elementID
```

In most cases, you can also drop the `document.all.` part of the reference and begin with only the element ID.

Every element object has an entirely new set of properties and methods that give scripters a level of control over document content unlike anything seen before. These properties and methods are explored in more detail in Chapter 26, "Generic HTML objects," but several groups of properties deserve special mention here.

Four properties (`innerHTML`, `innerText`, `outerHTML`, and `outerText`) provide read/write access to the actual content within the body of a document. This means that you no longer have to use text boxes to display calculated output from scripts. You can modify content inside paragraphs, table cells, or anywhere, on the fly. The browser's rendering engine immediately reflows a document when the dimensions of an element's content change. That feature puts the *Dynamic* in *Dynamic HTML*. To those of us who scripted the static pages of earlier browsers, this feature — taken for granted today — was nothing short of a revelation.

The series of offset properties are related to the position of an element on the page. These properties are distinct from the kind of positioning performed by CSS. Therefore, you can get the dimensions and location of any element on the page, making it easier to move positionable content atop elements that are part of the document and that may appear in various locations due to the browser window's current size.

Finally, the `style` property is the gateway to CSS specifications defined for the element. It is important that the script can modify the numerous properties of the `style` object. Therefore, you can modify font specifications, colors, borders, and the positioning properties after the page loads. The dynamic reflow of the page takes care of any layout changes that the alteration requires (for example, adjusting to a bigger font size).

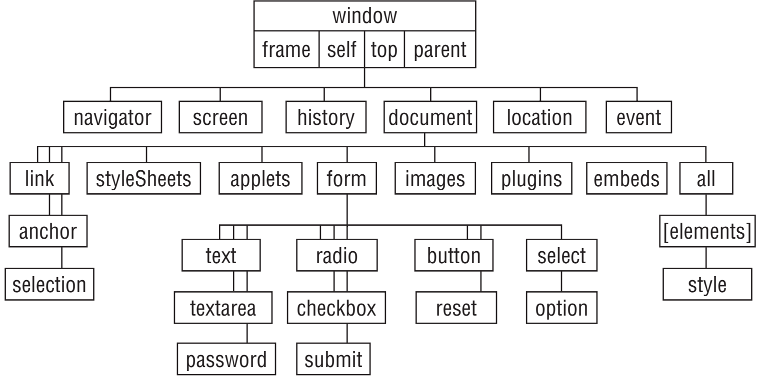
Element containment hierarchy

Although Internet Explorer 4 still recognizes the element hierarchy of the original object model (see Figure 25-1), the DOM for Internet Explorer 4 does not extend this kind of hierarchy fully into other elements. If it did, it would mean that `td` elements inside a table might have to be addressed via its next outer `tr` or `table` element (just as a form control element must be addressed through its containing `form` element). Figure 25-2 shows how all HTML elements are grouped under the `document` object. The `document.all` array flattens the containment hierarchy, as far as referencing objects goes. A reference to the most deeply nested TD element is still `document.all.cellID`. The highlighted pathway from the `window` object is the predominant reference path used when working with the Internet Explorer 4 document object hierarchy.

Element containment in Internet Explorer 4, however, is important for other reasons. Because an element can inherit some style sheet attributes from an element that contains it, you should devise a document's HTML by embedding every piece of content in a container. Paragraph elements are text containers (with start and end tags), not tall line breaks between text chunks. Internet Explorer 4 introduced the notion of a parent-child relationship between a container and elements nested within it. Also, the position of an element may be calculated relative to the position of its next outermost positioning context.

FIGURE 25-2

The Internet Explorer 4 document object hierarchy.



The bottom line here is that element containment doesn't have anything to do with object references (like the original object model). It has everything to do with the *context* of an element relative to the rest of the page's content.

Cascading Style Sheets

By arriving a bit later to market with its version 4 browser than Netscape, Microsoft benefited from having the CSS Level 1 specification more fully developed before the browser's release. Therefore, the implementation is far more complete than that of Navigator 4 (though it is not 100 percent compatible with the standard).

The scriptability of style sheet properties is a bit at odds with the first-generation CSS specification, which seemed to ignore the potential of scripting styles with JavaScript. Many CSS attribute names are hyphenated words (for example, `text-align`, `z-index`), even though hyphens are not allowed in identifier names in JavaScript. This necessitated conversion of the multiword CSS attribute names to camelCase JavaScript property names. Therefore, `text-align` becomes `textAlign`, and `z-index` becomes `zIndex`. You can access all of these properties through an element's `style` property:

```
document.all.elementID.style.stylePropertyName
```

or

```
document.getElementById("myElement").style.stylePropertyName
```

One byproduct of the scriptability of style sheets in Internet Explorer 4 and later is what you might call the *phantom page syndrome*. This occurs when the layout of a page is handled after the primary HTML for the page has downloaded to the browser. As the page loads, not all content may be visible, or it may be in a visual jumble. An `onload` event handler in the page then triggers scripts to set styles or content for the page. Elements jump around to get to their final resting places. This may be disconcerting to some users who at first see a link to click, but by the time the cursor reaches the click location, the page has reflowed, thereby moving the link somewhere else on the page.

Note

For Internet Explorer users with 32-bit Windows operating systems, Internet Explorer 4 includes some extra features in the object model that can enhance presentations. *Filters* are style sheet additives that offer a variety of visual effects on body text. For example, you can add a drop shadow or a glowing effect to text simply by applying filter styles to the text, or you can create the equivalent of a slide presentation by placing the content of each slide in a positioned `div` element. Although filters follow the CSS syntax, they are not part of the W3C specification. ■

Event bubbling

Just as Netscape invented an event model for Navigator 4, so did Microsoft for Internet Explorer 4. Unfortunately for cross-browser scripters, the two event models are quite different. Instead of events trickling down the hierarchy to the target element, an Internet Explorer event starts at the target element and, unless instructed otherwise, bubbles up through the element containment hierarchy to reach the `window` object eventually. At any object along the way, an event handler can perform additional processing on that event, if desired. Therefore, if you want a single event handler to process all click events for the page, assign the event handler to the `body` or `window` object so the events reach those objects (provided that the event bubbling isn't canceled by some other object along the containment hierarchy).

Internet Explorer also has an `event` object (a property of the `window` object) that contains details about the event, such as the key pressed for a keyboard event and the location of a mouse event. Names for these properties are entirely different from the event object properties of Navigator 4.

Despite what seems like incompatible, if not completely opposite, event models in Navigator 4 and Internet Explorer 4, you can make a single set of scripts handle events in both browsers; see Chapter 32, "Event Objects" and Chapter 59, "Application: Cross-Browser DHTML Map Puzzle" (on the CD-ROM) for examples. The Internet Explorer 4 event model continues to be the only model supported by Internet Explorer through version 7.

Internet Explorer 5+ Extensions

With the release of Internet Explorer 5, Microsoft built more onto the proprietary object model it launched with Internet Explorer 4. Although the range of objects remained pretty much the same, the number of properties, methods, and event handlers for the objects increased dramatically. Some of those additions were added to meet some of the specifications of the W3C DOM (discussed in the next section), occasionally causing a bit of incompatibility with Internet Explorer 4. But Microsoft also pushed ahead with features only for Windows users that may not necessarily become industry standards: DHTML behaviors and HTML applications.

A *DHTML behavior* is a chunk of script — saved as an external file — that defines some action (usually, a change of one or more style properties) that you can apply to any kind of element. The goal is to create a reusable component that you can load into any document whose elements require that behavior. As an example of a DHTML behavior, you can define a behavior that turns an element's text to red whenever the cursor rolls atop it, and reverts the text to black when the cursor rolls out. When you assign the behavior to an element in the document (through CSS-like rule syntax), the element picks up that behavior and responds to the user accordingly. You can apply that same behavior to any element(s) in the document.

Cross-Reference

You can see an example of a DHTML behavior in Chapter 26, in the description of the `addBehavior()` method; you can read an extended discussion in Chapter 50 (on the CD-ROM). ■

HTML applications (*HTAs,* in Microsoft parlance) are HTML files that include an XML element known as the `hta:application` element. You can download an HTA to Internet Explorer 5 or later from the server as though it were a web page (although its file extension is `.hta` rather than `.htm` or `.html`). A user can also install an HTA on a client machine so that it behaves very much like an application, with a desktop icon and significant control over the look of the window. HTAs are granted greater security privileges on the client so that this application can behave more like a regular program. In fact, you can elect to turn off the system menu bar and use DHTML techniques to build your own menu bar for the application. Implementation details of HTAs are beyond the scope of this book, but you should be aware of their existence. More information is available at `http://msdn.microsoft.com`.

The W3C DOM

Conflicting browser object models from Netscape and Microsoft made life difficult for developers. Scripters craved a standard that would serve as a common denominator, much as HTML and CSS standards did for content and styles. The W3C took up the challenge of creating a DOM standard: the W3C DOM.

The charter of the W3C DOM working group was to create a DOM that could be applied to both HTML and XML documents. Because an XML document can have tags of virtually any name (as defined by a Document Type Definition or XML Schema), it has no intrinsic structure or fixed vocabulary of elements, as an HTML document does. As a result, the DOM specification had to accommodate the known structure of HTML (as defined in the HTML 4 specification), as well as the unknown structure of an XML document.

To make this work effectively, the working group divided the DOM specification into two sections. The first, called the *Core DOM,* defines specifications for the basic document structure that HTML and XML documents share. This includes notions of a document containing elements that have tag names and attributes; an element is capable of containing zero or more other elements. The second part of the DOM specification addresses the elements and other characteristics that apply only to HTML. The HTML portion inherits all the features of the Core DOM, while providing a measure of backward compatibility to object models already implemented in legacy browsers and providing a framework for new features.

It is important for veteran scripters to recognize that the W3C DOM does not specify all features from existing browser object models. Many features of the Internet Explorer 4 (and later) object model are not part of the W3C DOM specification. This means that if you are comfortable in the Internet Explorer environment and wish to shift your focus to writing for the W3C DOM spec, you have to change some practices, as highlighted in this chapter. In many respects, especially with regard to DHTML applications, the W3C DOM is an entirely new DOM with new concepts that you must grasp before you can successfully script in the environment.

By the same token, you should be aware that whereas Mozilla-based browsers go to great lengths to implement all of DOM Level 1 and most of Level 2, Microsoft (for whatever reason) features only a partial implementation of the W3C DOM through Internet Explorer 5.5. Although IE6 and

later versions implement more W3C DOM features, some important parts — notably, W3C DOM events — are missing. Other modern browsers, such as Chrome 1+, Safari 1.3+, and Opera 9+, provide comprehensive W3C DOM support and have largely closed the gap to compete with Mozilla in terms of supporting the W3C DOM.

DOM levels

Like most W3C specifications, one version is rarely enough. The job of the DOM working group was too large to be swallowed whole in one sitting. Therefore, the DOM is a continually evolving specification. The timeline of specification releases rarely coincides with browser releases. Therefore, it is very common for any given browser release to include only some of the most recent W3C version.

The first formal specification, DOM Level 1, was released well after NN4 and IE4 shipped. The HTML portion of Level 1 includes the so-called DOM Level 0 (there is no published standard by that name). This is essentially the object model as implemented in Navigator 3 (and for the most part in Internet Explorer 3, plus image objects). Perhaps the most significant omission from Level 1 is an event model (it ignores even the simple event model implemented in NN2 and IE3).

DOM Level 2 builds on the work of Level 1. In addition to several enhancements of both the Core and HTML portions of Level 1, Level 2 adds significant new sections (published as separate modules) on the event model, ways of inspecting a document's hierarchy, XML namespaces, text ranges, style sheets, and style properties. Some modules of the Level 3 DOM have reached Recommendation status. Although IE is still a ways off from implementation to any significant degree, the other major browsers have at least partially implemented some of the modules, including some that are still in working draft status.

What stays the same

By adopting DOM Level 0 as the starting point of the HTML portion of the DOM, the W3C provided a way for a lot of existing script code to work even in a W3C DOM-compatible browser. Every object you see in the original object model, starting with the `document` object (see Figure 25-1) plus the image object, are in DOM Level 0. Almost all of the same object properties and methods are also available.

More important, when you consider the changes to referencing other elements in the W3C DOM, we're lucky that the old ways of referencing objects — such as forms, form control elements, and images — still work. Had the working group started with a clean slate, it is unlikely that the `document` object would have been given properties consisting of arrays of forms, links, and images.

The only potential problems you could encounter with your existing code have to do with a handful of properties that used to belong to the `document` object. In the new DOM, four style-related properties of the `document` object (`alinkColor`, `bgColor`, `linkColor`, and `vlinkColor`) become properties of the `body` object (referenced as `document.body`). In addition, the three link color properties pick up new names in the process (`aLink`, `link`, and `vLink`). It appears, however, that for now, IE6 and Moz1 maintain backward compatibility with the older document object color properties.

Also note that the DOM specification concerns itself only with the document and its content. Objects such as `window`, `navigator`, and `screen` are not part of the DOM specification through Level 2. Scripters are still at the mercy of browser makers for compatibility in these areas.

What isn't available

As mentioned earlier, the W3C DOM is not simply a restatement of existing browser specifications. Many convenience features of the Internet Explorer and Netscape Navigator object models do not appear in the W3C DOM. If you developed DHTML content in Internet Explorer 4 or later or in Navigator 4, you had to learn how to get along without some of these conveniences.

The Navigator 4 experiment with the `<layer>` tag was not successful in the W3C process. As a result, both the tag and the scripting conventions surrounding it do not exist in the W3C DOM. To some scripters' relief, the `document.layerName` referencing scenario (even more complex with nested layers) disappears from the object model. A positioned element is treated as just another element with some special style sheet attributes that enable you to move it anywhere on the page, stack it amid other positioned elements, or hide it from view.

Among popular Internet Explorer 4+ features missing from the W3C DOM are the `document.all` collection of HTML elements and four element properties that facilitate dynamic content: `innerHTML`, `innerText`, `outerHTML`, and `outerText`. W3C provides a new way for acquiring an array of all elements in a document, but generating HTML content to replace existing content or to be inserted in a document requires a tedious sequence of statements (see the section "New DOM concepts," later in this chapter). All the new browsers, however, have implemented the `innerHTML` property for HTML element objects, and with the exception of Firefox, have implemented the other three properties.

New HTML practices

Exploitation of DHTML possibilities in the W3C DOM relies on modern HTML practices that by now have been adopted by the majority of HTML authors. At the core of these practices (espoused by the HTML 4 specification) is making sure that all content is within an HTML container of some kind. Therefore, instead of using the `<p>` tag as a separator between blocks of running text, surround each paragraph of the running text with a `<p>...</p>` tag set. If you don't do it, the browser treats each `<p>` tag as the beginning of a paragraph and ends the paragraph element just before the next `<p>` tag or other block-level element.

Although browsers continue to accept the omission of certain end tags (for `td`, `tr`, and `li` elements, for instance) for backward compatibility, it is best to get into the habit of supplying these end tags if for no other reason than that they help you visualize where an element's sphere of influence truly begins and ends. Applying this as a best practice also means your code will validate.

Any element that you intend to script — whether to change its content or its style — should have an identifier assigned to the element's `id` attribute. The identifier should be a unique value within the context of the current web page. Form control elements still require `name` attributes if you submit the form content to a server. But you can freely assign the same or a different identifier value to a control's `id` attribute. Scripts can use either the `id` or the `document.formReference.elementName` reference to reach a control object. Identifiers are essentially the same as the values you assign to the `name` attributes of form and form input elements. Following the same rules for the `name` attribute value, an `id` identifier must be a single word (no whitespace); it cannot begin with a numeral (to prevent conflicts in JavaScript); and it should avoid punctuation symbols except for the underscore character.

New DOM concepts

With the W3C DOM comes several concepts that may be new to you unless you have worked extensively with the terminology of tree hierarchies. Concepts that have the most impact on your scripting are new ways of referencing elements and nodes.

Element referencing

Script references to objects in the DOM Level 0 are observed in the W3C DOM for backward compatibility. Therefore, a form input element whose `name` attribute is assigned the value `userName` is addressed just as it always is

```
document.forms[0].userName
```

or

```
document.formName.userName
```

But because all elements of a document are exposed to the `document` object, you can use the `document` object method designed to access any element whose ID is assigned. The method is `document.getElementById()`, and the sole parameter is a string version of the identifier of the object whose reference you want to get. To help put this in context with what you may have used with the Internet Explorer 4 object model, consider the following HTML paragraph tag:

```
<p id="myParagraph">...</p>
```

In Internet Explorer 4 or later, you can reference this element with

```
var elem = document.all.myParagraph;
```

Although the `document.all` collection is not implemented in the W3C DOM, the `document` object method (available in Internet Explorer 5 and later, Mozilla, Safari, and others) `getElementById()` enables you to access any element by its ID:

```
var elem = document.getElementById("myParagraph");
```

This method is considered the appropriate technique for referencing an element based upon its ID. Unfortunately for scripters, this method is difficult to type because it is case sensitive, so watch out for that ending lowercase *d*.

A hierarchy of nodes

The issue surrounding containers (described earlier) comes into play for the underlying architecture of the W3C DOM. Every element or free-standing chunk of text in an HTML (or XML) document is an object that is contained by its next outermost container. Let's look at a simple HTML document to see how this system works. Listing 25-1 is formatted to show the containment hierarchy of elements and string chunks.

LISTING 25-1

A Simple HTML Document

```
<html>
   <head>
      <title>
         A Simple Page
      </title>
```

continued

LISTING 25-1 *(continued)*

```
   </head>

   <body>
      <p id="paragraph1">
         This is the
         <em id="emphasis1">
            one and only
         </em>
         paragraph on the page.
      </p>
   </body>
</html>
```

What you don't see in the listing is a representation of the `document` object. The `document` object exists automatically when this page loads into a browser. It is important that the `document` object encompasses everything you see in Listing 25-1. Therefore, the `document` object has a single nested element: the `html` element. The `html` element in turn has two nested elements: `head` and `body`. The `head` element contains the `title` element, whereas the `title` element contains a chunk of text. Down in the `body` element, the `p` element contains three pieces: a string chunk, the `em` element, and another string chunk.

According to W3C DOM terminology, each container, stand-alone element (such as a `br` element), or text chunk is known as a *node* — a fundamental building block of the W3C DOM. Nodes have parent-child relationships when one container holds another. As in real life, parent-child relationships extend only between adjacent generations, so a node can have zero or more children. However, the number of third-generation nodes further nested within the family tree does not influence the number of children associated with a parent. Therefore, in Listing 25-1, the `html` node has two child nodes: `head` and `body`, which are *siblings* that have the same parent. The `body` element has one child (`p`), even though that child contains three children (two text nodes and an `em` element node).

If you draw a hierarchical tree diagram of the document in Listing 25-1, it should look like the illustration in Figure 25-3.

FIGURE 25-3

Tree diagram of nodes for the document in Listing 25-1.

```
document
+--<html>
    +--<head>
     |   +--<title>
     |       +--"A Simple Page"
     +--<body>
         +--<p ID="paragraph1">
             +--"This is the  "
             +--<em ID="emphasis1">
             |   +--"one and only"
             +--" paragraph on the page."
```

Note

If the document's source code contains a Document Type Definition (in a `DOCTYPE` element) above the `<html>` tag, the browser treats that `DOCTYPE` node as a sibling of the HTML element node. In that case, the root `document` node contains two child nodes. ■

The W3C DOM (through Level 2) defines 12 different types of nodes, 7 of which have direct application in HTML documents. These seven types of nodes appear in Table 25-2; the rest apply to XML. Of the 7 types, the three most common are the document, element, and text types. All W3C DOM browsers (including Internet Explorer 5 and later, Mozilla, Safari, and others) implement the three common node types, whereas Mozilla implements all of them, IE6 implements all but one, and Safari 1 implements all but two.

Applying the node types of Table 25-2 to the node diagram in Figure 25-3, you can see that the simple page consists of one document node, six element nodes, and four text nodes.

TABLE 25-2

W3C DOM HTML-Related Node Types

Type	Number	nodeName	nodeValue	Description	IE	Moz	Safari
Element	1	*tag name*	`Null`	Any HTML or XML tagged element	6+	1+	1+
Attribute	2	*attribute name*	*attribute value*	A name-value attribute pair in an element	6+	1+	1+
Text	3	`#text`	*text content*	A text fragment contained by an element	6+	1+	1+
Comment	8	`#comment`	*comment text*	HTML comment	6+	1+	4+
Document	9	`#document`	`Null`	Root `document` object	6+	1+	1+
DocumentType	10	`DOCTYPE`	`Null`	DTD specification	No	1+	4+
Fragment	11	`#document-fragment`	`Null`	Series of one or more nodes outside the document	6+	1+	1+

Node properties

A node has many properties, most of which are references to other nodes related to the current node. Table 25-3 lists all properties shared by all node types in DOM Level 2.

Note

You can find all the properties shown in Table 25-3, that also show themselves to be implemented in Internet Explorer 6+ or Moz1+, in Chapter 26, in the listing of properties that all HTML element objects have in common. That's because an HTML element, as a type of node, inherits all of the properties of the prototypical node. ■

TABLE 25-3

Node Object Properties (W3C DOM Level 2)

Property	Value	Description	IE6Win+	IE5Mac+	Moz1	Safari1
`nodeName`	String	Varies with node type (see Table 25-2)	Yes	Yes	Yes	Yes
`nodeValue`	String	Varies with node type (see Table 25-2)	Yes	Yes	Yes	Yes
`nodeType`	Integer	Constant representing each type	Yes	Yes	Yes	Yes
`parentNode`	Object	Reference to next outermost container	Yes	Yes	Yes	Yes
`childNodes`	Array	All child nodes in source order	Yes	Yes	Yes	Yes
`firstChild`	Object	Reference to first child node	Yes	Yes	Yes	Yes
`lastChild`	Object	Reference to last child node	Yes	Yes	Yes	Yes
`previous Sibling`	Object	Reference to sibling node up in source order	Yes	Yes	Yes	Yes
`nextSibling`	Object	Reference to sibling node next in source order	Yes	Yes	Yes	Yes
`attributes`	NodeMap	Array of attribute nodes	Yes	Some	Yes	Yes
`ownerDocument`	Object	Containing document object	Yes	Yes	Yes	Yes
`namespaceURI`	String	URI to namespace definition (element and attribute nodes only)	Yes	No	Yes	Yes
`Prefix`	String	Namespace prefix (element and attribute nodes only)	Yes	No	Yes	Yes
`localName`	String	Applicable to namespace-affected nodes	Yes	No	Yes	Yes

To help you see the meanings of the key node properties, Table 25-4 shows the property values of several nodes in the simple page shown in Listing 25-1. For each node column, find the node in Figure 25-3, and then follow the list of property values for that node, comparing the values against the actual node structure in Figure 25-3.

TABLE 25-4

Properties of Selected Nodes for a Simple HTML Document

Properties	Nodes			
	document	html	p	"one and only"
nodeType	9	1	1	3
nodeName	#document	html	p	#text
nodeValue	Null	null	null	"one and only"
parentNode	Null	document	body	em
previousSibling	Null	null	null	null
nextSibling	Null	null	null	null
childNodes	Html	head body	"This is the" em "paragraph on the page."	(none)
firstChild	Html	head	"This is the"	null
lastChild	Html	body	"paragraph on the page."	null

The `nodeType` property is an integer that is helpful in scripts that iterate through an unknown collection of nodes. Most content in an HTML document is of type 1 (an HTML element) or 3 (a text node), with the outermost container, the document, of type 9. A node's `nodeName` property is either the name of the node's tag (for an `HTML` element) or a constant value (preceded by a # [hash mark], as shown in Table 25-2). And, while it may surprise some, the `nodeValue` property is `null` except for the text node type, in which case the value is the actual string of text of the node. In other words, for `HTML` elements, the W3C DOM does not expose a container's HTML as a string.

The Object-Oriented W3C DOM

If you are familiar with concepts of object-oriented (OO) programming, you will appreciate the OO tendencies in the way the W3C defines the DOM. The `Node` object includes sets of properties (see Table 25-3) and methods (see Table 25-5) that are inherited by every object based on the `Node`. Most of the objects that inherit the `Node`'s behavior have their own properties and/or methods that define their specific behaviors. Figure 25-4 shows (in W3C DOM terminology) the inheritance tree from the `Node` root object. Most items are defined in the Core DOM, whereas items shown in boldface are from the HTML DOM portion.

continued

continued

FIGURE 25-4

W3C DOM Node object inheritance tree.

```
Node
+--Document
|   +--HTMLDocument
+--CharacterData
|   +--Text
|   |  +--CDATASection
|   +--Comment
+--Attr
+--Element
|   +--HTMLElement
|        +--  (Each specific HTML element)
+--DocumentType
+--DocumentFragment
+--Notation
+--Entity
+--Entity Reference
+--ProcessingInstruction
```

You can see from the preceding figure that individual HTML elements inherit properties and methods from the generic HTML element, which inherits from the Core `Element` object, which in turn inherits from the basic `Node`.

It isn't important to know the `Node` object inheritance to script the DOM. But it does help in understanding the ECMA Script Language Binding appendix of the W3C DOM recommendation, as well as how a simple element object winds up with so many properties and methods associated with it.

It is doubtful that you will use all of the relationship-oriented properties of a node, primarily because there is some overlap in how you can reach a particular node from any other. The `parentNode` property is important because it is a reference to the current node's immediate container. Although the `firstChild` and `lastChild` properties point directly to the first and last children inside a container, most scripts generally use the `childNodes` property with array notation inside a `for` loop to iterate through child nodes. If there are no child nodes, the `childNodes` array has a length of zero.

Node methods

Actions that modify the HTML content of a node in the W3C DOM world primarily involve the methods defined for the prototype `Node`. Table 25-5 shows the methods and their support in the W3C DOM–capable browsers.

The important methods for modifying content are `appendChild()`, `insertBefore()`, `removeChild()`, and `replaceChild()`. Note, however, that all of these methods assume that the point of view for the action is from the parent of the nodes being affected by the methods.

For example, to delete an element (using removeChild()), you don't invoke that method on the element being removed, but on its parent element. This leaves open the possibility of creating a library of utility functions that obviate having to know too much about the precise containment hierarchy of an element. A simple function that lets a script appear to delete an element actually does so from its parent:

```
function removeElement(elemID)
{
   var elem = document.getElementById(elemID);
   elem.parentNode.removeChild(elem);
}
```

TABLE 25-5

Node Object Methods (W3C DOM Level 2)

Method	Description	IE5+	Moz1	Safari 1
appendChild(newChild)	Adds child node to end of current node	Yes	Yes	Yes
cloneNode(deep)	Grabs a copy of the current node (optionally with children)	Yes	Yes	Yes
hasChildNodes()	Determines whether current node has children (Boolean)	Yes	Yes	Yes
insertBefore(new, ref)	Inserts new child in front of another child	Yes	Yes	Yes
removeChild(old)	Deletes one child	Yes	Yes	Yes
replaceChild(new, old)	Replaces an old child with a new one	Yes	Yes	Yes
isSupported(feature, version)	Determines whether the node supports a particular feature	No	Yes	Yes

If this seems like a long way to go to accomplish the same result as setting the outerHTML property of an Internet Explorer 4 or later object to empty, you are right. Although some of this convolution makes sense for XML, the W3C working group doesn't seem to have HTML scripters' best interests in mind, unfortunately. All is not lost, however, as you see later in this chapter.

Generating new node content

The final point about the node structure of the W3C DOM focuses on the similarly gnarled way scripters must go about generating content that they want to add or replace on a page. For text-only changes (for example, the text inside a table cell), there is both an easy and a hard way to perform the task. For HTML changes, there is only the hard way (plus a handy workaround discussed later). Let's look at the hard way first and then pick up the easy way for text changes.

To generate a new node in the DOM, you look to the variety of methods that are defined for the Core DOM's `document` object (and are therefore inherited by the HTML `document` object). A node creation method is defined for nearly every node type in the DOM. The two important ones for HTML documents are `createElement()` and `createTextNode()`. The first generates an element with whatever tag name (string) you pass as a parameter; the second generates a text node with whatever text you pass.

When you first create a new element, it exists only in the browser's memory and not as part of the document containment hierarchy. Moreover, the result of the `createElement()` method is a reference to an empty element, except for the name of the tag. For example, to create a new `p` element, use

```
var newElem = document.createElement("p");
```

The new element has no ID, attributes, or any content. To assign some attributes to this element, you can use the `setAttribute()` method (a method of every element object) or assign a value to the object's corresponding property. For example, to assign an identifier to the new element, use either

```
newElem.setAttribute("id", "newP");
```

or

```
newElem.id = "newP";
```

Both ways are perfectly legal. Even though the element has an ID at this point, it is not yet part of the document, so you cannot retrieve it via the `document.getElementById()` method.

To add some content to the paragraph, you next generate a text node as a separate object:

```
var newText = document.createTextNode("This is the second paragraph.");
```

Again, this node is just sitting around in memory waiting for you to apply it as a child of some other node. To make this text the content of the new paragraph, you can append the node as a child of the paragraph element that is still in memory:

```
newElem.appendChild(newText);
```

If you were able to inspect the HTML that represents the new paragraph element, it would look like the following:

```
<p id="newP">This is the second paragraph.</p>
```

The new paragraph element is ready for insertion into a document. Using the document shown in Listing 25-1, you can append it as a child of the `body` element:

```
document.body.appendChild(newElem);
```

At last, the new element is part of the document containment hierarchy. Now you can reference it just like any other element in the document.

Replacing node content

The addition of the paragraph shown in the last section requires a change to a portion of the text in the original paragraph (since the first paragraph is no longer the one and only paragraph on the page). As mentioned earlier, you can perform text changes via the `replaceChild()` method or by assigning new text to a text node's `nodeValue` property. Let's see how each approach works to change the text of the first paragraph's `em` element from one and only to first.

To use `replaceChild()`, a script first must generate a valid text node with the new text:

```
var newText = document.createTextNode("first");
```

The next step is to use the `replaceChild()` method. But recall that the point of view for this method is the parent of the child being replaced. The child here is the text node inside the `em` element, so you must invoke the `replaceChild()` method on the `em` element. Also, the `replaceChild()` method requires two parameters. The first parameter is the new node; the second is a reference to the node to be replaced. Because the script statements get pretty long with the `getElementById()` method, an intermediate step grabs a reference to the text node inside the `em` element:

```
var oldChild = document.getElementById("emphasis1").childNodes[0];
```

Now the script is ready to invoke the `replaceChild()` method on the `em` element, swapping the old text node with the new:

```
document.getElementById("emphasis1").replaceChild(newText, oldChild);
```

If you want to capture the old node before it disappears, be aware that the `replaceChild()` method returns a reference to the replaced node (which is only in memory at this point and not part of the document node hierarchy). You can assign the method statement to a variable and use that old node somewhere else, if needed.

This may seem like a long way to go; it is, especially if the HTML you are generating is complex. Fortunately, you can take a simpler approach for replacing text nodes. All it requires is a reference to the text node being replaced. You can assign that node's `nodeValue` property its new string value:

```
document.getElementById("emphasis1").childNodes[0].nodeValue = "first";
```

When an element's content is entirely text (for example, a table cell that already has a text node in it), this is the most streamlined way to swap text on the fly using W3C DOM syntax. This doesn't work for the creation of the second paragraph text earlier in this chapter because the text node did not exist yet. The `createTextNode()` method had to create it explicitly.

Also remember that a text node does not have any inherent style associated with it. The style of the containing HTML element governs the style of the text. If you want to change not only the text node's text, but also how it looks, you have to modify the `style` property of the text node's parent element. Browsers that perform these kinds of content swaps and style changes automatically reflow the page to accommodate changes in the size of the content.

To summarize, Listing 25-2 is a live version of the modifications made to the original document shown in Listing 25-1. The new version includes a button and a script that makes the changes described throughout this discussion of nodes. Reload the page to start over.

LISTING 25-2

Adding/Replacing DOM Content

```
<html>
<head>
   <title>A Simple Page</title>
   <script type="text/javascript">
   function modify()
   {
      var newElem = document.createElement("p");
      newElem.id = "newP";
      var newText = document.createTextNode("This is the second paragraph.");
      newElem.appendChild(newText);
      document.body.appendChild(newElem);
      document.getElementById("emphasis1").childNodes[0].nodeValue = "first";
   }
   </script>
</head>

<body>
   <button onclick="modify()">Add/Replace Text</button>

   <p id="paragraph1">This is the <em id="emphasis1">one and
   only</em> paragraph on the page.</p>
</body>
</html>
```

Cross-Reference

Chapter 26 details node properties and methods that are inherited by all HTML elements. Most are implemented in all modern W3C DOM browsers. Also look to the reference material for the `document` object in Chapter 29 for other valuable W3C DOM methods. ■

A de facto standard: innerHTML

Microsoft was the first to implement the `innerHTML` property of all element objects starting with Internet Explorer 4. Although the W3C DOM has not supported this property, scripters frequently find it more convenient to modify content dynamically by way of a string containing HTML markup than by creating and assembling element and text nodes. As a result, most modern W3C DOM browsers, including Moz1 and Safari 1, support the read/write `innerHTML` property of all element objects as a de facto standard.

When you assign a string containing HTML markup to the `innerHTML` of an existing element, the browser automatically inserts the newly rendered elements into the document node tree. You may also use `innerHTML` with unmarked text to perform the equivalent of the Internet Explorer–only `innerText` property.

Despite the apparent convenience of the innerHTML property compared with the step-by-step process of manipulating element and text node objects, browsers operate on nodes much more efficiently than on assembly of long strings. This is one case where less JavaScript code does not necessarily translate to greater efficiency.

Static W3C DOM HTML objects

The Moz1+ DOM (but unfortunately, not Internet Explorer 5 or later) adheres to the core JavaScript notion of prototype inheritance with respect to the object model. When a page loads into a Moz1+ browser, the browser creates HTML objects based on the prototypes of each object defined by the W3C DOM. For example, if you use The Evaluator Sr. (discussed in Chapter 4, "JavaScript Essentials") to see what kind of object the myP paragraph object is — enter document.getElementById("myP") in the top text box and click the Evaluate button — it reports that the object is based on the HTMLParagraphElement object of the DOM. Every instance of a p element object in the page inherits its default properties and methods from HTMLParagraphElement (which in turn inherits from HTMLElement, Element, and Node objects — all detailed in the JavaScript binding appendix of the W3C DOM specification).

You can use scripting to add properties to the prototypes of some of these static objects. To do so, you must use new features added to Moz1+ that are a part of JavaScript 1.5 and ECMAScript 5. Two new methods, __defineGetter__() and __defineSetter__(), enable you to assign functions to a custom property of an object.

Note

These methods are Mozilla specific. To prevent their collision with standardized implementations of these features in ECMAScript, the underscore characters on either side of the method name are pairs of underscore characters. ■

The functions execute whenever the property is read (the function assigned via the __defineGetter__() method) or modified (the function assigned through the __defineSetter__() method). The common way to define these functions is in the form of an anonymous function (see Chapter 23). The formats for the two statements that assign these behaviors to an object prototype are as follows:

```
object.prototype.__defineGetter__("propName",
      function([param1[,...[,paramN]]]) {
  // statements
  return returnValue;
})
object.prototype.__defineSetter__("propName",
      function([param1[,...[,paramN]]]) {
  // statements
  return returnValue;
})
```

The example in Listing 25-3 demonstrates how to add a read-only property to every HTML element object in the current document. The property, called childNodeDetail, returns an object. The object has two properties: one for the number of element child nodes and one for the number of text child nodes. Note that the this keyword in the function definition is a reference to the object for which the property is calculated. And because the function runs each time a script statement reads

the property, any scripted changes to the content after the page loads are reflected in the returned property value.

LISTING 25-3

Adding a Read-Only Prototype Property to All HTML Element Objects

```
<script type="text/javascript">
if (HTMLElement)
{
   HTMLElement.prototype.__defineGetter__("childNodeDetail", function()
   {
      var result = {elementNodes:0, textNodes:0 }
      for (var i = 0; i < this.childNodes.length; i++)
      {
         switch (this.childNodes[i].nodeType)
         {
            case 1:
               result.elementNodes++;
               break;
            case 3:
               result.textNodes++;
               break;
         }
      }
      return result;
   })
}
</script>
```

To access the property, use it like any other property of the object. For example:

```
var BodyNodeDetail = document.body.childNodeDetail;
```

The returned value in this example is an object, so you use regular JavaScript syntax to access one of the property values:

```
var BodyElemNodesCount = document.body.childNodeDetail.elementNodes;
```

Bidirectional event model

Despite the seemingly conflicting event models of NN4 (trickle down) and IE4 (bubble up), the W3C DOM event model (defined in Level 2) manages to employ both event propagation models. This gives the scripter the choice of where along an event's propagation path the event gets processed. To prevent conflicts with existing event model terminology, the W3C model invents many new terms for properties and new methods for events. Some coding probably requires W3C DOM–specific handling in a page aimed at multiple object models.

The W3C event model also introduces a new concept called the event listener. An *event listener* is essentially a mechanism that instructs an object to respond to a particular kind of event — very much

like the way the event handler attributes of HTML tags respond to events. But the DOM recommendation points out that it prefers a more script-oriented way of assigning event listeners: the addEventListener() method available for every node in the document hierarchy. Through this method, you advise the browser whether to force an event to bubble up the hierarchy (the default behavior that is also in effect if you use the HTML attribute type of event handler) or to be captured at a higher level.

Functions invoked by the event listener receive a single parameter consisting of the event object whose properties contain contextual details about the event (details such as the position of a mouse click, character code of a keyboard key, or a reference to the target object). For example, if a form includes a button whose job is to invoke a calculation function, the W3C DOM prefers the following way of assigning the event handler:

```
document.getElementById("calcButton").addEventListener("click",
doCalc, false);
```

The addEventListener() method takes three parameters. The first parameter is a string of the event to listen for; the second is a reference to the function to be invoked when that event fires; and the third parameter is a Boolean value. When you set this Boolean value to true, it turns on event capture whenever this event is directed to this target. The function then takes its cue from the event object passed as the parameter:

```
function doCalc(evt)
{
   // get shortcut reference to input button's form
   var form = evt.target.form;
   var results = 0;
   // other statements to do the calculation //
   form.result.value = results;
}
```

To modify an event listener, you use the removeEventListener() method to get rid of the old listener, and then employ addEventListener() with different parameters to assign the new one.

Preventing an event from performing its default action is also a different procedure in the W3C event model than in Internet Explorer. In Internet Explorer 4 (as well as Navigator 3 and 4), you can cancel the default action by allowing the event handler to evaluate to return false. Although this still works in Internet Explorer 5 and later, Microsoft includes another property of the window.event object, called returnValue. Setting that property to false anywhere in the function invoked by the event handler also kills the event before it does its normal job. But the W3C event model uses a method of the event object, preventDefault(), to keep the event from its normal task. You can invoke this method anywhere in the function that executes when the event fires.

Detailed information about an event is contained in an event object that must be passed to an event handler function where details may be read. If you assign event handlers via the W3C DOM addEventListener() method or an event handler property, the event object is passed automatically as the sole parameter to the event handler function. Include a parameter variable to catch the incoming parameter:

```
function swap(evt)
{
   // statements here to work with W3C DOM event object
}
```

But if you assign events through a tag attribute, you must explicitly pass the event object in the call to the function:

```
<a href="http://www.example.com" onmouseover="swap(event)">
```

Unfortunately, as of Internet Explorer 8 for Windows and Internet Explorer 5 for Macintosh, the W3C DOM event model has yet to be supported by Microsoft. You can, however, make the Internet Explorer and W3C event models work together if you assign event handlers by way of object properties or tag attributes, and throw in a little object detection as described later in this chapter, and in more detail in Chapter 32.

Scripting Trends

Although browser scripting had humble beginnings as a way to put some intelligence into form controls, the capabilities of the JavaScript language and DOM have inspired many a web developer to create what are essentially applications. Popular implementations of web-based email systems use extensive scripting and background communication with the server to keep pages updated quickly without the need to fetch and re-render the complete page each time you delete a message from the inbox list. It's not uncommon for large projects to involve multiple scripters (along with specialists in CSS, server programming, artists, and writers). Wrangling all the code can be a chore.

Separating content from scripting

Those who use CSS to style their sites have learned that separating style definitions from the HTML markup makes a huge improvement in productivity when it comes time to change colors or font specifications throughout a site. Instead of having to modify hundreds of `<font>` tag specifications scattered around the site, all it takes is a simple tweak of a single CSS rule in one `.css` file for that change to be implemented immediately across the board.

The notion of using HTML purely for a page's structure has also impacted scripting. It is rare these days for a professional scripter to put an event handler attribute inside an HTML tag. That would be considered too much mixing of content with behavior. In other words, the HTML markup should be able to stand on its own so that those with nonscriptable browsers (including those with vision or motor disabilities who use specialized browsers) can still get the fundamental information provided by the page. Any scripting that impacts the display or behavior of the page is added to the page after the HTML markup has loaded and rendered. Even assigning events to elements is done by script after the page load.

Script code is more commonly linked into a page from an external `.js` file. This isn't part of the separation of content and scripts trend, but a practice that offers many benefits, such as the same code being instantly usable on multiple pages. Additionally, when projects involve many code chefs, scripters can work on their code while writers work on the HTML and designers work on their external CSS code.

Note

You will see lots of examples in this book that use event handler attributes inside tags, and scripts embedded within the page. This approach is used primarily for simplicity in demonstrating a language or DOM feature. ■

Using the W3C DOM where possible

Basic support for W3C DOM element referencing and content manipulation has been implemented in mainstream browsers for so long that you can be assured that composing scripts for that model will work for the bulk of your visitors. That's not to say you can assume that every visitor is equipped that way, but the hassles that scripters used to endure to support conflicting object models are behind us for the most part. The days of writing extensive branching code for IE and Netscape are not-so-fond memories.

You still want to use object detection techniques to guard against the occasional old browser that stops by. That's where the technique of assigning event handlers by scripts can save a lot of headaches.

Except for some initializations that might occur while the page loads, most script execution in a web page occurs at the instigation of an event: A user clicks a button, types something in a text box, chooses from a `select` element, and so on. You can prevent older browsers from tripping up on W3C DOM syntax by doing your fundamental object detection right in the event assignment code, as in the following simplified example:

```
function setUpEvents()
{
   if (document.getElementById)
   {
      // statements to bind events to elements
   }
}
window.onload = setUpEvents;
```

Now, browsers that don't have even minimum support for the W3C DOM won't generate script errors when users click or type, because those events won't be assigned for those browsers. Then scripts that survive your object detection query can also modify the page, as you saw in Listing 4-2 in Chapter 4.

Handling events

You will still find some places where the W3C DOM isn't enough. This is particularly true in processing events, where Internet Explorer (at least through version 8) does not support the W3C DOM way of getting details about an event to the event handler function. The W3C DOM automatically passes the `event` object as a parameter to a handler function. In the Internet Explorer model, the `event` object is a property of the `window` object. Therefore, your functions have to equalize the differences where necessary. For example, to obtain a single variable representing the `event` object, regardless of browser, you can use a construction similar to the following:

```
function calculate(evt)
{
   evt = (evt) ? evt : window.event;
   // more statements to process event
}
```

Additional branching is necessary to inspect important details of the event. For example, the Internet Explorer event object property pointing to the object that received the event is called `srcElement`, whereas the W3C DOM version is called `target`. Again, a little bit of equalizing code in the event handler function can handle the disparity. When your script has a reference to the element receiving

the event, you can start using W3C DOM properties and methods of the element, because Internet Explorer supports those. You can find more details on event objects in Chapter 32.

Standards Compatibility Modes (DOCTYPE Switching)

Both Microsoft and Netscape/Mozilla discovered that they had, over time, implemented CSS features in ways that ultimately differed from the published standards that came later (usually after much wrangling among working-group members). To compensate for these differences and make a clean break to be compatible with the standards, the major browser makers decided to let the page author's choice of `<!DOCTYPE>` header element details determine whether the document was designed to follow the old way (sometimes called *quirks mode*) or the standards-compatible way. The tactic, known informally as *DOCTYPE switching,* is implemented in Internet Explorer 6 and later, Internet Explorer 5 for the Mac, all Mozilla-based browsers, and all WebKit-based browsers.

Although most of the differences between the two modes are small, there are some significant differences between the two modes in Internet Explorer 6 and later, particularly when styles or DHTML scripts rely on elements designed with borders, margins, and padding. Microsoft's original box model measured the dimensions of elements in a way that differed from the eventual CSS standard.

To place the affected browsers in CSS standards–compatible mode, you should include a `<!DOCTYPE>` element at the top of every document that specifies any of the following details (the first `<!DOCTYPE>` statement is for HTML5):

```
<!DOCTYPE html>

<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.0 Transitional//EN"
        "http://www.w3.org/TR/REC-html40/loose.dtd">

<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.0 Frameset//EN"
        "http://www.w3.org/TR/REC-html40/frameset.dtd">

<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.0//EN"
        "http://www.w3.org/TR/REC-html40/strict.dtd">

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
        "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Frameset//EN"
        "http://www.w3.org/TR/xhtml1/DTD/xhtml1-frameset.dtd">

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Strict//EN"
        "http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd">

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.1//EN"
        "http://www.w3.org/TR/xhtml11/DTD/xhtml11.dtd">
```

Be aware, however, that older versions of Internet Explorer for Windows, such as Internet Explorer 5 or Internet Explorer 5.5, are ignorant of the standards-compatible mode and will use the old Microsoft quirks mode regardless of the `<!DOCTYPE>` setting. But using a standards-compliant mode DOCTYPE is more likely to force your content and style sheets to render similarly across the latest browsers.

Where to Go from Here

These past two chapters provided an overview of the core language and object model issues that anyone designing pages that use JavaScript must confront. The goal here is to stimulate your own thinking about how to embrace or discard levels of compatibility with your pages as you balance your desire to generate cool pages and serve your audience. From here on, the difficult choices are up to you.

To help you choose the objects, properties, methods, and event handlers that best suit your requirements, all the chapters in Part III and the rest of Part IV provide in-depth references to the DOM and core JavaScript language features. Observe the compatibility ratings for each language term very carefully to help you determine which features best suit your audience's browsers. Most example listings are complete HTML pages that you can load in various browsers to see how they work. Many others invite you to explore how things work through The Evaluator Sr. (see Chapter 4). Play around with the files, making modifications to build your own applications or expanding your working knowledge of JavaScript in the browser environment.

The language and object models have grown in the handful of years they have been in existence. The amount of language vocabulary has increased astronomically. It takes time to drink it all in and feel comfortable that you are aware of the powers available to you. Don't worry about memorizing the vocabulary. It's more important to acquaint yourself with the features and come back later when you need the implementation details.

Be patient. Be persistent. The reward will come.

CHAPTER

26

Generic HTML Element Objects

IN THIS CHAPTER

- **Working with HTML element objects**
- **Common properties and methods**
- **Event handlers of all element objects**

The object model specifications implemented in Internet Explorer 4+ and W3C (Mozilla-based and WebKit-based) browsers feature a large set of scriptable objects that represent what we often call *generic* HTML elements. Generic elements can be divided into two groups. One group, such as the `band strike` elements, defines font styles to be applied to enclosed sequences of text. The need for these elements (and the objects that represent them) is all but gone due to more page designers using style sheets. The second group of elements assigns context to content within their start and end tags. Examples of contextual elements include `h1`, `blockquote`, and the ubiquitous `p` element. Although browsers sometimes have consistent visual ways of rendering contextual elements by default (for example, the large bold font of an `<h1>` tag), the specific rendering is not the intended purpose of the tags. No formal standard dictates that text within an `em` element must be italicized: The style simply has become the custom since the very early days of browsers.

All of these generic elements share a large number of scriptable properties, methods, and event handlers. The sharing extends not only among generic elements, but also among virtually every renderable element — even if it has additional, element-specific properties, methods, and/or event handlers that we cover in depth in other chapters of this reference. Rather than repeat the details of these shared properties, methods, and event handlers for each object throughout this reference, we describe them in detail only in this chapter (unless there is a special behavior, bug, or trick associated with the item in some object described elsewhere). In succeeding reference chapters, each object description includes a list of the object's properties, methods, and event handlers, but we do not list shared items over and over (making it hard to find items that are unique to a particular element). Instead, you see a pointer back to this chapter for the items in common with generic HTML element objects.

Generic Objects

Table 26-1 lists all of the objects that we treat in this reference as *generic* objects. All of these objects share the properties, methods, and event handlers described in succeeding sections and have no special items that require additional coverage elsewhere in this book.

Syntax

To access element properties or methods, use this:

```
(IE4+)     [document.all.]objectID.property | method([parameters])
(IE5+/W3C) document.getElementById(objectID).property | method([parameters])
```

Note

It's important to note that unless you have the specific need of supporting IE4, which is highly unlikely at this point in time, you should rely solely on the latter approach of referencing element properties and methods via the `getElementById()` **method.** ■

About these objects

All objects listed in Table 26-1 are document object model (DOM) representations of HTML elements that influence either the font style or the context of some HTML content. The large set of properties, methods, and event handlers associated with these objects also applies to virtually every other DOM object that represents an HTML element. Discussions about object details in this chapter apply to dozens of other objects described in succeeding chapters of this reference section.

Properties

accessKey

Value: One-character string Read/Write

Compatibility: WinIE4+, MacIE4+, NN7+, Moz-, Safari+, Opera+, Chrome+

***elementObject*.accessKey**

For many elements, you can specify a keyboard character (letter, numeral, or punctuation symbol) that — when typed as an Alt+key combination (on the Win32 OS platform), a Ctrl+key combination (on the MacOS), or a Shift+Esc+key combination (on Opera) — brings focus to that element. An element that has focus is the one that is set to respond to keyboard activity. If the newly focused element is out of view in the document's current scroll position, the document is scrolled to bring that focused element into view (also see the `scrollIntoView()` method). The character you specify can be an uppercase or lowercase value, but these values are not case sensitive. If you assign the same letter to more than one element, the user can cycle through all elements associated with that `accessKey` value.

Internet Explorer gives some added powers to the `accessKey` property in some cases. For example, if you assign an `accessKey` value to a `label` element object, the focus is handed to the form element associated with that label. Also, when elements such as buttons have focus, pressing the spacebar acts the same as clicking the element with a mouse.

Exercise some judgment in selecting characters for `accessKey` values. If you assign a letter that is normally used to access one of the browser's built-in menus (for example, Alt+F for the File menu in IE), that `accessKey` setting overrides the browser's normal behavior. To users who rely on keyboard access to menus, your control over that key combination can be disconcerting. In other browsers your `accessKey` assignment will not override the browser's normal behavior.

Example

Listing 26-1 shows an example of how to use the `accessKey` property to manipulate the keyboard interface for navigating a web page. When you load the script in Listing 26-1, adjust the height of the browser window so that you can see nothing below the second dividing rule. Enter any character in the Settings portion of the page and press Enter. (The Enter key may cause your computer to beep.) Pressing the Enter key does not do anything visible in your browser; it just assigns the character you entered into the textbox to the appropriate element. Then hold down the Alt (Windows) or Ctrl (Mac) key (or Shift+Esc keys in Opera) while pressing the same keyboard key. The element from below the second divider should come into view.

Note

The property assignment event handling technique employed throughout the code in this chapter and much of the book is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) method. A modern cross-browser event handling technique is explained in detail in Chapter 32. ■

LISTING 26-1

Controlling the accessKey Property

HTML: jsb26-01.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>accessKey Property</title>
```

```
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-01.js"></script>
   </head>
   <body>
      <h1>accessKey Property Lab</h1>
      <hr />
      Settings:<br />
      <form name="input">
        Assign an accessKey value to the Button below and press Return:
        <input type="text" size="2" maxlength="1"
               onkeypress="assignKey('button', this)" />
        <br />
        Assign an accessKey value to the Text Box below and press Return:
        <input type="text" size="2" maxlength="1"
               onkeypress="return assignKey('text', this)" />
        <br />
        Assign an accessKey value to the Table below (IE5.5+ only)
        and press Return:
        <input type="text" size="2" maxlength="1"
               onkeypress="return assignKey('table', this)" />
      </form>
      <br />
      Then press Alt (Windows) or Control (Mac) or ShiftESC (Opera) + the key
      <br />
      <em>Size the browser window to view nothing lower than this line.</em>
      <hr />
      <form name="output" onsubmit="return false">
         <input type="button" id="access1" value="Standard Button" />
         <input type="text" id="access2" />
      </form>
      <table id="myTable" cellpadding="10" border="2">
         <tr>
            <th>Quantity</th>
            <th>Description</th>
            <th>Price</th>
         </tr>
         <tbody bgcolor="red">
            <tr>
               <td width="100">4</td>
               <td>Primary Widget</td>
               <td>$14.96</td>
            </tr>
            <tr>
               <td>10</td>
               <td>Secondary Widget</td>
               <td>$114.96</td>
            </tr>
         </tbody>
      </table>
   </body>
</html>
```

continued

LISTING 26-1 *(continued)*

JavaScript: jsb26-01.js

```
function assignKey(type, elem)
{
   if (window.event)       // IE, Opera, Safari, Chrome
   {
      if (window.event.keyCode == 13)
      {
         switch (type)
         {
            case "button":
               document.getElementById("access1").accessKey = elem.value;
               break;
            case "text":
               document.getElementById("access2").accessKey = elem.value;
               break;
            case "table":
               document.getElementById("myTable").accessKey = elem.value;
         }
         return false;
      }
   }
}
```

Related Item: `scrollIntoView()` method

all[]

Value: Array of nested element objects Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+ (partial), Opera+, Chrome+ (partial)

Originally exclusive to Internet Explorer, the `all` property is a collection (array) of every HTML element and (in IE5+) XML tag within the scope of the current object. Opera now supports it fully, while WebKit-based browsers (such as Safari and Chome) support it only as a property of the document object. Even so, you should strongly consider using the `document.getElementById()` method (as described in Chapter 29), which is the official W3C and cross-browser approach for referencing elements. The `document.getElementById()` method is supported in IE5+.

Items in this array appear in source-code order, and the array is oblivious to element containment among the items. For HTML element containers, the source-code order is dependent on the position of the start tag for the element; end tags are not counted. But for XML tags, end tags appear as separate entries in the array.

Every `document.all` collection contains objects for the `html`, `head`, `title`, and `body` element objects even if the actual HTML source code omits the tags. The object model creates these objects for every document that is loaded into a window or frame. Although the `document.all` reference may be the most common usage, the `all` property is available for any container element. For example, `document.forms[0].all` exposes all elements defined within the first form of a page.

You can access any element that has an identifier assigned to its `id` attribute by that identifier in string form (as well as by index integer). Rather than use the performance-costly `eval()` function to convert a string to an object reference, use the string value of the name as an array index value:

```
var paragraph = document.all["myP"];
```

Internet Explorer enables you to use either square brackets or parentheses for single collection index values. Thus, the following two examples evaluate identically:

```
var paragraph = document.all["myP"];
var paragraph = document.all("myP");
```

In the rare case that two or more elements within the `all` collection have the same ID, the syntax for the string index value returns a collection of just those identically named elements. But you can use a second argument (in parentheses) to signify the integer of the initial collection and thus single out a specific instance of that named element:

```
var secondRadio = document.all("group0",1);
```

As a more readable alternative, you can use the `item()` method (described later in this chapter) to access the same kinds of items within a collection:

```
var secondRadio = document.all.item("group0",1);
```

Also see the `tags()` method (later in this chapter) as a way to extract a set of elements from an `all` collection that matches a specific tag name.

Example

Use The Evaluator (see Chapter 4) to experiment with the `all` collection. Enter the following statements one at a time in the lower text box, and review the results in the text area for each:

```
document.all
myTable.all
myP.all
```

If you encounter a numbered element within a collection, you can explore that element to see which tag is associated with it. For example, if one of the results for the `document.all` collection says `document.all.8=[object]`, enter the following statement in the topmost text box:

```
document.all[8].tagName
```

Related Items: `item()`, `tags()`, `document.getElementById()` methods

attributes[]

Value: Array of attribute object references Read-Only

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `attributes` property consists of an array of attributes specified for an element. In IE5+, the `attributes` array contains an entry for every possible property that the browser has defined for its elements — even if the attribute is not set explicitly in the HTML tag. Also, any attributes that

you add later via script facilities such as the `setAttribute()` method are not reflected in the `attributes` array. In other words, the IE5+ `attributes` array is fixed, using default values for all properties except those that you explicitly set as attributes in the HTML tag.

Mozilla browsers' `attributes` property returns an array that is a named node map (in W3C DOM terminology) — an object that has its own properties and methods to read and write attribute values. For example, you can use the `getNamedItem(attrName)` and `item(index)` methods on the array returned from the `attributes` property to access individual attribute objects via W3C DOM syntax.

IE5 and Mozilla had different ideas about what an attribute object should be. Mozilla is dependent on the W3C DOM node inheritance model, discussed in Chapter 25. In the past, the larger set of properties in the W3C DOM node were solely supported by Mozilla. Now, as you can see, IE supports more of the W3C DOM. Table 26-2 shows the variety of properties of an attribute object as defined by the two object models. The WebKit-based browsers offer the same property support as Mozilla, while Opera lies in between.

TABLE 26-2

Attribute Object Properties

Property	IE5	Moz	Description
`attributes`	Yes	Yes	Array of nested attribute objects (null)
`childNodes`	No	Yes	Child node array
`firstChild`	No	Yes	First child node
`lastChild`	No	Yes	Last child node
`localName`	No	Yes	Name within current namespace
`name`	Yes	Yes	Attribute name
`nameSpaceURI`	Yes	Yes	XML namespace URI
`nextSibling`	Yes	Yes	Next sibling node
`nodeName`	Yes	Yes	Attribute name
`nodeType`	Yes	Yes	Node type (2)
`nodeValue`	Yes	Yes	Value assigned to attribute
`ownerDocument`	Yes	Yes	Document object reference
`ownerElement`	Yes	Yes	Element node reference
`parentNode`	Yes	Yes	Parent node reference
`prefix`	Yes	Yes	XML namespace prefix
`previousSibling`	Yes	Yes	Previous sibling node
`specified`	Yes	Yes	Whether attribute is explicitly specified (Boolean)
`value`	Yes	Yes	Value assigned to attribute

The most helpful property of an attribute object is the Boolean `specified` property. In IE, this lets you know whether the attribute is explicitly specified in the element's tag. Because Mozilla returns only explicitly specified attributes in the `attributes` array, the value in Mozilla is always `true`. Most of the time, however, you'll probably use an element object's `getAttribute()` and `setAttribute()` methods to read and write attribute values.

Example

Use The Evaluator (see Chapter 4) to examine the values of the `attributes` array for some of the elements in that document. Enter each of the following expressions in the bottom text box, and see the array contents in the Results text area for each:

```
document.body.attributes
document.getElementById("myP").attributes
document.getElementById("myTable").attributes
```

If you have both IE5+ and a W3C DOM–compatible browser, compare the results you get for each of these expressions. To view the value of a single attribute in WinIE5+ by accessing the `attributes` array, enter the following statement in the top text box:

```
document.getElementById("myForm2").attributes["name"].value
```

For W3C browsers, IE6+, and MacIE5, use the W3C DOM syntax:

```
document.getElementById("myForm2").attributes.getNamedItem("name").value
```

Related Items: `getAttribute()`, `mergeAttributes()`, `removeAttribute()`, `setAttribute()` methods

baseURI

Value: Full URI string — Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

This property reveals the full path to the source from which the element was served. The property is handy in applications that import XML data, in which case the source of an XML element is likely different from the HTML page in which it is being processed.

behaviorUrns[]

Value: Array of behavior URN strings — Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The Internet Explorer `behaviorUrns` property is designed to provide a list of addresses, in the form of *URNs (Uniform Resource Names)*, of all behaviors assigned to the current object. If there are no behaviors, the array has a length of zero. In practice, however, IE5+ always returns an array of empty strings. Perhaps the potential exposure of URNs by script was deemed to be a privacy risk.

Related Item: `urns()` method

canHaveChildren

Value: Boolean — Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

***elementObject*.canHaveChildren**

Useful in some dynamic content situations, the `canHaveChildren` property reveals whether a particular element is capable of containing a child (nested) element. Most elements that have start and end tags (particularly the generic elements covered in this chapter) can contain nested elements. A nested element is referred to as a *child* of its parent container.

Example

Listing 26-2 shows an example of how to use the `canHaveChildren` property to visually identify elements on a page that can have nested elements. This example uses color to demonstrate the difference between an element that can have children and one that cannot. The first button sets the `color` style property of every visible element on the page to red. Thus, elements (including the normally non-childbearing ones such as `hr` and `input`) are affected by the color change. But if you reset the page and click the largest button, only those elements that can contain nested elements receive the color change.

LISTING 26-2

Reading the canHaveChildren Property

HTML: jsb26-02.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>canHaveChildren Property</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-02.js"></script>
   </head>
   <body>
      <h1>canHaveChildren Property Lab</h1>
      <hr />
      <form name="input">
         <input type="button" value="Color All Elements" onclick="colorAll()" />
         <br />
         <input type="button" value="Reset" onclick="history.go(0)" />
         <br />
         <input type="button" value="Color Only Elements That Can Have Children"
                onclick="colorChildBearing()" />
      </form>
      <br />
      <hr />
      <form name="output">
         <input type="checkbox" checked="checked" />Your basic checkbox
         <input type="text" name="access2" value="Some textbox text." />
      </form>
      <table id="myTable" cellpadding="10" border="2">
         <tr>
            <th>Quantity</th>
            <th>Description</th>
            <th>Price</th>
         </tr>
```

```
      <tbody>
         <tr>
            <td width="100">4</td>
            <td>Primary Widget</td>
            <td>$14.96</td>
         </tr>
         <tr>
            <td>10</td>
            <td>Secondary Widget</td>
            <td>$114.96</td>
         </tr>
      </tbody>
   </table>
  </body>
</html>
```

JavaScript: jsb26-02.js

```
function colorAll()
{
   var elems = document.getElementsByTagName("*");
   for (var i = 0; i < elems.length; i++)
   {
      elems[i].style.color = "red";
   }
}

function colorChildBearing()
{
   var elems = document.getElementsByTagName("*");
   for (var i = 0; i < elems.length; i++)
   {
      if (elems[i].canHaveChildren)
      {
         elems[i].style.color = "red";
      }
   }
}
```

Related Items: `childNodes`, `firstChild`, `lastChild`, `parentElement`, `parentNode` properties; `appendChild()`, `hasChildNodes()`, `removeChild()` methods

canHaveHTML

Value: Boolean Read-Only and Read/Write

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Not all HTML elements are containers of HTML content. The `canHaveHTML` property lets scripts find out whether a particular object can accept HTML content, such as for insertion or replacement by object methods. The value for a `p` element, for example, is `true`. The value for a `br` element is `false`. The property is read-only for all elements except HTML Components, in which case it is read/write.

Example

Use The Evaluator (see Chapter 4) in WinIE5+ to experiment with the `canHaveHTML` property. Enter the following statements in the top text box, and observe the results:

```
document.getElementById("input").canHaveHTML
document.getElementById("myP").canHaveHTML
```

The first statement returns `false` because an `input` element (the top text box, in this case) cannot have nested HTML. But the `myP` element is a `p` element that gladly accepts HTML content.

Related Items: `appendChild()`, `insertAdjacentHTML()`, `insertBefore()` methods

childNodes[]

Value: Array of node objects Read-Only

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `childNodes` property consists of an array of node objects contained by the current object. Note that child nodes consist of both element objects and text nodes. Therefore, depending on the content of the current object, the number of `childNodes` and children collections may be different.

Caution

If you use the `childNodes` array in a `for` loop that iterates through a sequence of HTML (or XML) elements, watch out for the possibility that the browser treats source-code whitespace (blank lines between elements and even simple carriage returns between elements) as text nodes. This potential problem affects MacIE5 and W3C-based browsers. If present, these extra text nodes occur primarily surrounding block elements. ■

Note

Most looping activity through the `childNodes` array aims to examine, count, or modify element nodes within the collection. If that is your script's goal, test each node returned by the `childNodes` array, and verify that the `nodeType` property is `1` (element) before processing that node; otherwise, skip the node. The skeletal structure of such a loop follows:

```
for (var i = 0; i < myElem.childNodes.length; i++)
{
   if (myElem.childNodes[i].nodeType == 1)
   {
      statements to work on element node i
   }
}
```

The presence of these phantom text nodes also impacts the nodes referenced by the `firstChild` and `lastChild` properties, described later in this chapter. ■

Example

Listing 26-3 contains an example of how you might code a function that walks the child nodes of a given node. The `walkChildNodes()` function shown in the listing accumulates and returns a hierarchical list of child nodes from the point of view of the document's HTML element (the default) or any element whose ID you pass as a string parameter. This function is embedded in The Evaluator so

that you can inspect the child node hierarchy of that page or (when using `evaluator.js` for debugging as described in Chapter 48 on the CD-ROM) the node hierarchy within any page you have under construction. Try it out in The Evaluator by entering the following statements in the top text box:

```
walkChildNodes()
walkChildNodes(document.getElementById("myP"))
```

The results of this function show the nesting relationships among all child nodes within the scope of the initial object. It also shows the act of drilling down to further `childNodes` collections until all child nodes are exposed and catalogued. Text nodes are labeled accordingly. The first 15 characters of the actual text are placed in the results to help you identify the nodes when you compare the results against your HTML source code.

LISTING 26-3

Collecting Child Nodes

```
<!-- xmp tags added for display of HTML in a browser window -->
<xmp>
   function walkChildNodes(objRef, n)
   {
      var obj;
      if (objRef)
      {
         if (typeof objRef == "string")
         {
            obj = document.getElementById(objRef);
         }
         else
         {
            obj = objRef;
         }
      }
      else
      {
         obj = (document.body.parentElement) ?
            document.body.parentElement : document.body.parentNode;
      }
      var output = "";
      var indent = "";
      var i, group, txt;
      if (n)
      {
         for (i = 0; i < n; i++)
         {
            indent += "+---";
         }
      }
      else
```

continued

LISTING 26-3 *(continued)*

```
      {
         n = 0;
         output += "Child Nodes of <" + obj.tagName;
         output += ">\n====================\n";
      }
      group = obj.childNodes;
      for (i = 0; i < group.length; i++)
      {
         output += indent;
         switch (group[i].nodeType)
         {
            case 1:
               output += "<" + group[i].tagName;
               output += (group[i].id) ? " ID=" + group[i].id : "";
               output += (group[i].name) ? " NAME=" + group[i].name : "";
               output += ">\n";
               break;
            case 3:
               txt = group[i].nodeValue.substr(0,15);
               output += "[Text:\"" + txt.replace(/[\r\n]/g,"<cr>");
                  if (group[i].nodeValue.length > 15)
                  {
                     output += "...";
                  }
               output += "\"]\n";
               break;
            case 8:
               output += "[!COMMENT!]\n";
               break;
            default:
               output += "[Node Type = " + group[i].nodeType + "]\n";
         }
         if (group[i].childNodes.length > 0)
         {
           output += walkChildNodes(group[i], n+1);
         }
      }
      return output;
   }
</xmp>
```

children

Value: Array of element objects Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera+, Chrome+

The `children` property consists of an array of element objects contained by the current object. Unlike the `childNodes` property, `children` does not take into account text nodes, but focuses strictly on the HTML (and XML) element containment hierarchy from the point of view of the current object. Children exposed to the current object are immediate children only. If you want to get all element objects nested within the current object (regardless of how deeply nested they are), use the `all` collection instead.

Example

Listing 26-4 shows how you can use the `children` property to walk the child nodes of a given node. This function accumulates and returns a hierarchical list of child elements from the point of view of the document's HTML element (the default) or any element whose ID you pass as a string parameter. This function is embedded in The Evaluator so that you can inspect the parent–child hierarchy of that page or (when using `evaluator.js` for debugging as described in Chapter 48 on the CD-ROM) the element hierarchy within any page you have under construction. Try it out in The Evaluator by entering the following statements in the top text box:

```
walkChildren("myTable")
```

Notice in this example that the `walkChildren()` function is called with the name of an element instead of a call to `document.getElementId()`. This reveals the flexibility of the `walkChildren()` function and how it can operate on either an object or the name of an object (element). The `walkChildNodes()` function in Listing 26-3 offers the same flexibility.

The results of the `walkChildren()` function show the nesting relationships among all parent and child elements within the scope of the initial object. It also shows the act of drilling down to further `children` collections until all child elements are exposed and cataloged. The element tags also display their `id` and/or `name` attribute values if any are assigned to the elements in the HTML source code.

cite

Value: URL string   Read/Write

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cite` property contains a URL that serves as a reference to the source of an element, as in the author of a quote. The property is intended to apply to only the `blockquote`, `q`, `del`, and

ins element objects, but IE supports it in a wider range of text content objects. This may or may not be a mistake, so it's probably not a safe bet to use the property outside its intended elements.

className

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

A *class name* is an identifier that is assigned to the class attribute of an element. To associate a cascading style sheets (CSS) rule with several elements in a document, assign the same identifier to the class attributes of those elements, and use that identifier (preceded by a period) as the CSS rule's selector. An element's className property enables the application of different CSS rules to that element under script control. Listing 26-5 shows an example of such a script.

Example

The style of an element toggles between on and off in Listing 26-5 by virtue of setting the element's className property alternatively to an existing style sheet class selector name and an empty string. When you set the className to an empty string, the default behavior of the h1 element governs the display of the first header. A click of the button forces the style sheet rule to override the default behavior in the first h1 element.

   </body>
</html>
```

JavaScript: jsb26-05.js

```
function toggleSpecialStyle(elemID)
{
   var elem = (document.all) ? document.all(elemID) :
               document.getElementById(elemID);
      if (elem.className == "")
      {
         elem.className = "special";
      }
      else
      {
         elem.className = "";
      }
}
```

You can also create multiple versions of a style rule with different class selector identifiers and apply them at will to a given element.

Related Items: `rule`, `stylesheet` objects (Chapter 38); `id` property

`clientHeight`
`clientWidth`

Value: Integer   Read-Only

Compatibility: WinIE4+, MacIE4+, NN7, Moz1.0.1+, Safari+, Opera+, Chrome+

These two properties by and large reveal the pixel height and width of the content within an element whose style sheet rule includes height and width settings. In theory, these measures do not take into account any margins, borders, or padding that you add to an element by way of style sheets. In practice, however, different combinations of borders, margins, and padding influence these values in unexpected ways. One of the more reliable applications of the `clientHeight` property enables you to discover, for example, where the text of an overflowing element ends. To read the rendered

dimensions of an element, you are better served across browsers with the `offsetHeight` and `offsetWidth` properties.

For the `document.body` object, the `clientHeight` and `clientWidth` properties return the inside height and width of the window or frame (plus or minus a couple of pixels). These take the place of desirable, but nonexistent, window properties in IE.

Unlike earlier versions, Internet Explorer 5+ expanded the number of objects that employ these properties to include virtually all objects that represent HTML elements. Values for these properties in Mozilla-based browsers are zero except for `document.body`, which measures the browser's current content area.

Example

Listing 26-6 for IE includes an example of how to size content dynamically on a page based on the client-area width and height. This example calls upon the `clientHeight` and `clientWidth` properties of a `div` element that contains a paragraph element. Only the width of the `div` element is specified in its style sheet rule, which means that the paragraph's text wraps inside that width and extends as deeply as necessary to show the entire paragraph. The `clientHeight` property describes that depth. The `clientHeight` property then calculates where a logo image should be positioned immediately after `div`, regardless of the length of the text. As a bonus, the `clientWidth` property helps the script center the image horizontally with respect to the paragraph's text.

LISTING 26-6

Using clientHeight and clientWidth Properties

HTML: jsb26-06.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>clientHeight and clientWidth Properties</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-06.js"></script>
   </head>
   <body>
      <button onclick="showLogo()">Position and Show Logo Art</button>
      <div id="myDIV" style="width:200px">
         <p>Lorem ipsum dolor sit amet, consectetaur adipisicing elit, sed do
            eiusmod tempor incididunt ut labore et dolore magna aliqua. Ut enim
            adminim veniam, quis nostrud exercitation ullamco laboris nisi ut
            aliquip ex ea commodo consequat. Duis aute irure dolor in
            reprehenderit involuptate velit esse cillum dolore eu fugiat nulla
            pariatur. Excepteur sint occaecat cupidatat non proident.
         </p>
      </div>
      <div id="logo" style="position:absolute; width:120px; visibility:hidden">
         <img alt="image" src="logo.gif" />
      </div>
   </body>
</html>
```

continued

LISTING 26-6 *(continued)*

```
JavaScript: jsb26-01.js
function showLogo()
{
   var paragraphW = document.getElementById("myDIV").clientWidth;
   var paragraphH = document.getElementById("myDIV").clientHeight;
   // correct for Windows/Mac discrepancies
   var paragraphTop = (document.getElementById("myDIV").clientTop) ?
      document.getElementById("myDIV").clientTop :
      document.getElementById("myDIV").offsetTop;
   var logoW = document.getElementById("logo").style.pixelWidth;
   // center logo horizontally against paragraph
   document.getElementById("logo").style.pixelLeft = (paragraphW-logoW) / 2;
   // position image immediately below end of paragraph
   document.getElementById("logo").style.pixelTop = paragraphTop + paragraphH;
   document.getElementById("logo").style.visibility = "visible";
}
```

To assist in the vertical positioning of the logo, the `offsetTop` property of the `div` object provides the position of the start of the `div` with respect to its outer container (the `body`). Unfortunately, MacIE uses the `clientTop` property to obtain the desired dimension. That measure (assigned to the `paragraphTop` variable), plus the `clientHeight` of the `div`, provides the top coordinate of the image.

Related Items: `offsetHeight`, `offsetWidth` properties

clientLeft
clientTop

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera+, Chrome+

The purpose and names of the `clientLeft` and `clientTop` properties are confusing at best. Unlike the `clientHeight` and `clientWidth` properties, which apply to the content of an element, the `clientLeft` and `clientTop` properties return essentially no more information than the thickness of a border around an element — provided that the element is positioned. If you do not specify a border or do not position the element, the values are zero (although the `document.body` object can show a couple of pixels in each direction without explicit settings). If you are trying to read the left and top coordinate positions of an element, the `offsetLeft` and `offsetTop` properties are more valuable in WinIE; as shown in Listing 26-6, however, the `clientTop` property returns a suitable value in MacIE. Virtually all elements have the `clientLeft` and `clientTop` properties in IE5+, whereas support in MacIE is less consistent.

Related Items: `offsetLeft`, `offsetTop` properties

contentEditable

Value: Boolean Read/Write

Compatibility: WinIE5.5+, MacIE-, NN-, Moz+, Safari+, Opera+, Chrome+

IE5.5 introduced the concept of editable HTML content on a page. Element tags can include a `contentEditable` attribute whose value is echoed via the `contentEditable` property of the element. The default value for this property is `inherit`, which means that the property inherits whatever setting this property has in the hierarchy of HTML containers outward to the body. If you set the `contentEditable` property to `true`, that element and all nested elements set to inherit the value become editable; conversely, a setting of `false` turns off the option to edit the content. Some browsers automatically provide a visual cue for editable elements by giving an editable element a glowing blue border.

Example

Listing 26-7 demonstrates how to use the `contentEditable` property to create a very simple poetry editor. When you click the button of a freshly loaded page, the `toggleEdit()` function captures the opposite of the current editable state via the `contentEditable` property of the `div` that is subject to edit. You switch on editing for that element in the next statement by assigning the new value to the `contentEditable` property of the `div`. For added impact, turn the text of the `div` to red to provide additional user feedback about what is editable on the page. The button label is also switched to one that indicates the action invoked by the next click of that button.

LISTING 26-7

Using the contentEditable Property

HTML: jsb26-07.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Editable Content</title>
      <style type="text/css">
         .normal
         {
            color: black;
         }
         .editing
         {
            color: red;
         }
      </style>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-07.js"></script>
   </head>
   <body>
      <h1>Poetry Editor</h1>
      <hr />
      <p>Turn on editing to modify the following text:</p>
      <div id="noneditableText">
         Roses are red,
         <br />
         Violets are blue.
      </div>
```

continued

LISTING 26-7 *(continued)*

```
      <div id="editableText">
         Line 3,
         <br />
         Line 4.
      </div>
      <p>
         <button id="editBtn" onclick="toggleEdit()"
                 onfocus="this.blur()">Enable Editing</button>
      </p>
   </body>
</html>
```

JavaScript: jsb26-07.js

```
function toggleEdit()
{
   var newState = document.getElementById("editableText").contentEditable;
   // While contentEditable is boolean, different browsers behave differently
      if (newState == false || newState == "false" || newState == "inherit")
      {
         newState = true;
      }
      else
      {
         newState = false;
      }
   document.getElementById("editableText").contentEditable = newState;
   document.getElementById("editableText").className = (newState) ?
        "editing" : "normal";
   document.getElementById("editBtn").innerHTML = (newState) ?
        "Disable Editing" : "Enable Editing";
}
```

Related Item: `isContentEditable` property

currentStyle

Value: `style` object Read-Only

Compatibility: WinIE5+, MacIE5+, NN-, Moz-, Safari-, Opera-, Chrome-

Every element has style attributes applied to it, even if those attributes are the browser's default settings. Because an element's `style` object reflects only those properties whose corresponding attributes are explicitly set via CSS statements, you cannot use the `style` property of an `element` object to view default style settings applied to an element. That's where the `currentStyle` property comes in.

This property returns a read-only `style` object that contains values for every possible `style` property applicable to the element. If a `style` property is explicitly set via CSS statement or script adjustment, the current reading for that property is also available here. Thus, a script can inquire about any property to determine whether it should change to meet some scripted design goal.

For example, if you surround some text with an `<em>` tag, the browser by default turns that text into an italic font style. This setting is not reflected in the element's `style` object (`fontStyle` property) because the italic setting was not set via CSS; by contrast, the `element` object's `currentStyle.fontStyle` property reveals the true, current `fontStyle` property of the element as italic.

Example

To change a `style` property setting, access it via the element's `style` object. Use The Evaluator (see Chapter 4) to compare the properties of the `currentStyle` and `style` objects of an element. For example, an unmodified copy of The Evaluator contains an `em` element whose ID is `"myEM"`. Enter `document.getElementById("myEM").style` in the bottom property listing text box and press Enter. Notice that most of the property values are empty. Now enter `document.getElementById("myEM").currentStyle` in the property listing text box and press Enter. Every property has a value associated with it.

Related Items: `runtimeStyle`, `style` objects (Chapter 38); `window.getComputedStyle()` for W3C DOM browsers (Chapter 27)

dateTime

Value: Date string Read-Only

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `dateTime` property contains a date/time value that is used to establish a timestamp for an element. Similar to the `cite` property, the `dateTime` property is intended to apply to a lesser number of element objects (`del` and `ins`) than is actually supported in IE. This may or may not be a mistake, so it's probably not a safe bet to use the property outside its intended elements.

dataFld
dataFormatAs
dataSrc

Value: String Read/Write

Compatibility: WinIE4+, MacIE5, NN-, Moz-, Safari-, Opera-, Chrome-

The `dataFld`, `dataFormatAs`, and `dataSrc` properties (along with more element-specific properties such as `dataPageSize` and `recordNumber`) are part of the Internet Explorer data-binding facilities based on ActiveX controls. The Win32 versions of IE4 and later have several ActiveX objects built into the browsers that facilitate direct communication between a web page and a data source. Data sources include text files, XML data, HTML data, and external databases (MacIE supports text files only). Data binding is a very large topic, much of which extends more to discussions about Microsoft Data Source Objects (DSOs), ODBC, and JDBC — subjects well beyond the scope of this book. But data binding is a powerful tool and can be of use even if you are not a database guru. Therefore, this discussion of the three primary properties — `dataFld`, `dataFormatAs`, and `dataSrc` — briefly covers data binding through Microsoft's *Tabular Data Control DSO*. This allows any page to access, sort, display, and filter (but not update) data downloaded into a web page from an external text file (commonly, comma- or tab-delimited data).

You can load data from an external text file into a document with the help of the *Tabular Data Control* (TDC). You retrieve the data by specifying the TDC object within an `<object>` tag set and specifying additional parameters, such as the URL of the text file and field delimiter characters. The `object`

element can go anywhere within the body of your document. (We tend to put it at the bottom of the code so that all normal page rendering happens before the control loads.) Retrieving the data simply brings it into the browser and does not, on its own, render the data on the page.

If you haven't worked with embedded objects in IE, the classid attribute value might seem a bit strange. The most perplexing part to some is the long value of numeric data signifying the *Globally Unique Identifier* (GUID) for the object, which is IE's way of uniquely identifying objects. You must enter this value exactly as shown in the following example for the proper ActiveX TDC to run. The HTML syntax for this object is as follows:

```
<object id="objName" classid="clsid:333C7BC4-460F-11D0-BC04-0080C7055A83">
   <param name="DataURL" value="URL">
   [additional optional parameters]
</object>
```

Table 26-3 lists the parameters available for the TDC. Only the DataURL parameter is required. Other parameters — such as FieldDelim, UseHeader, RowDelim, and EscapeChar — may be helpful, depending on the nature of the data source.

TABLE 26-3

Tabular Data Control Parameters

Parameter	Description
CharSet	Character set of the data source file. Default is latin1.
DataURL	URL of data source file (relative or absolute).
EscapeChar	Character used to escape delimiter characters that are part of the data. Default is empty. A common value is "\".
FieldDelim	Delimiter character between fields within a record. Default is comma (,). For a Tab character, use a value of .
Language	ISO language code of source data. Default is en-us.
TextQualifier	Optional character surrounding a field's data. Default is empty.
RowDelim	Delimiter character between records. Default is newline (NL).
UseHeader	Set to true if the first row of data in the file contains field names. Default is false.

The value you assign to the object element's id attribute is the identifier that your scripts use to communicate with the data after the page and data completely load. Therefore, you can have as many uniquely named TDCs loaded in your page as there are data source files you want to access at the same time.

The initial binding of the data to HTML elements usually comes when you assign values to the datasrc and datafld attributes of the elements. The datasrc attribute points to the dso identifier (matching the id attribute of the object element, preceded by a hash symbol), whereas the datafld attribute points to the name of the field whose data should be extracted. When you use

data binding with an interactive element such as a table, multiple records are displayed in consecutive rows of the table (more about this in a moment).

Adjust the `dataSrc` and `dataFld` properties if you want the same HTML element (other than a table) to change the data that it displays. These properties apply to a subset of HTML elements that can be associated with external data: `a`, `applet`, `body`, `button`, `div`, `frame`, `iframe`, `img`, `input` (most types), `label`, `marquee`, `object`, `param`, `select`, `span`, and `textarea` objects.

In some cases, your data source may store chunks of HTML-formatted text for rendering inside an element. Unless directed otherwise, the browser renders a data source field as plain text — even if the content contains HTML formatting tags. But if you want the HTML to be observed during rendering, you can set the `dataFormatAs` property (or, more likely, the `dataformatas` attribute of the tag) to `HTML`. The default value is `text`.

Example

Listing 26-8 is a simple document that has two TDC objects associated with it. The external files are different formats of the U.S. Bill of Rights document. One file is a traditional, tab-delimited data file consisting of only two records. The first record is a tab-delimited sequence of field names (named `"Article1"`, `"Article2"`, and so on). The second record is a tab-delimited sequence of article content defined in HTML:

```
<h1>ARTICLE I</h1>
<p>Congress shall make...</p>
```

The second file is a raw-text file consisting of the full Bill of Rights with no HTML formatting attached.

When you load Listing 26-8, only the first article of the Bill of Rights appears in a blue-bordered box. Buttons enable you to navigate to the previous and next articles in the series. Because the data source is a traditional, tab-delimited file, the `nextField()` and `prevField()` functions calculate the name of the next source field and assign the new value to the `dataFld` property. All of the data is already in the browser after the page loads, so cycling through the records is as fast as the browser can reflow the page to accommodate the new content.

         {
            display:none;
         }
      </style>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-08.js"></script>
   </head>
   <body>
      <h1>U.S. Bill of Rights</h1>
      <form>
         <input type="button" value="Toggle Complete/Individual"
                onclick="toggleComplete()" />
         <span id="buttonWrapper" class="">
            <input type="button" value="Prev" onclick="prevField()" />
            <input type="button" value="Next" onclick="nextField()" />
         </span>
      </form>
      <div id="display" datasrc="#rights_html" datafld="Article1"
           dataformatas="HTML">
      </div>
      <object id="rights_html"
              classid="clsid:333C7BC4-460F-11D0-BC04-0080C7055A83">
         <param name="DataURL" value="Bill of Rights.txt" />
         <param name="UseHeader" value="True" />
         <param name="FieldDelim" value="&#09;" />
      </object>
      <object id="rights_raw"
              classid="clsid:333C7BC4-460F-11D0-BC04-0080C7055A83">
         <param name="DataURL" value="Bill of Rights (no format).txt" />
         <param name="FieldDelim" value="\" />
         <param name="RowDelim" value="\" />
      </object>
   </body>
</html>
```

JavaScript: jsb26-08.js

```
function nextField()
{
   var elem = document.getElementById("display");
   var fieldName = elem.dataFld;
   var currFieldNum = parseInt(fieldName.substring(7, fieldName.length),10);
   currFieldNum = (currFieldNum == 10) ? 1 : ++currFieldNum;
   elem.dataFld = "Article" + currFieldNum;
}
function prevField()
{
   var elem = document.getElementById("display");
   var fieldName = elem.dataFld;
   var currFieldNum = parseInt(fieldName.substring(7, fieldName.length),10);
```

```
   currFieldNum = (currFieldNum == 1) ? 10 : --currFieldNum;
   elem.dataFld = "Article" + currFieldNum;
}

function toggleComplete()
{
   if (document.getElementById("buttonWrapper").className == "")
   {
      document.getElementById("display").dataSrc = "#rights_raw";
      document.getElementById("display").dataFld = "column1";
      document.getElementById("display").dataFormatAs = "text";
      document.getElementById("buttonWrapper").className = "hiddenControl";
   }
   else
   {
      document.getElementById("display").dataSrc = "#rights_html";
      document.getElementById("display").dataFld = "Article1";
      document.getElementById("display").dataFormatAs = "HTML";
      document.getElementById("buttonWrapper").className = "";
   }
}
```

Another button on the page enables you to switch between the initial piecemeal version of the document and the unformatted version in its entirety. To load the entire document as a single record, the `FieldDelim` and `RowDelim` parameters of the second `object` element eliminate their default values by replacing them with characters that don't appear in the document at all. And because the external file does not have a field name in the file, the default value (`column1` for the lone column in this document) is the data field. Thus, in the `toggleComplete()` function, the `dataSrc` property is changed to the desired `object` element ID; the `dataFld` property is set to the correct value for the data source; and the `dataFormatAs` property is changed to reflect the different intention of the source content (to be rendered as HTML or as plain text). When the display shows the entire document, you can hide the two radio buttons by assigning a `className` value to the `span` element that surrounds the buttons. The `className` value is the identifier of the class selector in the document's style sheet. When the `toggleComplete()` function resets the `className` property to empty, the default properties (normal inline display style) take hold.

One further example demonstrates the kind of power available to the TDC under script control. Listing 26-9 displays table data from a tab-delimited file of Academy Awards information. The data file has eight columns of data, and each column heading is treated as a field name: Year, Best Picture, Best Director, Best Director Film, Best Actress, Best Actress Film, Best Actor, and Best Actor Film. For the design of the page, only five fields from each record appear: Year, Film, Director, Actress, and Actor. Notice in the listing that the HTML for the table and its content is bound to the data source object and the fields within the data.

The dynamic part of this example is apparent in how you can sort and filter the data, after it is loaded into the browser, without further access to the original source data. The TDC object features `Sort` and `Filter` properties that enable you to act on the data currently loaded in the browser. The simplest kind of sorting indicates on which field (or fields, via a semicolon-delimited list of field names) the entire data set should be sorted. Leading the name of the sort field is either a plus (to indicate ascending) or minus (descending) symbol. After setting the `data` object's `Sort` property, invoke its

Reset() method to tell the object to apply the new property. The data in the bound table is immediately redrawn to reflect any changes.

Similarly, you can tell a data collection to display records that meet specific criteria. In Listing 26-9, two select lists and a pair of radio buttons provide the interface to the Filter property's settings. For example, you can filter the output to display only those records in which the Best Picture was the same picture of the winning Best Actress's performance. Simple filter expressions are based on field names:

```
dataObj.Filter = "Best Picture" = "Best Actress Film";
```

LISTING 26-9

```

Related Items: `recordNumber`, `table.dataPageSize` properties

dir

Value: `"ltr" | "rtl"` Read/Write

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `dir` property (based on the `dir` attribute of virtually every text-oriented HTML element) controls whether an element's text is rendered left to right (the default) or right to left. By and large, this property (and HTML attribute) is necessary only when you need to override the default directionality of a language's character set as defined by the Unicode standard.

Example

Changing this property value in a standard U.S. version of a browser only makes the right margin the starting point for each new line of text (in other words, the characters are not rendered in reverse order). You can experiment with this in The Evaluator by entering the following statements in the expression evaluation field:

```
document.getElementById("myP").dir = "rtl"
```

Related Item: `lang` property

disabled

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Though only form elements have a `disabled` property in IE4 and IE5, this property is associated with every HTML element in IE5.5+. W3C DOM browsers apply the property only to form control and `style` element objects. Disabling an HTML element (like form elements) usually gives the element a dimmed look, indicating that it is not active. A disabled element does not receive any events. It also cannot receive focus, either manually or by script. But a user can still select and copy a disabled body text element.

Note

If you disable a form control element, the element's data is not submitted to the server with the rest of the form elements. If you need to keep a form control locked down but still submit it to the server, use the `form` element's `onsubmit` event handler to enable the form control right before the form is submitted. ■

Example

Use The Evaluator (see Chapter 4) to experiment with the `disabled` property on both form elements (IE4+ and W3C) and regular HTML elements (WinIE5.5+). For IE4+ and W3C browsers, see what happens when you disable the output text area by entering the following statement in the top text box:

```
document.forms[0].output.disabled = true
```

The text area is disabled for user entry, although you can still set the field's `value` property via script (which is how the `true` returned value got there).

If you have WinIE5.5+, disable the `myP` element by entering the following statement in the top text box:

```
document.getElementById("myP").disabled = true
```

The sample paragraph's text turns gray.

Related Item: `isDisabled` property

document

Value: `document` object Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera+, Chrome-

In the context of HTML element objects as exposed in IE4+/Opera, the `document` property is a reference to the document that contains the object. Though it is unlikely that you will need to use this property, `document` may come in handy for complex scripts and script libraries that handle objects in a generic fashion and do not know the reference path to the document containing a particular object. You might need a reference to the document to inspect it for related objects. The W3C version of this property is `ownerDocument`.

Example

The following simplified function accepts a parameter that can be any object in a document hierarchy. The script finds out the reference of the object's containing document for further reference to other objects:

```
function getCompanionFormCount(obj)
{
   var ownerDoc = obj.document;
   return ownerDoc.forms.length;
}
```

Because the `ownerDoc` variable contains a valid reference to a `document` object, the `return` statement uses that reference to return a typical property of the document object hierarchy.

Related Item: `ownerDocument` property

filters[]

Value: Array Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

Filters are IE-specific style sheet add-ons that offer a greater variety of font rendering (such as drop shadows) and transitions between hidden and visible elements. Each filter specification is a `filter` object. The `filters` property contains an array of `filter` objects defined for the current element. You can apply filters to the following set of elements: `bdo`, `body`, `button`, `fieldset`, `img`, `input`, `marquee`, `rt`, `ruby`, `table`, `td`, `textarea`, `th`, and positioned `div` and `span` elements. See Chapter 38 for details about style sheet filters.

Related Item: `filter` object

firstChild
lastChild

Value: Node object reference Read-Only

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

W3C DOM-based DOMs are built around an architecture known as a *node map*. Each object defined by HTML is a node in the map. A node has relationships with other nodes in the document — relationships described in family terms of parents, siblings, and children.

A *child node* is an element that is contained by another element. The container is the parent of such a child. Just as an HTML element can contain any number of child elements, so can a parent object have zero or more children. A list of those children (returned as an array) can be read from an object by way of its `childNodes` property:

```
var nodeArray = document.getElementById("elementID").childNodes;
```

Though you can use this array (and its `length` property) to get a reference to the first or last child node, the `firstChild` and `lastChild` properties offer shortcuts to those positions. These are helpful when you wish to insert a new child before or after all of the others, and you need a reference point for methods that add elements to the document's node list.

Example

Listing 26-10 contains an example of how to use the `firstChild` and `lastChild` properties to access child nodes. These two properties come in handy in this example, which adds and replaces `li` elements to an existing `ol` element. You can enter any text you want to appear at the beginning or end of the list. Using the `firstChild` and `lastChild` properties simplifies access to the ends of the list. For the functions that replace child nodes, the example uses the `replaceChild()` method. Alternatively for IE4+, you can modify the `innerText` property of the objects returned by the `firstChild` or `lastChild` property. This example is especially interesting to watch when you add items to the list: The browser automatically renumbers items to fit the current state of the list.

Caution

See the discussion of the `childNodes` property earlier in this chapter for details about the presence of phantom nodes in some browser versions. The problem may influence your use of the `firstChild` and `lastChild` properties. ■

Note

As handy as it may be, in a strict W3C approach to JavaScript, you wouldn't use the `innerHTML` property because it isn't officially part of the W3C standard. However, it is often too powerful a convenience property to ignore, as much of the code throughout this book is a testament. The book does show the W3C node manipulation alternative to `innerHTML` in some examples. Refer to Chapter 29 for a thorough explanation and examples of the W3C alternative to `innerHTML`. ■

height
width

Value: Integer or percentage string Read/Write and Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `height` and `width` properties described here are not the identically named properties that belong to an element's style. Rather, these properties reflect the values normally assigned to `height` and `width` attributes of elements such as `img`, `applet`, `table`, and so on. As such, these properties are accessed directly from the object (for example, `document.getElementById("myTable").width`) rather than through the `style` object (for example, `document.getElementById("myDIV").style.width`). Only elements for which the HTML 4.*x* standard provides `height` and `width` attributes have the corresponding properties.

Values for these properties are either integer pixel values (numbers or strings) or percentage values (strings only). If you need to perform some math on an existing percentage value, use the `parseInt()` function to extract the numeric value for use with math calculations. If an element's `height` and `width` attributes are set as percentage values, you can use the `offsetHeight` and `offsetWidth` properties in many modern browsers to get the rendered pixel dimensions.

Property values are read/write for the `image` object in most recent browser versions because you can resize an `image` object in after the page loads. Properties are read/write for some other objects (such as the `table` object) — but not necessarily all others that support these properties.

In general, you cannot set the value of these properties to something less than is required to render the element. This is particularly true of a table. If you attempt to set the `height` value to less than the amount of pixels required to display the table as defined by its style settings, your changes have no effect (even though the property value retains its artificially low value). For other objects, however, you can set the size to anything you like, and the browser scales the content accordingly (images, for example). If you want to see only a segment of an element (in other words, to crop the element), use a style sheet to set the element's clipping region.

Example

The following example demonstrates how to use the `width` property by increasing the width of a table by 10 percent:

```
var tableW = parseInt(document.getElementById("myTable").width);
document.getElementById("myTable").width = (tableW * 1.1) + "%";
```

Because the initial setting for the `width` attribute of the `table` element is set as a percentage value, the script calculation extracts the number from the percentage width string value. In the second statement, the old number is increased by 10 percent and turned into a percentage string by appending the percentage symbol to the value. The resulting string value is assigned to the `width` property of the table.

Related Items: `clientHeight`, `clientWidth` properties; `style.height`, `style.width` properties

hideFocus

Value: Boolean Read/Write

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

In IE for Windows, button types of form controls and links display a dotted rectangle around some part of the element whenever that element has focus. If you set the `tabindex` attribute or `tabIndex` property of any other kinds of elements in IE5+, they, too, display that dotted line when given focus. You can still let an element receive focus but hide that dotted line by setting the `hideFocus` property of the element object to `true` (default value is `false`).

Hiding focus does not disable the element. In fact, if the element about to receive focus is scrolled out of view, the page scrolls to bring the element into view. Form controls that respond to keyboard action (for example, pressing the spacebar to check or uncheck a checkbox control) also continue to work as normal. For some designers, the focus rectangle harms the design goals of the page. The `hideFocus` property gives them more control over the appearance while maintaining consistency of operation with other pages. There is no corresponding HTML attribute for a tag, so you can use an `onload` event handler in the page to set the `hideFocus` property of desired objects after the page loads.

Example

Use The Evaluator (see Chapter 4) to experiment with the `hideFocus` property in WinIE5.5+. Enter the following statement in the top text box to assign a `tabIndex` value to the `myP` element so that by default, the element receives focus and the dotted rectangle:

```
document.getElementById("myP").tabIndex = 1
```

Press the Tab key several times until the paragraph receives focus. Now disable the focus rectangle:

```
document.getElementById("myP").hideFocus = true
```

If you now press the Tab key several times, the dotted rectangle does not appear around the paragraph. To prove that the element still receives focus, scroll the page down to the bottom so that the paragraph is not visible (you may have to resize the window). Click one of the focusable elements at the bottom of the page and then press the Tab key slowly until the Address field toolbar has focus. Press the Tab key once. The page scrolls to bring the paragraph into view, but there is no focus rectangle around the element.

Related Items: `tabIndex` property; `srcollIntoView()` method

id

Value: String (See text)

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `id` property returns the identifier assigned to an element's `id` attribute in the HTML code. A script cannot modify the ID of an existing element or assign an ID to an element that lacks one. But if a script creates a new element object, an identifier may be assigned to it by way of the `id` property.

Example

Rarely do you need to access this property in a script — unless you write an authoring tool that iterates through all elements of a page to extract the IDs assigned by the author. You can retrieve an object reference when you know the object's `id` property (via the `document.getElementById(elemID)` method). But if for some reason your script doesn't know the ID of, say, the second paragraph of a document, you can extract that ID as follows:

```
var elemID = document.getElementsByTagName("p")[1].id;
```

Related Item: `className` property

innerHTML
innerText

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

One way that Internet Explorer exposes the contents of an element is through the `innerHTML` and `innerText` properties. (NN6+/Moz offer only the `innerHTML` property.) All content defined by these inner properties consists of document data that is contained by an element's start and end tags but does not include the tags themselves (see the `outerText` and `outerHTML` properties). Setting these inner properties is a common way to modify a portion of a page's content after the page loads.

The `innerHTML` property contains not only the text content for an element as seen on the page, but also every bit of HTML tagging that is associated with that content. (If there are no tags in the content, the text is rendered as is.) For example, consider the following bit of HTML source code:

```
<p id="paragraph1">"How <em>are</em> you?" he asked.</p>
```

The value of the paragraph object's innerHTML property (document.getElementById ("paragraph1").innerHTML) is

```
"How <em>are</em> you?" he asked.
```

The browser interprets any HTML tags included in a string you assign to an element's innerHTML property as tags. This also means that you can introduce entirely new nested elements (or child nodes in the modern terminology) by assigning a slew of HTML content to an element's innerHTML property. The document's object model adjusts itself to the newly inserted content.

By contrast, the innerText property knows only about the text content of an element container. In the example you just saw, the value of the paragraph's innerText property (document .getElementById("paragraph1").innerText) is

```
"How are you?" he asked.
```

It's important to remember that if you assign a string to the innerText property of an element, and that string contains HTML tags, the tags and their angle brackets appear in the rendered page and are not interpreted as live tags.

The W3C DOM Level 3 adds a textContent property that serves as the standard equivalent of innerText. IE does not support textContent.

Do not modify the innerHTML property to adjust the HTML for frameset, html, head, or title objects. You may modify table constructions through either innerHTML or the various table-related methods that create or delete rows, columns, and cells (see Chapter 41). It is also safe to modify the contents of a cell by setting its innerHTML or innerText property.

When the HTML you insert includes a <script> tag, be sure to include the defer attribute to the opening tag. This goes even for scripts that contain function definitions, which you might consider to be deferred automatically.

The innerHTML property is not supported by the W3C DOM, but it does share widespread support in all modern browsers. You could argue that a pure W3C DOM node manipulation approach is more structured than just assigning HTML code to innerHTML, but the ease of making a single property assignment has so far won out in the practicality of everyday scripting. Whenever possible, the examples in this book use the W3C approach to alter the HTML code for a node, but there are several instances where innerHTML is simply too concise an option to resist.

Example

Listing 26-11 contains an example of how to use the innerHTML and innerText properties to alter dynamically the content within a page. The page generated in the listing contains an h1 element label and a paragraph of text. The purpose is to demonstrate how the innerHTML and innerText properties differ in their intent. Two text boxes contain the same combination of text and HTML tags that replaces the inner content of the paragraph's label.

If you apply the default content of the first text box to the innerHTML property of the label1 object, the italic style is rendered as such for the first word. In addition, the text in parentheses is rendered with the help of the small style sheet rule assigned by virtue of the surrounding <span> tags. But if you apply that same content to the innerText property of the label object, the tags are rendered as is.

Use this as a laboratory to experiment with some other content in both text boxes. See what happens when you insert a <br> tag within some text in both text boxes.

      }
}
```

Related Items: `outerHTML`, `outerText`, `textContent` properties; `replaceNode()` method

isContentEditable

Value: Boolean Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari 1.2+, Opera+, Chrome+

The `isContentEditable` property returns a Boolean value indicating whether a particular element object is set to be editable (see the discussion of the `contentEditable` property earlier in this chapter). This property is helpful because if a parent element's `contentEditable` property is set to `true`, a nested element's `contentEditable` property likely is set to its default value `inherit`. But because its parent is editable, the `isContentEditable` property of the nested element returns `true`.

Example

Use The Evaluator (see Chapter 4) to experiment with both the `contentEditable` and `isContentEditable` properties on the `myP` and nested `myEM` elements (reload the page to start with a known version). Check the current setting for the `myEM` element by typing the following statement in the top text box:

```
myEM.isContentEditable
```

This value is `false` because no element upward in the element containment hierarchy is set to be editable yet. Next, turn on editing for the surrounding `myP` element:

```
myP.contentEditable = true
```

At this point, the entire `myP` element is editable because its child element is set, by default, to inherit the edit state of its parent. Prove it by entering the following statement in the top text box:

```
myEM.isContentEditable
```

Although the `myEM` element is shown to be editable, no change has accrued to its `contentEditable` property:

```
myEM.contentEditable
```

This property value remains the default `inherit`.

Related Item: `contentEditable` property

isDisabled

Value: Boolean Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `isDisabled` property returns a Boolean value that indicates whether a particular element object is set to be disabled (see the discussion of the `disabled` property earlier in this chapter). This property is helpful; if a parent element's `disabled` property is set to `true`, a nested element's `disabled` property likely is set to its default value of `false`. But because its parent is disabled, the `isDisabled` property of the nested element returns `true`. In other words, the `isDisabled` property returns the actual disabled status of an element regardless of its `disabled` property.

Example

Use The Evaluator (see Chapter 4) to experiment with both the `disabled` and `isDisabled` properties on the `myP` and nested `myEM` elements (reload the page to start with a known version). Check the current setting for the `myEM` element by typing the following statement in the top text box:

```
myEM.isDisabled
```

This value is `false` because no element upward in the element containment hierarchy is set for disabling yet. Next, disable the surrounding `myP` element:

```
myP.disabled = true
```

At this point, the entire `myP` element (including its children) is disabled. Prove it by entering the following statement in the top text box:

```
myEM.isDisabled
```

Although the `myEM` element is shown as disabled, no change has accrued to its `disabled` property:

```
myEM.disabled
```

This property value remains the default `false`.

Related Item: `disabled` property

isMultiLine

Value: Boolean Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `isMultiLine` property returns a Boolean value that reveals whether the element object is capable of occupying or displaying more than one line of text. It is important that this value does not reveal whether the element actually occupies multiple lines; rather, it indicates the potential of doing so. For example, a text `input` element cannot wrap to multiple lines, so its `isMultiLine` property is `false`. However, a `button` element can display multiple lines of text for its label, so it reports `true` for the `isMultiLine` property.

Example

Use The Evaluator (see Chapter 4) to read the `isMultiLine` property for elements on that page. Try the following statements in the top text box:

```
document.body.isMultiLine
document.forms[0].input.isMultiLine
myP.isMultiLine
myEM.isMultiLine
```

All but the text field form control report that they are capable of occupying multiple lines.

isTextEdit

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `isTextEdit` property reveals whether an object can have a WinIE `TextRange` object created with its content (see Chapter 33 on the CD-ROM). You can create `TextRange` objects from only a limited selection of objects in IE4+ for Windows: `body`, `button`, button, image and radio type `input`, and `textarea`. This property always returns `false` in MacIE.

Example

Good coding practice dictates that your script check for this property before invoking the `createTextRange()` method on any object. A typical implementation is as follows:

```
if (document.getElementById("myObject").isTextEdit)
{
   var myRange = document.getElementById("myObject").createTextRange();
   // [more statements that act on myRange]
}
```

Related Items: `createRange()` method; `TextRange` object (Chapter 33 on the CD-ROM)

lang

Value: ISO language code string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `lang` property governs the written language system used to render an element's text content when overriding the default browser's language system. The default value for this property is an empty string unless the corresponding `lang` attribute is assigned a value in the element's tag. Modifying the property value by script control does not appear to have any effect in the current browser implementations.

Example

Values for the `lang` property consist of strings containing valid ISO language codes. Such codes have, at minimum, a primary language code (for example, `"fr"` for French) plus an optional region specifier (for example, `"fr-ch"` for Swiss French). The code to assign a Swiss German value to an element looks like the following:

```
document.getElementById("specialSpan").lang = "de-ch";
```

language

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-

IE4+'s architecture allows for multiple scripting engines to work with the browser. Two engines are included with the basic Windows version browser: JScript (compatible with JavaScript) and Visual Basic Scripting Edition (VBScript). The default scripting engine is JScript. But if you wish to use VBScript or some other scripting language in statements that are embedded within event handler attributes of a tag, you can specifically direct the browser to apply the desired scripting engine to those script statements by way of the `language` attribute of the tag. The `language` property provides scripted access to that property. Unless you intend to modify the event handler HTML code and replace it with a statement in VBScript (or any other non-JScript-compatible language installed with your browser), you do not need to modify this property (or read it, for that matter).

Valid values include `JScript`, `javascript`, `vbscript`, and `vbs`. Third-party scripting engines have their own identifier for use with this value. Internet Explorer 5 observes `language="xml"` as well. Be aware that this attribute was deprecated in HTML4.01, so depending on the `DOCTYPE` you use, code using this attribute will not validate. You can accomplish the same objective with `type` (see Chapter 4).

Related Item: `script` element object

lastChild

(See `firstChild`)

length

Value: Integer Read-Only and Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `length` property returns the number of items in an array or collection of objects. Its most common application is as a boundary condition in a `for` loop. Though arrays and collections commonly use integer values as index values (always starting with zero), the `length` value is the actual number of items in the group. Therefore, to iterate through all items of the group, the condition expression should include a less-than (<) symbol rather than a less-than-or-equal (<=) symbol, as in the following:

```
for (var i = 0; i < someArray.length; i++)
{
  // [statements for the loop to process]
}
```

For decrementing through an array (in other words, starting from the last item in the array and working toward the first), the initial expression must initialize the counting variable as the length minus one:

```
for (var i = someArray.length - 1; i >= 0; i--)
{
  // [statements for the loop to process]
}
```

For most arrays and collections, the `length` property is read-only and governed solely by the number of items in the group. But in more recent versions of the browsers, you can assign values to some object arrays (`areas`, `options`, and the `select` object) to create placeholders for data assignments. See the discussions of the `area`, `select`, and `option` element objects for details. A plain JavaScript array can also have its `length` property value modified by script to either trim items from the end of the array or reserve space for additional assignments. See Chapter 18 for more about the `Array` object.

Example

You can try the following sequence of statements in the top text box of The Evaluator to see how the `length` property returns values (and sets them for some objects). Note that some statements work in only some browser versions.

```
(All browsers)  document.forms.length
(All browsers)  document.forms[0].elements.length
(All browsers)    document.images.length
(NN4+)          document.layers.length
(All browsers)          document.all.length
(IE5+, W3C)     document.getElementById("myTable").childNodes.length
```

All of these statements are shown primarily for completeness. Unless you have a good reason to support legacy browsers, the last technique (IE5+, W3C) should be used to access the `length` property.

Related Items: `area`, `select`, `option`, and `Array` objects

localName
namespaceURI
prefix

Value: String   Read-Only

Compatibility: WinIE8+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The three properties `localName`, `namespaceURI`, and `prefix` apply to any node in an XML document that associates a namespace URI with an XML tag. Although NN6 exposes all three properties for all element (and node) objects, the properties do not return the desired values. However, Mozilla-based browsers, including NN7+, remedy the situation. To understand better what values these three properties represent, consider the following XML content:

```
<x xmlns:bk='http://bigbooks.org/schema'>
    <bk:title>To Kill a Mockingbird</bk:title>
</x>
```

The element whose tag is `<bk:title>` is associated with the Namespace URI defined for the block, and the element's `namespaceURI` property would return the string `http:// bigbooks .org/schema`. The tag name consists of a prefix (before the colon) and the local name (after the colon). In the preceding example, the `prefix` property for the element defined by the `<bk:title>` tag would be `bk`, whereas the `localName` property would return `title`. The `localName` property of any node returns the same value as its `nodeName` property value, such as `#text` for a text node.

For more information about XML Namespaces, visit `http://www.w3.org/TR/REC-xml-names`.

Related Items: `scopeName`, `tagUrn` properties

nextSibling
previousSibling

Value: Object reference Read-Only

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

A *sibling node* is one that is at the same nested level as another node in the hierarchy of an HTML document. For example, the following `p` element has two child nodes (the `em` and `span` elements). Those two child nodes are siblings.

```
<p>MegaCorp is <em>the</em> source of the
   <span class="hot">hottest</span> gizmos.</p>
```

Sibling order is determined solely by the source-code order of the nodes. Therefore, in the previous example, the `em` node has no `previousSibling` property. Meanwhile, the `span` node has no `nextSibling` property (meaning that these properties return `null`). These properties provide another way to iterate through all nodes at the same level.

Example

The following function assigns the same class name to all child nodes of an element:

```
function setAllChildClasses(parentElem, className)
{
   var childElem = parentElem.firstChild;
      while (childElem.nextSibling)
      {
         childElem.className = className;
         childElem = childElem.nextSibling;
      }
}
```

This example is certainly not the only way to achieve the same results. Using a `for` loop to iterate through the `childNodes` collection of the parent element is an equally valid approach.

Related Items: `firstChild`, `lastChild`, `childNodes` properties; `hasChildNodes()`, `insertAdjacentElement()` methods

nodeName

Value: String Read-Only

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

For HTML and XML elements, the name of a node is the same as the tag name. The `nodeName` property is provided for the sake of consistency with the node architecture specified by the formal W3C DOM standard. The value, just like the `tagName` property, is an all-uppercase string of the tag name (even if the HTML source code is written with lowercase tags).

Some nodes, such as the text content of an element, do not have a tag. The `nodeName` property for such a node is a special value: `#text`. Another kind of node is an attribute of an element. For an attribute, the `nodeName` is the name of the attribute. See Chapter 25 for more about `Node` object properties.

Example

The following function demonstrates one (not very efficient) way to assign a new class name to every `p` element in an IE5+ document:

```
function setAllPClasses(className)
{
   for (var i = 0; i < document.all.length; i++)
   {
      if (document.all[i].nodeName == "P")
      {
         document.all[i].className = className;
      }
   }
}
```

A more efficient approach uses the `getElementsByTagName()` method to retrieve a collection of all `p` elements and then iterate through them directly.

Related Item: `tagName` property

nodeType

Value: Integer　　　　Read-Only

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The W3C DOM specification identifies a series of constant values that denote categories of nodes. Every node has a value that identifies its type, all browsers currently support the `nodeType` property on all node types as objects, but this has not always been the case. Table 26-4 lists the `nodeType` values; all the values are considered part of the W3C DOM Level 2 specification.

The `nodeType` value is automatically assigned to a node, whether the node exists in the document's HTML source code or is generated on-the-fly via a script. For example, if you create a new element node through any of the ways available by script (for example, by assigning a string encased in HTML tags to the `innerHTML` property or by explicitly invoking the `document.createElement()` method), the new element assumes a `nodeType` of `1`.

Mozilla-based browsers and Safari go one step further in supporting the W3C DOM specification by implementing a set of `Node` object property constants for each of the `nodeType` values. Table 26-5 lists the entire set as defined in the DOM Level 2 specification. Substituting these constants for `nodeType` integers can improve the readability of a script. For example, instead of

```
if (myElem.nodeType == 1)
{
  // [statements to process if true]
}
```

***elementObject*.nodeType**

TABLE 26-4

nodeType Property Values

Value	Description
1	Element node
2	Attribute node
3	Text (#text) node
4	CDATA section node
5	Entity reference node
6	Entity node
7	Processing instruction node
8	Comment node
9	Document node
10	Document type node
11	Document fragment node
12	Notation node

TABLE 26-5

W3C DOM nodeType Constants

Reference	nodeType Value
Node.ELEMENT_NODE	1
Node.ATTRIBUTE_NODE	2
Node.TEXT_NODE	3
Node.CDATA_SECTION_NODE	4
Node.ENTITY_REFERENCE_NODE	5
Node.ENTITY_NODE	6
Node.PROCESSING_INSTRUCTION_NODE	7
Node.COMMENT_NODE	8
Node.DOCUMENT_NODE	9
Node.DOCUMENT_TYPE_NODE	10
Node.DOCUMENT_FRAGMENT_NODE	11
Node.NOTATION_NODE	12

it is much easier to see what's going on with

```
if (myElem.nodeType == Node.ELEMENT_NODE)
{
  // [statements to process if true]
}
```

Example

You can experiment with viewing `nodeType` property values in The Evaluator. The `p` element whose ID is `myP` is a good place to start. The `p` element itself is a `nodeType` of `1`:

```
document.getElementById("myP").nodeType
```

This element has three child nodes: a string of text (`nodeName #text`), an `em` element (`nodeName em`), and the rest of the text of the element content (`nodeName #text`). If you view the `nodeType` of either of the text portions, the value comes back as `3`:

```
document.getElementById("myP").childNodes[0].nodeType
```

Related Item: `nodeName` property

nodeValue

Value: Number, string, or null Read/Write

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

For a text node, the `nodeValue` property consists of the actual text for that node. Such a node cannot contain any further nested elements, so the `nodeValue` property offers another way of reading and modifying what Internet Explorer implements as an element's `innerText` property (but in the W3C DOM, you must reference the child text node of an element to get or set its node value).

Of the node types implemented in the W3C DOM–capable browsers, only the text and attribute types have readable values. The `nodeValue` property of an element type of node returns a `null` value. For an attribute node, the `nodeValue` property consists of the value assigned to that attribute. According to the W3C DOM standard, attribute values should be reflected as strings. WinIE5, however, returns values of type `Number` when the value is all numeric characters. Even if you assign a string version of a number to such a `nodeValue` property, it is converted to a `Number` type internally. Other browsers return `nodeValue` values as strings in all cases (and convert numeric assignments to strings).

Example

You can use the `nodeValue` property to carry out practical tasks. As an example, `nodeValue` can be used to increase the width of a `textarea` object by 10 percent. The `nodeValue` is converted to an integer before performing the math and reassignment:

```
function widenCols(textareaElem)
{
   var colWidth = parseInt(textareaElem.attributes["cols"].nodeValue, 10);
   textareaElem.attributes["cols"].nodeValue = (colWidth * 1.1);
}
```

As another example, you can replace the text of an element, assuming that the element contains no further nested elements:

```
function replaceText(elem, newText)
{
   if (elem.childNodes.length == 1 && elem.firstChild.nodeType == 3)
   {
      elem.firstChild.nodeValue = newText;
   }
}
```

The function builds in one final verification that the element contains just one child node and that it is a text type. An alternative version of the assignment statement of the second example uses the `innerText` property in IE with identical results:

```
elem.innerText = newText;
```

You could also use the `textContent` property in any browser except IE to achieve the same concise result:

```
elem.textContent = newText;
```

Related Items: `attributes`, `innerText`, `nodeType` properties

offsetHeight
offsetWidth

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

These properties, which ostensibly report the height and width of any element, have had a checkered history due to conflicts between interpretations of the CSS box model by Microsoft and the W3C. Both properties were invented by Microsoft for IE4. Although they are not currently part of any W3C standard (they are included in the Working Draft of the CSSOM View Module), other modern browsers, including Mozilla-based browsers, WebKit-based browsers, and Presto-based browsers, implement the properties because they're so valuable to scripters.

Assuming that you specify style sheet rules for the width or height of an inline (nonpositioned) element, the `offsetHeight` and `offsetWidth` properties act differently depending on whether the page puts the browser in standards-compatible mode (via the DOCTYPE). More specifically, when IE6+ is set to standards-compatible mode (by DOCTYPE switching, as described in Chapter 25), the properties measure the pixel dimensions of the element's content plus any padding or borders, excluding margins. This is also the default behavior for Mozilla and WebKit, which adhere to the W3C box model. In quirks mode, however, the default IE6+ behavior is to return a height and width of only the element's content, with no accounting for padding, borders, or margins. For versions of IE prior to IE6, this is the only behavior.

Note that for a normal block-level element whose height and width are not specified, the `offsetHeight` is determined by the actual height of the content after all text flows. But the `offsetWidth` always extends the full width of the containing element. Therefore, the `offsetWidth` property does not reveal the rendered width of text content that is narrower than the full parent element width. For example, a `p` element consisting of only a few words may report an `offsetWidth` of many hundreds of pixels because the paragraph's block extends the full width

of the `body` element that represents the containing parent of the `p` element. To find out the actual width of text within a full-width, block-level element, wrap the text within an inline element (such as a `span`), and inspect the `offsetWidth` property of the `span`.

Example

With IE4+, you can substitute the `offsetHeight` and `offsetWidth` properties for `clientHeight` and `clientWidth` in Listing 26-6. The reason is that the two elements in question have their widths hard-wired in style sheets. Thus, the `offsetWidth` property follows that lead rather than observing the default width of the parent (BODY) element.

With IE5+ and W3C browsers, you can use The Evaluator to inspect the `offsetHeight` and `offsetWidth` property values of various objects on the page. Enter the following statements in the top text box:

```
document.getElementById("myP").offsetWidth
document.getElementById("myEM").offsetWidth
document.getElementById("myP").offsetHeight
document.getElementById("myTable").offsetWidth
```

Related Items: `clientHeight`, `clientWidth` properties

offsetLeft
offsetTop

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `offsetLeft` and `offsetTop` properties can suffer from the same version vagaries that afflict `offsetHeight` and `offsetWidth` properties when borders, margins, and padding are associated with an element and DOCTYPE switching is a factor. However, the `offsetLeft` and `offsetTop` properties are valuable in providing pixel coordinates of an element within the positioning context of the parent element — even when the elements are not positioned explicitly.

Note

The `offsetLeft` and `offsetTop` properties for positioned elements in MacIE do not return the same values as the `style.left` and `style.top` properties of the same element. See Listing 40-5 on the CD-ROM for an example of how to correct these discrepancies without having to hard-wire the precise pixel differences in your code. ■

The element used as a coordinate context for these properties is whatever element the `offsetParent` property returns. This means that to determine the precise position of any element, you may have to add some code that iterates through the `offsetParent` hierarchy until that property returns `null`.

As with the `offsetHeight` and `offsetWidth` properties, the `offsetLeft` and `offsetTop` properties are not yet part of the W3C DOM specification; they are supported across most browsers because they are convenient for some scriptable Dynamic HTML (DHTML) tasks. Through these two properties, a script can read the pixel coordinates of any block-level or inline element. Measurements are made relative to the `body` element, but this may change in the future. See the discussion later in this chapter about the `offsetParent` property.

Example

The following IE script statements use all four offset dimensional properties to size and position a `div` element so that it completely covers a `span` element located within a `p` element. This can be for a fill-in-the-blank quiz that provides text entry fields elsewhere on the page. As the user gets an answer correct, the blocking `div` element is hidden to reveal the correct answer.

```
document.all.blocker.style.pixelLeft = document.all.span2.offsetLeft
document.all.blocker.style.pixelTop = document.all.span2.offsetTop
document.all.blockImg.height = document.all.span2.offsetHeight
document.all.blockImg.width = document.all.span2.offsetWidth
```

Because the `offsetParent` property for the `span` element is the `body` element, the positioned `div` element can use the same positioning context (it's the default context, anyway) for setting the `pixelLeft` and `pixelTop` style properties. (Remember that positioning properties belong to an element's `style` object.) The `offsetHeight` and `offsetWidth` properties can read the dimensions of the `span` element (the example has no borders, margins, or padding to worry about) and assign them to the dimensions of the image contained by the blocker `div` element.

This example is also a bit hazardous in some implementations. If the text of `span2` wraps to a new line, the new `offsetHeight` value has enough pixels to accommodate both lines. But the `blockImg` and `blocker div` elements are block-level elements that render as a simple rectangle. In other words, the `blocker` element doesn't turn into two separate strips to cover the pieces of `span2` that spread across two lines.

Related Items: `clientLeft`, `clientTop`, `offsetParent` properties

offsetParent

Value: Object reference Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `offsetParent` property returns a reference to the object that acts as a positioning context for the current element. Values for the `offsetLeft` and `offsetTop` properties are measured relative to the top-left corner of the `offsetParent` object.

The returned object is usually, but not always, the next outermost block-level container. For most document elements, the `offsetParent` object is the `document.body` object (with exceptions for some elements in some browsers).

Table cells, for example, have different `offsetParent` elements in different browsers:

Browser	td offsetParent
WinIE4	`tr`
WinIE5+/NN7+/Moz-based/WebKit-based/Presto-based	`table`
MacIE	`table`
NN6	`body`

Fortunately, the property behaves predictably for positioned elements in most modern browsers. For example, a first-level positioned element's `offsetParent` element is the `body`; the `offsetParent`

of a nested positioned element (for example, one absolute-positioned div inside another) is the next outer container (in other words, the positioning context of the inner element).

Example

You can use the offsetParent property to help you locate the position of a nested element on the page. Listing 26-12 demonstrates how a script can walk up the hierarchy of offsetParent objects in IE for Windows to assemble the location of a nested element on a page. The goal of the exercise in Listing 26-12 is to position an image at the top-left corner of the second table cell. The entire table is centered on the page.

The onload event handler invokes the setImagePosition() function. The function first sets a Boolean flag that determines whether the calculations should be based on the client or offset sets of properties. WinIE4 and MacIE5 rely on client properties, whereas WinIE5+ works with the offset properties. The discrepancies even out, however, with the while loop. This loop traverses the offsetParent hierarchy starting with the offsetParent of the cell out to the document.body object. In IE5+ and other browsers, the while loop executes only three times (for the td, table, and body elements) because just the table element exists between the cell and the body; in IE4, the loop executes four times to account for the tr and table elements up the hierarchy. The loop terminates when the offsetParent is null. Finally, the cumulative values of left and top measures are applied to the positioning properties of the div object's style, and the image is made visible.

```
         </tr>
      </table>
      <img id="myImg" alt="image" src="end.gif" height="12" width="12"
           style="visibility:hidden;" />
   </body>
</html>
```

JavaScript: jsb26-12.js

```
function setImagePosition()
{
   var x = 0;
   var y = 0;
   var offsetPointer = document.getElementById("myCell"); // cElement;
      while (offsetPointer)
      {
         x += offsetPointer.offsetLeft;
         y += offsetPointer.offsetTop;
         offsetPointer = offsetPointer.offsetParent;
      }
   // correct for MacIE body margin factors
   if (navigator.userAgent.indexOf("Mac") != -1 &&
       typeof document.body.leftMargin != "undefined")
   {
      x += document.body.leftMargin;
      y += document.body.topMargin;
   }
   document.getElementById("myImg").style.left = x + "px";
   document.getElementById("myImg").style.top = y + "px";
   document.getElementById("myImg").style.visibility = "visible";
}
```

Related Items: `offsetLeft`, `offsetTop`, `offsetHeight`, `offsetWidth` properties

outerHTML
outerText

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari 1.3+, Opera+, Chrome+

One way that Internet Explorer, WebKit-based browsers, and Presto-based browsers expose an entire element to scripting is by way of the `outerHTML` and `outerText` properties. The primary distinction between these two properties is that `outerHTML` includes the element's start and end tags, whereas `outerText` includes only rendered text that belongs to the element (including text from any nested elements).

The `outerHTML` property contains not only the text content for an element as seen on the page, but also every bit of HTML tagging associated with that content. For example, consider the following bit of HTML source code:

```
<p id="paragraph1">"How <em>are</em> you?" he asked.</p>
```

The value of the `p` object's `outerHTML` property (`document.all.paragraph1. outerHTML`) is exactly the same as that of the source code.

The browser interprets any HTML tags in a string that you assign to an element's `outerHTML` property. This means that you can delete (set the property to an empty string) or replace an entire tag with this property. The document's object model adjusts itself to whatever adjustments you make to the HTML in this manner.

In contrast, the `outerText` property knows only about the text content of an element container. In the preceding example, the value of the paragraph's `outerText` property (`document.all.paragraph1.innerText`) is

```
"How are you?" he asked.
```

If this looks familiar, it's because in most cases the `innerText` and `outerText` properties of an existing element return the same strings.

Example

Listing 26-13 demonstrates how to use the `outerHTML` and `outerText` properties to access and modify web-page content dynamically. The page generated by Listing 26-13 (WinIE4+/WebKit-or Presto-based browsers) contains an `h1` element label and a paragraph of text. The purpose is to demonstrate how the `outerHTML` and `outerText` properties differ in their intent. Two text boxes contain the same combination of text and HTML tags that replaces the element that creates the paragraph's label.

If you apply the default content of the first text box to the `outerHTML` property of the `label1` object, the `h1` element is replaced by a `span` element whose `class` attribute acquires a different style sheet rule defined earlier in the document. Notice that the ID of the new `span` element is the same as that of the original `h1` element. This allows the script attached to the second button to address the object. But this second script replaces the element with the raw text (including tags). The element is gone, and any subsequent attempt to change the `outerHTML` or `outerText` properties of the `label1` object causes an error because there is no longer a `label1` object in the document.

Use this laboratory to experiment with some other content in both text boxes.

         document.getElementById("label1").outerHTML = content;
      }
}
```

Related Items: `innerHTML`, `innerText` properties; `replaceNode()` method

ownerDocument

Value: Document object reference Read-Only

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `ownerDocument` property belongs to any element or node in the W3C DOM. The property's value is a reference to the document node that ultimately contains the element or node. If a script encounters a reference to an element or node (perhaps it has been passed as a parameter to a function), the object's `ownerDocument` property provides a way to build references to other objects in the same document or to access properties and methods of the document objects. IE's proprietary version of this property is simply `document`.

Example

Use The Evaluator (see Chapter 4) to explore the `ownerDocument` property. Enter the following statement in the top text box:

```
document.body.childNodes[5].ownerDocument
```

The result is a reference to the `document` object. You can use that to inspect a property of the document, as shown in the following statement, which you should enter in the top text box:

```
document.body.childNodes[5].ownerDocument.URL
```

This returns the `document.URL` property for the document that owns the child node.

Related Item: `document` object

parentElement

Value: Element object reference or `null` Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari 1.2+, Opera+, Chrome+

The `parentElement` property returns a reference to the next outermost HTML element from the current element. This parent-child relationship of elements is often, but not always, the same as a parent-child node relationship (see the `parentNode` property later in this chapter). The difference is that the `parentElement` property deals only with HTML elements as reflected as document objects, whereas a node is not necessarily an HTML element (for example, an attribute or text chunk).

There is also a distinction between `parentElement` and `offsetParent` properties. The latter returns an element that may be many generations removed from a given element but is the immediate parent with regard to positioning context. For example, a `td` element's `parentElement` property is most likely its enclosing `tr` element, but a `td` element's `offsetParent` property is its `table` element (unless you're dealing with WinIE4).

A script can walk the element hierarchy outward from an element with the help of the `parentElement` property. The top of the parent chain is the `html` element. Its `parentElement` property returns `null`.

Example

You can experiment with the `parentElement` property in The Evaluator. The document contains a `p` element named `myP`. Type each of the following statements from the left column in the top expression evaluation text box and press Enter to see the results.

Expression	IE	WebKit/Presto
`document.getElementById ("myP").tagName`	`p`	`P`
`document.getElementById ("myP").parentElement`	`[object]`	`object HTMLHtmlElement`
`document.getElementById("myP"). parentElement.tagName`	`body`	`body`
`document.getElementById("myP"). parentElement.parentElement`	`[object]`	`object HTMLBodyElement`
`document.getElementById("myP"). parentElement.parentElement.tagName`	`html`	`html`
`document.getElementById("myP"). parentElement.parentElement. parentElement`	`null`	`null`

Related Items: `offsetParent`, `parentNode` properties

parentNode

Value: Node object reference or `null` Read-Only

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

`parentNode` is a W3C property returns a reference to the next outermost node that is reflected as an object belonging to the document. For a standard element object, the `parentNode` property is the same as IE/WebKit and Presto browser's `parentElement` because both objects happen to have a direct parent-child node relationship as well as a parent-child element relationship.

Other kinds of content, however, can be nodes, including text fragments within an element. A text fragment's `parentNode` property is the next outermost node or element that encompasses that fragment. A text node object in IE/Opera does not have a `parentElement` property.

Example

Use The Evaluator to examine the `parentNode` property values of both an element and a nonelement node. Begin with the following two statements, and watch the results of each:

```
document.getElementById("myP").parentNode.tagName
document.getElementById("myP").parentElement.tagName (IE/WebKit/Presto browsers)
```

Now examine the properties from the point of view of the first text fragment node of the `myP` paragraph element:

```
document.getElementById("myP").childNodes[0].nodeValue
document.getElementById("myP").childNodes[0].parentNode.tagName
document.getElementById("myP").childNodes[0].parentElement (WebKit only)
```

Notice in IE and Opera that the text node does not have a `parentElement` property.

Related Items: `childNodes`, `nodeName`, `nodeType`, `nodeValue`, `parentElement` properties

parentTextEdit

Value: Element object reference or `null` Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

Only a handful of objects in IE's object model are capable of creating text ranges (see the `TextRange` object in Chapter 33 on the CD-ROM). To find an object's next outermost container capable of generating a text range, use the `parentTextEdit` property. If an element is in the hierarchy, that element's object reference is returned. Otherwise (for example, `document.body.parentTextEdit`), the value is `null`. MacIE always returns a value of `null` because the browser doesn't support the `TextRange` object.

Example

Listing 26-14 contains an example that demonstrates how to use the `parentTextEdit` property to create a text range. The page resulting from Listing 26-14 contains a paragraph of Latin text and three radio buttons that select the size of a paragraph chunk: one character, one word, or one sentence. If you click anywhere within the large paragraph, the `onclick` event handler invokes the `selectChunk()` function. The function first examines which of the radio buttons is selected to determine how much of the paragraph to highlight (select) around the point at which the user clicks.

After the script employs the `parentTextEdit` property to test whether the clicked element has a valid parent capable of creating a text range, it calls on the property again to help create the text range. From there, `TextRange` object methods shrink the range to a single insertion point, move that point to the spot nearest the cursor location at click time, expand the selection to encompass the desired chunk, and select that bit of text.

Notice one workaround for the `TextRange` object's `expand()` method anomaly: If you specify a sentence, IE doesn't treat the beginning of a `p` element as the starting end of a sentence automatically. A camouflaged (white text color) period is appended to the end of the previous element to force the `TextRange` object to expand only to the beginning of the first sentence of the targeted `p` element.

LISTING 26-14

Using the parentTextEdit Property

```
    for (var i = 0; i < document.forms[0].chunk.length; i++)
    {
       if (document.forms[0].chunk[i].checked)
       {
          chunk = document.forms[0].chunk[i].value;
          break;
       }
    }
    var x = window.event.clientX;
    var y = window.event.clientY;
    if (window.event.srcElement.parentTextEdit)
    {
       range = window.event.srcElement.parentTextEdit.createTextRange();
       range.collapse();
       range.moveToPoint(x, y);
       range.expand(chunk);
       range.select();
    }
}
```

Related Items: `isTextEdit` property; `TextRange` object (Chapter 33, "Body Text Objects" on the CD-ROM)

prefix

(See `localName`)

previousSibling

(See `nextSibling`)

readyState

Value: String (integer for `OBJECT` object) Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

A script can query an element in IE to find out whether it has loaded all ancillary data (for example, external image files or other media files) before other statements act on that object or its data. The `readyState` property lets you know the loading status of an element.

Table 26-6 lists the possible values and their meanings.

For most HTML elements, this property always returns `complete`. Most of the other states are used by elements such as `img`, `embed`, and `object`, which load external data and even start other processes (such as ActiveX controls) to work.

One word of caution: Do not expect the `readyState` property to reveal whether an object exists in the document (for example, `uninitialized`). If the object does not exist, it cannot have a `readyState` property; the result is a script error for an undefined object. If you want to run a script only after every element and its data are fully loaded, trigger the function by way of the `onload` event handler for the `body` element or the `onreadystatechange` event handler for the object (and check that the `readyState` property is `complete`).

TABLE 26-6

readyState Property Values

HTML Value	OBJECT Value	Description
complete	4	Element and data are fully loaded.
interactive	3	Data may not be loaded fully, but user can interact with element.
loaded	2	Data is loaded, but object may be starting up.
loading	1	Data is loading.
uninitialized	0	Object has not started loading data yet.

Example

To witness a `readyState` property other than `complete` for standard HTML, you can try examining the property in a script that immediately follows an `<img>` tag:

```
...
<img id="myImg" src="someImage.gif">
<script type="text/javaScript">
   alert(document.getElementById("myImg").readyState);
</script>
...
```

Putting this fragment into a document that is accessible across a slow network helps. If the image is not in the browser's cache, you might get the `uninitialized` or `loading` result. The former means that the `img` object exists, but it has not started receiving the image data from the server. If you reload the page, chances are that the image will load instantaneously from the cache, and the `readyState` property will report `complete`.

Related Item: `onreadystatechange` event handler

recordNumber

Value: Integer or `null` Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

Virtually every object has a `recordNumber` property, but it applies only to elements used in Internet Explorer data binding to represent repeated data. For example, if you display 30 records from an external data store in a table, the `tr` element in the table is represented only once in the HTML. However, the browser repeats the table row (and its component cells) to accommodate all 30 rows of data. If you click a row, you can use the `recordNumber` property of the `tr` object to see which record was clicked. A common application of this facility is in data binding situations that allow for updating records. For example, script a table so that clicking an uneditable row of data displays that record's data in editable text boxes elsewhere on the page. If an object is not bound to a data source, or if it is a nonrepeating object bound to a data source, the `recordNumber` property is `null`.

Example

Listing 26-15 shows how to use the `recordNumber` property to navigate to a specific record in a sequence of data. The data source is a small, tab-delimited file consisting of 20 records of Academy Awards data. Thus, the table that displays a subset of the fields is bound to the data source object. Also bound to the data source object are three `span` objects embedded within a paragraph near the top of the page. As the user clicks a row of data, three fields from that clicked record are placed in the bound `span` objects.

The script part of this page is a mere single statement. When the user triggers the `onclick` event handler of the repeated `tr` object, the function receives as a parameter a reference to the `tr` object. The data store object maintains an internal copy of the data in a `recordset` object. One of the properties of this `recordset` object is the `AbsolutePosition` property, which is the integer value of the current record that the data object points to (it can point to only one row at a time, and the default row is the first row). The statement sets the `AbsolutePosition` property of the `recordset` object to the `recordNumber` property for the row that the user clicks. Because the three `span` elements are bound to the same data source, they are immediately updated to reflect the change to the data object's internal pointer to the current record. Notice, too, that the third `span` object is bound to one of the data source fields not shown in the table. You can reach any field of a record because the data source object holds the entire data source content. However, in actual practice, it would be disconcerting for the visitor to your web site to see something like the name of the film the best actor was in when that information is not reflected in the table below (some visitor's might even start muttering "bug").

{
   document.oscars.recordset.AbsolutePosition = row.recordNumber;
}
```

Related Items: `dataFld`, `dataSrc` properties; `table`, `tr` objects (Chapter 41)

runtimeStyle

Value: `style` object Read-Only

Compatibility: WinIE5+, MacIE5+, NN-, Moz-, Safari-, Opera-, Chrome-

You can determine the browser default settings for style sheet attributes with the help of the `runtimeStyle` property. The `style` object that this property returns contains all style attributes and the default settings at the time the page loads. This property does not reflect values assigned to elements by style sheets in the document or by scripts. The default values returned by this property differ from the values returned by the `currentStyle` property. The latter includes data about values that are not assigned explicitly by style sheets yet are influenced by the default behavior of the browser's rendering engine. In contrast, the `runtimeStyle` property shows unassigned style values as empty or zero.

Example

To change a style property setting, access it via the element's `style` object. Use The Evaluator (see Chapter 4) to compare the properties of the `runtimeStyle` and `style` objects of an element. For example, an unmodified copy of The Evaluator contains an `em` element whose ID is `"myEM"`. Enter both

```
document.getElementById("myEM").style.color
```

and

```
document.getElementById("myEM").runtimeStyle.color
```

in the top text box in turn. Initially, both values are empty. Now assign a color to the `style` property via the top text box:

```
document.getElementById("myEM").style.color = "red"
```

If you type the two earlier statements in the top box, you can see that the `style` object reflects the change, whereas the `runtimeStyle` object holds onto its original (empty) value.

Related Items: `currentStyle` property; `style` object (Chapter 38)

scopeName
tagUrn

Value: String Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `scopeName` property is associated primarily with XML code that is embedded within a document. When you include XML, you can specify one or more XML Namespaces that define the owner of a custom tag name, thus aiming toward preventing conflicts of identical custom tags from different sources in a document.

The XML Namespace is assigned as an attribute of the `<html>` tag that surrounds the entire document:

```
<html xmlns:fred='http://www.someURL.com'>
```

After that, the Namespace value precedes all custom tags linked to that Namespace:

```
<fred:FIRST_Name id="fredFirstName"/>
```

To find out the Namespace owner of an element, you can read the `scopeName` property of that element. For the preceding example, the `scopeName` returns `fred`. For regular HTML elements, the returned value is always `HTML`. The `tagURN` property sits alongside `scopeName` and stores the URI for the namespace.

The `scopeName` property is available only in Win32 and UNIX flavors of IE5+. The comparable properties for `scopeName` and `tagURN` in the W3C DOM are `prefix` and `namespaceURI`.

Example

If you have a sample document that contains XML and a namespace spec, you can use `document.write()` or `alert()` methods to view the value of the `scopeName` property. The syntax is

```
document.getElementById("elementID").scopeName
```

Related Item: `tagUrn` property

scrollHeight
scrollWidth

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN7+, Moz1.0.1+, Safari+, Opera+, Chrome+

The `scrollHeight` and `scrollWidth` properties contain the pixel measures of an object, regardless of how much of the object is visible on the page. Therefore, if the browser window displays a vertical scroll bar, and the body extends below the bottom of the viewable space in the window, the `scrollHeight` takes into account the entire height of the body as though you were to scroll downward and see the entire element. For most elements that don't have their own scroll bars, the `scrollHeight` and `scrollWidth` properties have the same values as the `clientHeight` and `clientWidth` properties.

Example

Use The Evaluator (see Chapter 4) to experiment with these two properties of the `textarea` object, which displays the output of evaluations and property listings. To begin, enter the following in the bottom one-line text box to list the properties of the `body` object:

```
document.body
```

This displays a long list of properties for the `body` object. Now enter the following property expression in the top one-line text box to see the `scrollHeight` property of the output `textarea` when it holds the dozens of lines of property listings:

```
document.getElementById("myTextArea").scrollHeight
```

The result, some number probably in the hundreds, is now displayed in the output `textarea`. This means that you can scroll the content of the `output` element vertically to reveal that number of pixels. Click the Evaluate button once more. The result, 13 or 14, is a measure of the `scrollHeight` property of the `textarea` that had only the previous result in it. The scrollable height of that content was only 13 or 14 pixels, the height of the font in the `textarea`. The `scrollWidth` property of the output `textarea` is fixed by the width assigned to the element's `cols` attribute (as calculated by the browser to determine how wide to make the text area on the page).

Related Items: `clientHeight` , `clientWidth` properties; `window.scroll()` method

scrollLeft
scrollTop

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN7+, Moz1.0.1+, Safari+, Opera+, Chrome+

If an element is scrollable (in other words, it has its own scroll bars), you can find out how far the element is scrolled in the horizontal and vertical direction via the `scrollLeft` and `scrollTop` properties. These values are pixels. For nonscrollable elements, these values are always zero — even if they are contained by elements that are scrollable. For example, if you scroll a browser window (or frame in a multiframe environment) vertically, the `scrollTop` property of the `body` object is whatever the pixel distance is between the top of the object (now out of view) and the first visible row of pixels of the element. But the `scrollTop` value of a table that is in the document remains zero.

Netscape browsers prior to version 7 (Mozilla) treat scrolling of a `body` element from the point of view of the window. If you want to find out the scrolled offset of the current page in these browsers, use `window.scrollX` and `window.scrollY`.

Scripts that involve tracking mouse events in IE need to take into account the `scrollLeft` and `scrollTop` properties of the body to compensate for scrolling of the page. See the `Event` object in Chapter 32.

Example

Use The Evaluator (see Chapter 4) to experiment with these two properties of the `textarea` object, which displays the output of evaluations and property listings. To begin, enter the following in the bottom one-line text box to list the properties of the `body` object:

```
document.body
```

This displays a long list of properties for the `body` object. Use the `textarea`'s scroll bar to page down a couple of times. Now enter the following property expression in the top one-line text box to see the `scrollTop` property of the output `textarea` after you scroll:

```
document.getElementById("myTextArea").scrollTop
```

The result, some number, is now displayed in the output `textarea`. This means that the content of the `output` element was scrolled vertically. Click the Evaluate button once more. The result, `0`, is a measure of the `scrollTop` property of the `textarea` that had only the previous result in it. There wasn't enough content in the `textarea` to scroll, so the content was not scrolled at all. The `scrollTop` property, therefore, is zero. The `scrollLeft` property of the output is always zero because the `textarea` element is set to wrap any text that overflows the width of the element. No horizontal scroll bar appears in this case, and the `scrollLeft` property never changes.

Related Items: `clientLeft`, `clientTop` properties; `window.scroll()` method

sourceIndex

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera+, Chrome+

The `sourceIndex` property returns the numeric index (zero-based) of the object within the entire document, which is the group of all elements in the document.

Example

Although the operation of this property is straightforward, the sequence of elements exposed by the `document.all` property may not be. To that end, you can use The Evaluator (see Chapter 4) to experiment in IE4+ with the values that the `sourceIndex` property returns to see how the index values of the `document.all` collection follow the source code.

To begin, reload The Evaluator. Enter the following statement in the top text box to set a preinitialized global variable:

```
a = 0
```

When you evaluate this expression, a zero should appear in the Results box. Next, enter the following statement in the top text box:

```
document.all[a].tagName + " [" + a++ + "]"
```

There are a lot of plus signs in this statement, so be sure you enter it correctly. As you successively evaluate this statement (repeatedly click the Evaluate button), the global variable (`a`) is incremented, enabling you to walk through the elements in source-code order. The `sourceIndex` value for each HTML tag appears in square brackets in the Results box. You generally begin with the following sequence:

```
html [0]
head [1]
title [2]
```

You can continue until there are no more elements, at which point an error message appears because the value of `a` exceeds the number of elements in the `document.all` array. Compare your findings against the HTML source code view of The Evaluator.

Related Item: `item()` method

style

Value: `style` object reference Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `style` property is the gateway to an element's style sheet settings. The property's value is a `style` object whose properties enable you to read and write the style sheet settings for the element. Although scripts do not usually manipulate the `style` object as a whole, it is quite common in a DHTML page for scripts to get or set multiple properties of the `style` object to effect animation, visibility, and all appearance parameters of the element. Note that style properties returned through this object are only those that are explicitly set by the element's `style` attribute or by script.

You can find significant differences in the breadth of properties of the `style` object in different versions of IE and NN. See Chapter 38 for more details on the `style` object.

Example

Most of the action with the `style` property has to do with the `style` object's properties, so you can use The Evaluator here simply to explore the lists of `style` object properties available on as many

DHTML-compatible browsers as you have running. To begin, enter the following statement in the bottom, one-line text box to inspect the `style` property for the `document.body` object:

```
document.body.style
```

Now inspect the `style` property of the table element that is part of the original version of The Evaluator. Enter the following statement in the bottom text box:

```
document.getElementById("myTable").style
```

In both cases, the values assigned to the `style` object's properties are quite limited by default.

Related Items: `currentStyle`, `runtimeStyle` properties; `style` object (Chapter 38)

tabIndex

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `tabIndex` property controls where in the tabbing sequence the current object receives focus. This property obviously applies only to elements that can receive focus. IE5+ permits giving focus to more elements than most other browsers, but for all browsers compatible with this property, the primary elements for which you may want to control focus (namely, form input elements) are covered.

In general, browsers treat form elements as focusable elements by default. Nonform elements usually don't receive focus unless you specifically set their `tabIndex` properties (or `tabindex` tag attributes). If you set the `tabIndex` property of one form element to `1`, that element is first in the tabbing order. Meanwhile, the rest fall into source-code tabbing order on successive presses of the Tab key. If you set two elements to, say, `1`, the tabbing proceeds in source-code order for those two elements and then on to the rest of the elements in source-code order starting with the top of the page.

In Internet Explorer and Moz1.8+, you can remove an element from tabbing order entirely by setting its `tabIndex` property to `-1`. Users can still click those elements to make changes to form element settings, but tabbing bypasses the element.

Example

Listing 26-16 contains a sample script that demonstrates how to control the tab order of a form via the `tabIndex` property. This example demonstrates not only the way you can modify the tabbing behavior of a form on-the-fly, but also how to force form elements out of the tabbing sequence entirely. In this page, the top form (named `lab`) contains four elements. Scripts invoked by buttons in the bottom form control the tabbing sequence. Notice that the `tabindex` attributes of all bottom form elements are set to `-1`, which means that these control buttons are not part of the tabbing sequence.

When you load the page, the default tabbing order for the `lab` form control elements (default setting of zero) takes charge. If you start pressing the Tab key, the precise results at first depend on the browser you use. In IE, the Address field is first selected; next, the Tab sequence gives focus to the window (or frame, if this page were in a frameset); finally, the tabbing reaches the `lab` form. Continue pressing the Tab key, and watch how the browser assigns focus to each of the element types. In WebKit- and Presto-based browsers, as well as recent versions of Mozilla, the tabbing begins in the `lab` form. In NN6, however, you must click anywhere on the content to get the Tab key to start working on form controls.

The sample script inverts the tabbing sequence with the help of a `for` loop that initializes two variables that work in opposite directions as the looping progresses. This gives the last element the lowest

tabIndex value. The skip2() function simply sets the tabIndex property of the second text box to -1, removing it from the tabbing entirely (IE used to be the only browser that supported this, but all modern browsers support it). Notice, however, that you can click in the field and still enter text. (See the disabled property earlier in this chapter to see how to prevent field editing.) NN6 does not provide a tabIndex property setting that forces the browser to skip a form control; you should disable the control instead.

LISTING 26-16

Controlling the tabIndex Property

HTML: jsb26-16.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>tabIndex Property</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-16.js"></script>
   </head>
   <body>
      <h1>tabIndex Property Lab</h1>
      <hr />
      <form name="lab">
         Text box no. 1: <input type="text" name="text1" />
         <br />
         Text box no. 2: <input type="text" name="text2" />
         <br />
         <input type="button" value="A Button" />
         <br />
         <input type="checkbox" />And a checkbox
      </form>
      <hr />
      <form name="control">
         <input type="button" value="Invert Tabbing Order" tabindex="-1"
                onclick="invert()" />
         <br />
         <input type="button" value="Skip Text box no. 2"
                tabindex="-1" onclick="skip2()" />
         <br />
         <input type="button" value="Reset to Normal Order" tabindex="-1"
                onclick="resetTab()" />
      </form>
   </body>
</html>
```

JavaScript: jsb26-16.js

```
function invert()
{
   var form = document.lab;
   for (var i = 0, j = form.elements.length; i < form.elements.length; i++, j--)
```

```
   {
      form.elements[i].tabIndex = j;
   }
}

function skip2()
{
      document.lab.text2.tabIndex = -1;
}

function resetTab()
{
   var form = document.lab;
   for (var i = 0; i < form.elements.length; i++)
   {
      form.elements[i].tabIndex = 0;
   }
}
```

The final function, `resetTab()`, sets the `tabIndex` property value to zero for all `lab` form elements; this restores the default order.

Related Items: `blur()`, `focus()` methods

tagName

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `tagName` property returns a string of the HTML or XML tag name belonging to the object. All `tagName` values are returned in all-uppercase characters, even if the source code is written in all-lowercase characters or a mixture. This consistency makes it easier to perform string comparisons. For example, you can create a generic function that contains a `switch` statement to execute actions for some tags and not others. The skeleton of such a function looks like the following:

```
function  processObj(objRef)
{
   switch (objRef.tagName)
   {
      case "TR":
         [statements to deal with table row object]
         break;
      case "TD":
         [statements to deal with table cell object]
         break;
      case "COLGROUP":
         [statements to deal with column group object]
         break;
      default:
         [statements to deal with all other object types]
   }
}
```

Example

You can also see the `tagName` property in action in the example associated with the `sourceIndex` property discussed earlier in the chapter. In that example, the `tagName` property is read from a sequence of objects in source-code order.

Related Items: `nodeName` property; `getElementsByTagName()` method

tagUrn

(See `scopeName`)

textContent

Value: String Read/Write

Compatibility: WinIE-, MacIE-, NN-, Moz1.7+, Safari+, Opera+, Chrome+

This property stores the text string of a node, including any combined text nodes within an element. This means that the content of a node is reflected in the `textContent` property as a single string of text even if it has other nested elements, such as `em`. If you replace the content of a node with a string of text by setting the `textContent` property, all previous node content is replaced, including nested elements. You can think of the `textContent` property as the W3C DOM equivalent of IE's `innerText` property.

Related Item: `innerText` property

title

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The W3C standard states that you should use the `title` property (and `title` attribute) in an advisory role. Keep in mind that devices for the disabled use the `title` property and `title` attribute, so we recommend you always give them values. Most browsers interpret this role as text assigned to tooltips that pop up momentarily while the cursor rests atop an element. The advantage of having this property available for writing is that your scripts can modify an element's tooltip text in response to other user interaction on the page. A tooltip can provide brief help about the behavior of icons or links on the page. It can also convey a summary of key facts from the destination of a link, thus enabling a visitor to see vital information without having to navigate to the other page.

As with setting the status bar, we don't recommend using tooltips for conveying mission-critical information to the user. Not all users are patient enough to let the pointer pause for the tooltip to appear. On the other hand, a user may be more likely to notice a tooltip when it appears rather than a status-bar message (even though the latter appears instantaneously).

Example

Listing 26-17 provides a glimpse at how you can use the `title` property to establish tooltips for a page. A simple paragraph element has its `title` attribute set to `"First Time!"`, which is what the tooltip displays if you roll the pointer atop the paragraph and pause after the page loads. But an `onmouseover` event handler for that element increments a global variable counter in the script, and the `title` property of the paragraph object is modified with each mouseover action. The `count` value is made part of a string assigned to the `title` property. Notice that there is not a live connection between the `title` property and the variable; instead, the new value explicitly sets the `title` property.

LISTING 26-17

Controlling the title Property

HTML: jsb26-17.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>title Property</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-17.js"></script>
   </head>
   <body>
      <h1>title Property Lab</h1>
      <hr />
      <p id="myP" title="First Time!" onmouseover="incrementCount(this)">Roll
         the mouse over this paragraph a few times.
         <br />
         Then pause atop it to view the tooltip.
      </p>
   </body>
</html>
JavaScript: jsb26-17.js
// global counting variable
var count = 0;

function setToolTip(elem)
{
   elem.title = "You have previously rolled atop this paragraph " + count + "
       time(s).";
}

function incrementCount(elem)
{
   count++;
   setToolTip(elem);
}
```

Related Item: `window.status` property

uniqueID

Value: String Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

You can let the WinIE5+ browser generate an identifier (`id` property) for a dynamically generated element on the page with the aid of the `uniqueID` property. You should use this feature with care, because the ID it generates at any given time may differ from the ID generated the next time the element is created in the page. Therefore, you should use the `uniqueID` property when your scripts

require an unknown element to have an id property, but the algorithms are not expecting any specific identifier.

To guarantee that an element gets only one ID assigned to it while the object exists in memory, assign the value via the uniqueID property of that same object — not some other object. After you retrieve the uniqueID property of an object, the property's value stays the same no matter how often you access the property again. In general, you assign the value returned by the uniqueID property to the object's id property for other kinds of processing. (For example, the parameter of a getElementById() method requires the value assigned to the id property of an object.)

Example

Listing 26-18 demonstrates the recommended syntax for obtaining and applying a browser-generated identifier for an object. After you enter some text in the text box and click the button, the addRow() function appends a row to the table. The left column displays the identifier generated via the table row object's uniqueID property. IE5+ generates identifiers in the format "ms__idn", where *n* is an integer starting with zero for the current browser session. Because the addRow() function assigns uniqueID values to the row and the cells in each row, the integer for each row is three greater than the previous one. There is no guarantee that future generations of the browser will follow this format, so do not rely on the format or sequence in your scripts.

LISTING 26-18

Using the uniqueID Property

HTML: jsb26-18.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Inserting an WinIE5+ Table Row</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-18.js"></script>
   </head>
   <body>
      <table id="myTable" border="1">
         <tr>
            <th>Row ID</th>
            <th>Data</th>
         </tr>
         <tr id="firstDataRow">
            <td>firstDataRow</td>
            <td>Fred</td>
         </tr>
         <tr id="secondDataRow">
            <td>secondDataRow</td>
            <td>Jane</td>
         </tr>
      </table>
      <hr />
```

```
      <form>
         Enter text to be added to the table:
         <br />
         <input type="text" name="input" size="25" />
         <br />
         <input type='button' value='Insert Row'
                onclick='addRow(this.form.input.value)' />
      </form>
   </body>
</html>
```

JavaScript: jsb26-18.js

```
function addRow(item1)
{
   if (item1)
   {
      // assign long reference to shorter var name
      var theTable = document.getElementById("myTable");
      // append new row to the end of the table
      var newRow = theTable.insertRow(theTable.rows.length);
      // give the row its own ID
      newRow.id = newRow.uniqueID;

      // declare cell variable and data variable
      var newCell;
      var newText;

      // an inserted row has no cells, so insert the cells
      newCell = newRow.insertCell(0);
      // give this cell its own id
      newCell.id = newCell.uniqueID;
      // display the row's id as the cell text
      newText = document.createTextNode(newRow.id);
      newCell.appendChild(newText);
      newCell.bgColor = "yellow"
      // re-use cell var for second cell insertion
      newCell = newRow.insertCell(1);
      newCell.id = newCell.uniqueID;
      newText = document.createTextNode(item1);
      newCell.appendChild(newText);
   }
}
```

Related Items: `id` property; `getElementById()` method

unselectable

Value: String constant (`"on"` or `"off"`) Read/Write

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

This property controls the selectability of an element — that is, whether the element's content can be selected by the user. You might use this property to prevent a sensitive piece of data from being selected and copied.

Methods

addBehavior("*URL*")

Returns: Integer ID

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `addBehavior()` method imports an external Internet Explorer behavior and attaches it to the current object, thereby extending the properties and/or methods of that object. (See Chapter 51 on the CD-ROM for details on IE behaviors.) The sole parameter of the `addBehavior()` method is a URL pointer to the behavior component's code. This component may be in an external file (with an `.htc` extension), in which case the parameter can be a relative or absolute URL. IE also includes a library of built-in (default) behaviors, whose URLs are in the following format:

```
#default#behaviorName
```

Here, `behaviorName` is one of the default behaviors. If the behavior is imported into the document via the `object` tag, the `addBehavior()` method parameter is the ID of that element in the following format:

```
#objectID
```

When you add a behavior, the loading of the external code occurs asynchronously. This means that even though the method returns a value instantly, the behavior is not necessarily ready to work. Only when the behavior is fully loaded can it respond to events or allow access to its properties and methods. Behaviors loaded from external files observe domain security rules.

Example

Listing 26-19a shows what a behavior file looks like. It is the file used to demonstrate the `addBehavior()` method in Listing 26-19b. The behavior component and the HTML page that loads it must come from the same server and domain; they also must load via the same protocol (for example, `http://`, `https://`, and `file://` are mutually exclusive, mismatched protocols).

LISTING 26-19a

The makeHot.htc Behavior Component

```
<PUBLIC:ATTACH EVENT="onmousedown" ONEVENT="makeHot()" />
<PUBLIC:ATTACH EVENT="onmouseup" ONEVENT="makeNormal()" />
<PUBLIC:PROPERTY NAME="hotColor" />
<PUBLIC:METHOD NAME="setHotColor" />
<script type="text/jscript">
   var oldColor
   var hotColor = "red"

   function setHotColor(color)
   {
```

```
      hotColor = color
   }

   function makeHot()
   {
      if (event.srcElement == element)
      {
         oldColor = style.color
         runtimeStyle.color = hotColor
      }
   }

   function makeNormal()
   {
      if (event.srcElement == element)
      {
         runtimeStyle.color = oldColor
      }
   }
</script>
```

The object to which the component is attached is a simple paragraph object, shown in Listing 26-19b. When the page loads, the behavior is not attached, so clicking the paragraph text has no effect.

When you turn on the behavior by invoking the `turnOn()` function, the `addBehavior()` method attaches the code of the `makeHot.htc` component to the `myP` object. At this point, the `myP` object has one more property, one more method, and two more event handlers that are written to be made public by the component's code. If you want the behavior to apply to more than one paragraph in the document, you have to invoke the `addBehavior()` method for each paragraph object.

After the behavior file is instructed to start loading, the `setInitialColor()` function is called to set the new color property of the paragraph to the user's choice from the `select` list. But this can happen only if the component is fully loaded. Therefore, the function checks the `readyState` property of `myP` for completeness before invoking the component's function. If IE is still loading the component, the function is invoked again in 500 milliseconds.

As long as the behavior is loaded, you can change the color used to turn the paragraph hot. The function first ensures that the component is loaded by checking that the object has the new color property. If it does, the method of the component is invoked (as a demonstration of how to expose and invoke a component method). You can also simply set the property value.

   <head>
```

continued

LISTING 26-19b *(continued)*

```
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>addBehavior() and removeBehavior() Methods</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-19.js"></script>
   </head>
   <body>
      <h1>addBehavior() and removeBehavior() Method Lab</h1>
      <hr />
      <p id="myP">This is a sample paragraph. After turning on the behavior, it
         will turn your selected color when you mouse down anywhere in this
         paragraph.
      </p>
      <form>
         <input type="button" value="Switch On Behavior" onclick="turnOn()" />
         Choose a 'hot' color:
         <select name="colorChoice" onchange="setColor(this, this.value)">
            <option value="red">red</option>
            <option value="blue">blue</option>
            <option value="cyan">cyan</option>
         </select>
         <br />
         <input type="button" value="Switch Off Behavior"
                onclick="turnOff()" />
         <p>
            <input type="button" value="Count the URNs"
                   onclick="showBehaviorCount()" />
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb26-19.js

```
var myPBehaviorID;

function turnOn()
{
   myPBehaviorID = document.getElementById("myP").addBehavior("makeHot.htc");
   setInitialColor();
}

function setInitialColor()
{
   if (document.getElementById("myP").readyState == "complete")
   {
      var select = document.forms[0].colorChoice;
      var color = select.options[select.selectedIndex].value;
      document.getElementById("myP").setHotColor(color);
   }
   else
```

```
   {
      setTimeout("setInitialColor()", 500);
   }
}

function turnOff()
{
   document.getElementById("myP").removeBehavior(myPBehaviorID);
}

function setColor(select, color)
{
   if (document.getElementById("myP").hotColor)
   {
      document.getElementById("myP").setHotColor(color);
   }
   else
   {
      alert("This feature is not available. Turn on the Behavior first.");
      select.selectedIndex = 0;
   }
}

function showBehaviorCount()
{
   var num = document.getElementById("myP").behaviorUrns.length;
   var msg = "The myP element has " + num + " behavior(s). ";
   alert(msg);
}
```

To turn off the behavior, the `removeBehavior()` method is invoked. Notice that the `removeBehavior()` method is associated with the `myP` object, and the parameter is the ID of the behavior added earlier. If you associate multiple behaviors with an object, you can remove one without disturbing the others, because each has its own unique ID.

Related Items: `readyState` property; `removeBehavior()` method; IE behaviors (Chapter 51 on the CD-ROM)

addEventListener("eventType", listenerFunc, useCapture) removeEventListener("eventType", listenerFunc, useCapture)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The W3C DOM's event mechanism accommodates both event bubbling and trickling (see Chapter 32). Although the new mechanism supports the long-standing notion of binding an event to an element by way of HTML attributes (for example, the old `onclick` event handler), it encourages binding events by registering an event listener with an element. (In browsers that support the W3C event model, other ways of binding events — such as event handler attributes — are internally converted to registered events.)

To tell the DOM that an element should listen for a particular kind of event, use the `addEventListener()` method on the element object. The method requires three parameters. The first is a string version of the event type for which the element should listen. Event type strings do not include the well-used `on` prefix of event handlers; instead, the names consist only of the event and are usually in all lowercase (except for some special systemwide events preceded by DOM). Table 26-7 shows all the events recognized by the W3C DOM specification (including some new DOM ones that are not yet implemented in browsers).

TABLE 26-7

W3C DOM Event Listener Types

abort	error
blur	focus
change	load
click	mousedown
DOMActivate	mousemove
DOMAttrModified	mouseout
DOMCharacterDataModified	mouseover
DOMFocusIn	mouseup
DOMFocusOut	reset
DOMNodeInserted	resize
DOMNodeInsertedIntoDocument	scroll
DOMNodeRemoved	select
DOMNodeRemovedFromDocument	submit
DOMSubtreeModified	unload

Note that the event types specified in the DOM Level 2 are more limited than the wide range of events defined in IE4+. Also, the W3C temporarily tabled the issue of keyboard events until DOM Level 3. Fortunately, most W3C-compatible browsers implement keyboard events in a fashion that likely will appear as part of the W3C DOM Level 3.

The second parameter of the `addEventListener()` method is a reference to the JavaScript function to be invoked. This is the same form used to assign a function to an event property of an object (for example, `objReference.onclick = someFunction`), and it should *not* be a quoted string. This approach also means that you cannot specify parameters in the function call. Therefore, functions that need to reference forms or form control elements must build their own references (with the help of the event object's property that says which object is the event's target).

By default, the W3C DOM event model has events bubble upward through the element container hierarchy starting with the target object of the event (for example, the button being clicked). However, if you specify `true` for the third parameter of the `addEventListener()` method, event capture is

enabled for this particular event type whenever the current object is the event target. This means that any other event type targeted at the current object bubbles upward unless it, too, has an event listener associated with the object and the third parameter is set to `true`.

Using the `addEventListener()` method requires that the object to which it is attached already exists. Therefore, you most likely will use the method inside an initialization function triggered by the `onload` event handler for the page. (The `document` object can use `addEventListener()` for the load event immediately, because the `document` object exists early in the loading process.)

A script can also eliminate an event listener that was previously added by script. The `removeEventListener()` method takes the same parameters as `addEventListener()`, which means that you can turn off one listener without disturbing others. In fact, because you can add two listeners for the same event and listener function (one set to capture and one not — a rare occurrence indeed), the three parameters of the `removeEventListener()` enable you to specify precisely which listener to remove from an object.

Unlike the event capture mechanism of NN4, the W3C DOM event model does not have a global capture mechanism for an event type regardless of target. And with respect to Internet Explorer, the `addEventListener()` method is closely analogous to the IE5+ `attachEvent()` method. Also, event capture in IE5+ is enabled via the separate `setCapture()` method. Both the W3C and IE event models use their own syntaxes to bind objects to event handling functions, so the actual functions may be capable of serving both models with browser version branching required only for event binding. See Chapter 32 for more about event handling with these two event models.

Example

Listing 26-20 provides a compact workbench to explore and experiment with the basic W3C DOM event model. When the page loads, no event listeners are registered with the browser (except the control buttons, of course). But you can add an event listener for a `click` event in bubble and/or capture mode to the `body` element or the `p` element that surrounds the `span` holding the line of text. If you add an event listener and click the text, you see a readout of the element processing the event and information indicating whether the event phase is bubbling (3) or capture (1). With all event listeners engaged, notice the sequence of events being processed. Remove listeners one at a time to see the effect on event processing.

appendChild(*elementObject*)

Returns: Node object reference

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `appendChild()` method inserts an element or text node (defined by other code that comes before it) as the new, last child of the current element. Aside from the more obvious application of adding a new child element to the end of a sequence of child nodes, the `appendChild()` method is also practical for building element objects and their content before appending, replacing, or inserting the element into an existing document. The `document.createElement()` method generates a reference to an element of whatever tag name you assign as that method's parameter.

The `appendChild()` method returns a reference to the appended node object. This reference differs from the object that is passed as the method's parameter because the returned value represents the object as part of the document rather than as a freestanding object in memory.

Example

Listing 26-21 contains an example that shows how to use the `appendChild()` method in concert with `removeChild()` and `replaceChild()` to modify child elements in a document. Because many W3C DOM browsers treat source-code carriage returns as text nodes (and, thus, child nodes of their parent), the HTML for the affected list elements in Listing 26-21 is shown without carriage returns between elements.

The `append()` function creates a new `li` element and then uses the `appendChild()` method to attach the text box text as the displayed text for the item. The nested expression, `document.createTextNode(newData)`, evaluates to a legitimate node that is appended to the new `li` item. All of this occurs before the new `li` item is added to the document. In the final statement of the function, `appendChild()` is invoked from the vantage point of the `ul` element — thus adding the `li` element as a child node of the `ul` element.

Invoking the `replaceChild()` method in the `rplace()` function uses some of the same code. The main difference is that the `replaceChild()` method requires a second parameter: a reference to the child element to be replaced. This demonstration replaces the final child node of the `ul` list, so the function takes advantage of the `lastChild` property of all elements to get a reference to that final nested child. That reference becomes the second parameter to `replaceChild()`.

LISTING 26-21

Various Child Methods

HTML: jsb26-21.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>appendChild(), removeChild(), and replaceChild() Methods</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-21.js"></script>
   </head>
   <body>
      <h1>Child Methods</h1>
      <hr />
      Here is a list of items:
      <ul id="myUL"><li>First Item</li><li>Second Item</li></ul>
      <form>
         Enter some text to add/replace in the list:
         <input type="text" id="newListData" size="30" />
         <br />
         <input type="button" value="Append to List"
                onclick="append()" />
         <input type="button" value="Replace Final Item"
                onclick="rplace()" />
         <input type="button" value="Truncate List to 2 Items"
                onclick="truncateList()" />
      </form>
   </body>
</html>
```

JavaScript: jsb26-21.js

```
function append()
{
   var newData = document.getElementById("newListData").value;
   if (newData)
   {
      var newItem = document.createElement("LI");
      newItem.appendChild(document.createTextNode(newData));
      document.getElementById("myUL").appendChild(newItem);
   }
}

// Opera throws an error when use keyword replace, so....
function rplace()
{
   var newData = document.getElementById("newListData").value;
   if (newData)
   {
```

continued

LISTING 26-21 *(continued)*

```
      var newItem = document.createElement("LI");
      var lastChild = document.getElementById("myUL").lastChild;
      newItem.appendChild(document.createTextNode(newData));
      document.getElementById("myUL").replaceChild(newItem, lastChild);
   }
}

function truncateList()
{
   var oneChild;
   var mainObj = document.getElementById("myUL");
   while (mainObj.childNodes.length > 2)
   {
      oneChild = mainObj.lastChild;
      mainObj.removeChild(oneChild);
   }
}
```

The final part of the demonstration uses the `removeChild()` method to peel away all children of the `ul` element until just two items are left standing. Again, the `lastChild` property comes in handy as the `truncateList()` function keeps removing the last child until only two remain.

Related Items: `removeChild()`, `replaceChild()` methods; nodes and children (Chapter 25)

applyElement(*elementObject*[, *type*])

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `applyElement()` method enables you to insert a new element as the parent or child of the current object. An important feature of this method is that the new object is wrapped around the current object (if the new element is to become the parent) or the current object's content (if the new element is to become a child). When the new element becomes a child, all previous children are nested further by one generation to become immediate children of the new element. You can imagine how the resulting action of this method affects the containment hierarchy of the current element, so you must be careful how you use the `applyElement()` method.

One parameter, a reference to the object to be applied, is required. This object may be generated from constructions such as `document.createElement()` or from one of the child or node methods that returns an object. The second parameter is optional, and it must be one of the following values:

Parameter Value	Description
`outside`	New element becomes the parent of the current object.
`inside`	New element becomes the immediate child of the current object.

If you omit the second parameter, the default value (`outside`) is assumed. Listing 26-22 shows how the `applyElement()` method is used both with and without default values.

Example

To help you visualize the impact of the `applyElement()` method with its different parameter settings, Listing 26-22 enables you to apply a new element (an `em` element) to a `span` element inside a paragraph. At any time, you can view the HTML of the entire `p` element to see where the `em` element is applied, as well as its impact on the element containment hierarchy for the paragraph.

After you load the page, inspect the HTML for the paragraph before doing anything else. Notice the `span` element and its nested `code` element, both of which surround the one-word content. If you apply the `em` element inside the `span` element (click the middle button), the `span` element's first (and only) child element becomes the `em` element; the `code` element is now a child of the new `em` element.

LISTING 26-22

Using the applyElement() Method

HTML: jsb26-22.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>applyElement() Method</title>
      <style type="text/css">
         #mySpan
         {
            font-size:x-large;
         }
      </style>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-22.js"></script>
   </head>
   <body>
      <h1>applyElement() Method</h1>
      <hr />
      <p id="myP">A simple paragraph with a <span id="mySpan"><code>
      special</code></span> word in it. How special? Click an apply button,
          then click the show button.
      </p>
      <form>
         <input type="button" value="Apply &lt;EM&gt; Outside"
                onclick="applyOutside()" />
         <input type="button" value="Apply &lt;EM&gt; Inside"
                onclick="applyInside()" />
         <input type="button" value="Show &lt;P&gt; HTML..."
                onclick="showHTML()" />
         <br />
         <input type="button" value="Restore Paragraph"
                onclick="location.reload()" />
```

continued

LISTING 26-22 *(continued)*

```
      </form>
   </body>
</html>
```

JavaScript: jsb26-22.js

```
function applyOutside()
{
   var newItem = document.createElement("EM");
   newItem.id = newItem.uniqueID;
   // no 2nd argument--use default: outside
   document.getElementById("mySpan").applyElement(newItem);
}

function applyInside()
{
   var newItem = document.createElement("EM");
   newItem.id = newItem.uniqueID;
   document.getElementById("mySpan").applyElement(newItem, "inside");
}

function showHTML()
{
   alert(document.getElementById("myP").outerHTML);
}
```

The visible results of applying the `em` element inside and outside the `span` element in this case are the same. But you can see from the HTML results that each element impacts the element hierarchy quite differently.

Related Items: `insertBefore()`, `appendChild()`, `insertAdjacentElement()` methods

attachEvent("*eventName*", *functionRef*)
detachEvent("*eventName*", *functionRef*)

Returns: Boolean

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

The `attachEvent()` method originated as a means to bind events for IE behaviors (see Chapter 51 on the CD-ROM). But the method has gained acceptance as an IE alternative to the W3C `addEventListener()` event binding method. To illustrate the method's usage, we want you to first consider the following example of the typical property assignment approach to binding an event handler:

```
myObject.onmousedown = setHilite;
```

The version with `attachEvent()` is as follows:

```
myObject.attachEvent("onmousedown", setHilite);
```

Both parameters are required. The first parameter is a string version (case insensitive) of the event name. The second is a reference to the function to be invoked when the event fires for this object. A *function reference* is an unquoted, case-sensitive identifier for the function without any parentheses (which also means that you cannot pass parameters in this function call).

There is a subtle benefit to using `attachEvent()` over the event property binding approach. When you use `attachEvent()`, the method returns a Boolean value of `true` if the event binding succeeds. IE triggers a script error if the function reference fails, so don't rely on a returned value of `false` to catch these kinds of errors. Also, there is no validation that the object recognizes the event name.

If you have used `attachEvent()` to bind an event handler to an object's event, you can disconnect that binding with the `detachEvent()` method. The parameters are the same as for `attachEvent()`. The `detachEvent()` method cannot unbind events whose associations are established via tag attributes or event property settings.

The W3C DOM event model provides functionality similar to these IE-only methods: `addEventListener()` and `removeEventListener()`.

Example

Use The Evaluator (see Chapter 4) to create an anonymous function that is called in response to an `onmousedown` event of the first paragraph on the page. Begin by assigning the anonymous function to global variable `a` (already initialized in The Evaluator) in the top text box:

```
a = new Function("alert('Function created at " + (new Date()) + "')")
```

The quote marks and parentheses can get jumbled easily, so enter this expression carefully. When you enter the expression successfully, the Results box shows the function's text. Now assign this function to the `onmousedown` event of the `myP` element by entering the following statement in the top text box:

```
document.getElementById("myP").attachEvent("onmousedown", a)
```

The Results box displays `true` when successful. If you mouse down on the first paragraph after the evaluator panel, an alert box displays the date and time when the anonymous function was created (when the `new Date()` expression was evaluated).

Now disconnect the event relationship from the object by entering the following statement in the top text box:

```
document.getElementById("myP").detachEvent("onmousedown", a)
```

Related Items: `addEventListener()`, `detachEvent()`, `dispatchEvent()`, `fireEvent()`, `removeEventListener()` methods; event binding (Chapter 32)

blur()
focus()

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `blur()` method removes focus from an element, whereas the `focus()` method gives focus to an element. Even though the `blur()` and `focus()` methods have been around since the earliest scriptable browsers, not every focusable object has enjoyed these methods since the beginning.

***elementObject*.blur()**

Browsers before IE4 and NN6 limited these methods primarily to the `window` object and form control elements.

Windows

For window objects, the `blur()` method (NN3+, IE4+, Opera) pushes the referenced window to the back of all other open windows. If other browser suite windows (such as email or newsreader windows) are open, the window receiving the `blur()` method is placed behind these windows as well.

In Safari and Firefox, the `blur()` method pushes the referenced window only behind the window that opened it. In Chrome, the `window.blur()` method does not work, as demonstrated if you click the Put Me in Back button in Listing 26-23a. For that matter, the `window.focus()` method does not work in Chrome either, as demonstrated if you click the Bring Main to Front button in Listing 26-23a. The window.focus() method does not work in IE8 either.

Caution

When it works, the `window.blur()` method does not consistently adjust the stacking order of the current window in the different browsers. But a script in a window can invoke the `focus()` method of another window to bring that other window to the front (provided that a scriptable linkage, such as the `window.opener` property, exists between the two windows). ■

The minute you create another window for a user in your web-site environment, you must pay attention to window layer management. With browser windows so easily activated by the slightest mouse click, a user can lose a smaller window behind a larger one in a snap. Most inexperienced users don't think to check the Windows taskbar or browser menu bar (if the browser is so equipped) to see whether a smaller window is still open and then activate it. If that subwindow is important to your site design, you should present a button or other device in each window that enables users to switch among windows safely. The `window.focus()` method brings the referenced window to the front of all the windows.

Rather than supply a separate button on your page to bring a hidden window forward, you should build your window-opening functions in such a way that if the window is already open, the function automatically brings that window forward (as shown in Listing 26-23a). This removes the burden of window management from your visitors.

The key to success with this method is making sure that your references to the desired windows are correct. Therefore, be prepared to use the `window.opener` property to refer to the main window if a subwindow needs to bring the main window back into focus.

Form control elements

The `blur()` and `focus()` methods apply primarily to text-oriented form controls: text input, `select`, and `textarea` elements.

Just as a camera lens blurs when it goes out of focus, a text object blurs when it loses focus — when someone clicks or tabs out of the field. Under script control, `blur()` deselects whatever may be selected in the field, and the text insertion pointer leaves the field. The pointer does not proceed to the next field in tabbing order, as it does if you perform a blur by tabbing out of the field manually.

For a text object, having focus means that the text insertion pointer is flashing in that text object's field. Giving a field focus is like opening it up for human editing.

Setting the focus of a text box or `textarea` does not by itself enable you to place the cursor at any specified location in the field. The cursor usually appears at the beginning of the text. To prepare a field for entry to remove the existing text, use both the `focus()` and `select()` methods in series.

There is a caveat about using `focus()` and `select()` together to preselect the content of a text box for immediate editing: Many versions of Internet Explorer fail to achieve the desired results due to an internal timing problem. You can work around this problem (and remain compatible with other browsers) by initiating the focus and selection actions through a `setTimeout()` method.

A common design requirement is to position the insertion pointer at the end of a text box or `textarea` so that a user can begin appending text to existing content immediately. This is possible in IE4+ with the help of the `TextRange` object. The following script fragment moves the text insertion pointer to the end of a `textarea` element whose ID is `myTextarea`:

```
var range = document.getElementById("myTextarea").createTextRange();
range.move("textedit");
range.select();
```

You should be very careful in combining `blur()` or `focus()` methods with `onblur` and `onfocus` event handlers — especially if the event handlers display alert boxes. Many combinations of these events and methods can cause an infinite loop in which it is impossible to dismiss the alert dialog box completely. On the other hand, there is a useful combination for older browsers that don't offer a `disabled` property for text boxes. The following text box event handler can prevent users from entering text in a text box:

```
onfocus = "this.blur()";
```

Some operating systems and browsers enable you to give focus to elements such as buttons (including radio and checkbox buttons) and hypertext links (encompassing both `a` and `area` elements). Typically, once such an element has focus, you can accomplish the equivalent of a mouse click on the element by pressing the spacebar. This is helpful for accessibility to those who have difficulty using a mouse.

An unfortunate side effect of button focus in Win32 environments is that the focus highlight (a dotted rectangle) remains around the button after a user clicks it and until another object gets focus. You can eliminate this artifact for browsers and objects that implement the `onmouseup` event handler by including the following event handler in your buttons:

```
onmouseup = "this.blur()";
```

IE5.5+ recognizes the often undesirable effect of that dotted rectangle and lets scripts set the `hideFocus` property of an element to `true` to keep that rectangle hidden while giving the element focus. It is a trade-off for the user, however, because there is no visual feedback about which element has focus.

Other elements

For other kinds of elements that support the `focus()` method, you can bring an element into view in lieu of the `scrollIntoView()` method. Link (`a`) and `area` elements in Windows versions of IE

***elementObject*.blur()**

display the dotted rectangle around them after a user brings focus to them. To eliminate that artifact, use the same

```
onmouseup = "this.blur()";
```

event handler (or IE5.5+ `hideFocus` property) just described for form controls.

Example

Listing 26-23a contains an example of using the `focus()` and `blur()` methods to tinker with changing the focus of windows. This example creates a two-window environment; from each window, you can bring the other window to the front. The main window uses the object returned by `window.open()` to assemble the reference to the new window. In the subwindow (whose content is created entirely on-the-fly by JavaScript), `self.opener` is summoned to refer to the original window, whereas `self.blur()` operates on the subwindow itself. Blurring one window and focusing on another window yields the same result of sending the window to the back of the pile.

LISTING 26-23a

The window.focus() and window.blur() Methods

HTML: jsb26-23.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Window Focus() and Blur()</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-23.js"></script>
   </head>
   <body>
      <h1>Window focus() and blur() Methods</h1>
      <hr />
      <form>
         <input type="button" name="newOne" value="Show New Window"
                onclick="makeNewWindow()" />
      </form>
   </body>
</html>
```

JavaScript: jsb26-23.js

```
// declare global variable name
var newWindow = null;

function makeNewWindow()
{
   // check if window already exists
   if (!newWindow || newWindow.closed)
   {
      // store new window object in global variable
      newWindow = window.open("","","width=250,height=250");
      // pause briefly to let IE3 window finish opening
```

```
      setTimeout("fillWindow()",100);
   }
   else
   {
      // window already exists, so bring it forward
      newWindow.focus();
   }
}

// assemble new content and write to subwindow
function fillWindow()
{
   var newContent = "<html><head><title>Another Sub Window<\/title><\/head>";
   newContent += "<body bgColor='salmon'>";
   newContent += "<h1>A Salmon-Colored Subwindow.<\/h1>";
   newContent += "<form><input type='button' value='Bring Main to Front'
      onclick='self.opener.focus()'>";
   newContent += "<input type='button' value='Put Me in Back'
      onclick='self.blur()'>";
   newContent += "<\/form><\/body><\/html>";
   // write HTML to new window document
   newWindow.document.write(newContent);
   newWindow.document.close();
}
```

A key ingredient to the success of the `makeNewWindow()` function in Listing 26-23a is the first conditional expression. Because `newWind` is initialized as a `null` value when the page loads, that is its value the first time through the function. But after you open the subwindow the first time, `newWind` is assigned a value (the subwindow object) that remains intact even if the user closes the window. Thus, the value doesn't revert to `null` by itself. To catch the possibility that the user has closed the window, the conditional expression also sees whether the window is closed. If it is, a new subwindow is generated, and that new window's reference value is reassigned to the `newWind` variable. On the other hand, if the window reference exists and the window is not closed, the `focus()` method brings that subwindow to the front.

In Listing 26-23a you can see where the subwindow's content is created entirely on-the-fly by JavaScript. One of the nice little tools in IE and Firefox is the ability to view generated source. It's a little ugly, in that all the code is on a single line. We've formatted the generated source for you in Listing 26-23b so that you can see just what was created entirely on-the-fly in Listing 26.23a.

LISTING 26-23b

The Source Code Generated On-the-Fly in Listing 26-23a

```
<html>
   <head>
      <title>Another Sub Window</title>
   </head>
   <body bgcolor="salmon">
```

continued

LISTING 26-23b *(continued)*

```
      <h1>A Salmon-Colored Subwindow.</h1>
      <form>
         <input value="Bring Main to Front" onclick="self.opener.focus()"
               type="button">
         <input value="Put Me in Back" onclick="self.blur()" type="button">
      </form>
   </body>
</html>
```

You can see the `focus()` method for a text object in action in the description of the `select()` method for text objects in Chapter 36.

Related Items: `window.open()`, `document.formObject.textObject.select()` methods

clearAttributes()

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `clearAttributes()` method removes all attributes from an element except the `name` and `id` values. Thus, styles and event handlers are removed, as are custom attributes assigned in either the HTML source code or later by script. You should know that the `clearAttributes()` method does not alter the length of the element's `attributes` collection, because the collection always contains all possible attributes for an element. (See the `attributes` property for elements earlier in this chapter.)

This method is handy if you wish to construct an entirely new set of attributes for an element and prefer to start out with a blank slate. Be aware, however, that unless your scripts immediately assign new attributes to the element, the appearance of the element reverts to its completely unadorned form until you assign new attributes. This means that even positioned elements find their way back to their source-code order until you assign a new positioning style. If you simply want to change the value of one or more attributes of an element, it is faster to use the `setAttribute()` method or adjust the corresponding properties.

To accomplish a result in NN6+/Moz that simulates that of IE5+'s `clearAttributes()`, you must iterate through all attributes of an element and remove those attributes (via the `removeAttribute()` method) whose names are other than `id` and `name`.

Example

Use The Evaluator (see Chapter 4) to examine the attributes of an element before and after you apply `clearAttributes()`. To begin, display the HTML for the table element on the page by entering the following statement in the top text box:

```
myTable.outerHTML
```

Notice the attributes associated with the `<table>` tag. Look at the rendered table to see how attributes such as `border` and `width` affect the display of the table. Now enter the following statement in the top text box to remove all removable attributes from this element:

```
myTable.clearAttributes()
```

First, look at the table. The border is gone, and the table is rendered only as wide as is necessary to display the content with no cell padding. Finally, view the results of the `clearAttributes()` method in the `outerHTML` of the table again:

```
myTable.outerHTML
```

The source-code file has not changed, but the object model in the browser's memory reflects the changes you made.

Related Items: `attributes` property; `getAttribute()`, `setAttribute()`, `removeAttribute()`, `mergeAttributes()`, and `setAttributeNode()` methods

click()

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `click()` method lets a script perform nearly the same action as clicking an element. Before NN4 and IE4, the `click()` method invoked on a button did not trigger the `onclick` event handler for the object. This has significant impact if you expect the `onclick` event handler of a button to function even if a script performs the click. For earlier browser versions, you have to invoke the event handler statements directly. Also, just because a script is clicking a button, not all buttons in all platforms change their appearance in response. For example, NN4 on the Mac does not change the state of a checkbox clicked remotely.

If you want to script the action of clicking a button, you can safely invoke the resulting event handler function directly. And if the element is a radio button or checkbox, handle the change of state directly (for example, set the `checked` property of a checkbox) rather than expect the browser to take care of it for you.

Example

Use The Evaluator (see Chapter 4) to experiment with the `click()` method. The page includes various types of buttons at the bottom. You can click the checkbox, for example, by entering the following statement in the top text box:

```
document.myForm2.myCheckbox.click()
```

If you use a recent browser version, you most likely can see the checkbox change states between checked and unchecked each time you execute the statement.

Related Item: `onclick` event handler

cloneNode(*deepBoolean*)

Returns: Node object reference

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cloneNode()` method makes an exact copy of the current node object. This copy does not have a parent node or other relationship with any element after the copy exists (of course, the original node remains in place). The clone also does not become part of the document's object model (the node tree) unless you explicitly insert or append the node somewhere on the page. The copy includes all element attributes, including the `id` attribute. Because the value returned by the `cloneNode()` method is

a genuine `Node` object, you can operate on it with any `Node` object methods while it is still in the nondocument object state.

The Boolean parameter of the `cloneNode()` method controls whether the copy of the node includes all child nodes (`true`) or just the node itself (`false`). For example, if you clone a paragraph element by itself, the clone consists only of the raw element (equivalent of the tag pair, including attributes in the start tag) and none of its content. But including child nodes makes sure that all content within that paragraph element is part of the copy. This parameter is optional in IE5 (defaulting to `false`), but it is required in other W3C-compatible browsers.

Example

Use The Evaluator (see Chapter 4) to clone, rename, and append an element found in The Evaluator's source code. Begin by cloning the paragraph element named `myP` along with all of its content. Enter the following statement in the top text box:

```
a = document.getElementById("myP").cloneNode(true)
```

The variable `a` now holds the clone of the original node, so you can change its `id` attribute at this point by entering the following statement:

```
a.setAttribute("id", "Dolly")
```

If you want to see the properties of the cloned node, enter `a` in the bottom text box. The precise listing of properties you see depends on the browser you're using; in either case, you should be able to locate the `id` property, whose value is now `Dolly`.

As a final step, append this newly named node to the end of the `body` element by entering the following statement in the top text box:

```
document.body.appendChild(a)
```

You can now scroll down to the bottom of the page and see a duplicate of the content. But because the two nodes have different `id` attributes, they cannot confuse scripts that need to address one or the other.

Related Items: `Node` object (Chapter 25); `appendChild()`, `removeChild()`, `removeNode()`, `replaceChild()`, and `replaceNode()` methods

compareDocumentPosition(nodeRef)

Returns: Integer

Compatibility: WinIE-, MacIE-, NN6+, Moz1.4+, Safari+, Opera+, Chrome+

This method determines the tree position of one node with respect to another node. More specifically, the `nodeRef` object provided as a parameter (Node B) is compared with the object on which the method is called (Node A). The result is returned from the method as an integer value that can contain one or more of the comparison masks listed in Table 26-8.

The integer value returned by the `compareDocumentPosition()` method is actually a bitmask, which explains why the values in Table 26-8 are powers of 2. This allows the method to return multiple comparison values simply by adding them together. For example, a return value of `20` indicates that Node B is contained by Node A (`16`) and also that Node B follows Node A (4).

TABLE 26-8

Comparison Return Flags

Integer Value	Constant	Description
0		Node B and Node A are one and the same.
1	DOCUMENT_POSITION_DISCONNECTED	No connection exists between the nodes.
2	DOCUMENT_POSITION_PRECEDING	Node B precedes Node A.
4	DOCUMENT_POSITION_FOLLOWING	Node B follows Node A.
8	DOCUMENT_POSITION_CONTAINS	Node B contains Node A (and therefore precedes it).
16	DOCUMENT_POSITION_CONTAINED_BY	Node B is contained by Node A (and therefore follows it).
32	DOCUMENT_POSITION_IMPLEMENTATION_ SPECIFIC	The comparison is determined by the browser.

Related Item: `contains()` method

componentFromPoint(*x*,*y*)

Returns: String

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `componentFromPoint()` method assists in some event-related tasks. You can use it for a kind of collision detection (in other words, to determine whether an event occurs inside or outside a particular element). If the element has scroll bars, the method can provide additional information about the event, such as which component of the scroll bar the user activates.

A key aspect of this method is that you invoke it on any element that you want to use as the point of reference. For example, if you want to find out whether a `mouseup` event occurs in an element whose ID is `myTable`, invoke the method as follows:

```
var result = document.getElementById("myTable").componentFromPoint(↩
   event.clientX, event.clientY);
```

Parameters passed to the method are *x* and *y* coordinates. These coordinates do not have to come from an event, but the most likely scenario links this method with an event of some kind. Mouse events (other than `onclick`) work best.

The value returned by the method is a string that provides details about where the coordinate point is with respect to the current element. If the coordinate point is inside the element's rectangle, the returned value is an empty string. Conversely, if the point is completely outside the element, the returned value is the string `"outside"`. For scroll-bar pieces, the list of possible returned values is quite lengthy (as shown in Table 26-9).

TABLE 26-9

Returned Values for componentFromPoint()

Returned String	Element Component at Coordinate Point
(empty)	Inside the element content area
`outside`	Outside the element content area
`handleBottom`	Resize handle at bottom
`handleBottomLeft`	Resize handle at bottom left
`handleBottomRight`	Resize handle at bottom right
`handleLeft`	Resize handle at left
`handleRight`	Resize handle at right
`handleTop`	Resize handle at top
`handleTopLeft`	Resize handle at top left
`handleTopRight`	Resize handle at top right
`scrollbarDown`	Scroll-bar down arrow
`scrollbarHThumb`	Scroll-bar thumb on horizontal bar
`scrollbarLeft`	Scroll-bar left arrow
`scrollbarPageDown`	Scroll-bar page-down region
`scrollbarPageLeft`	Scroll-bar page-left region
`scrollbarPageRight`	Scroll-bar page-right region
`scrollbarPageUp`	Scroll-bar page-up region
`scrollbarRight`	Scroll-bar right arrow
`scrollbarUp`	Scroll-bar up arrow
`scrollbarVThumb`	Scroll-bar thumb on vertical bar

You do not have to use this method for most collision or event detection, however. The `event` object's `srcElement` property returns a reference to whatever object receives the event.

Example

Listing 26-24 demonstrates how the `componentFromPoint()` method can be used to determine exactly where a mouse event occurred. As presented, the method is associated with a `textarea` object that is specifically sized to display both vertical and horizontal scroll bars. As you click various areas of the `textarea` and the rest of the page, the status bar displays information about the location of the event with the help of the `componentFromPoint()` method.

The script uses a combination of the `event.srcElement` property and the `componentFromPoint()` method to help you distinguish how you can use each one for different types of event processing. The `srcElement` property is used initially as a filter to decide whether the status bar will reveal further processing about the `textarea` element's event details.

The `onmousedown` event handler in the `body` element triggers all event processing. IE events bubble up the hierarchy (and no events are canceled in this page), so all `mousedown` events eventually reach the `body` element. Then the `whereInWorld()` function can compare each `mousedown` event from any element against the text area's geography.

LISTING 26-24

Using the componentFromPoint() Method

HTML: jsb26-24.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>componentFromPoint() Method</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-24.js"></script>
   </head>
   <body onmousedown="whereInWorld()">
      <h1>componentFromPoint() Method</h1>
      <hr />
      <p>Tracking the mouseDown event relative to the textarea object. View
         results in status bar.
      </p>
      <form>
         <textarea id="myTextarea" wrap="off" cols="12" rows="4">
            This is Line 1
            This is Line 2
            This is Line 3
            This is Line 4
            This is Line 5
            This is Line 6
         </textarea>

   else
   {
      status = "mouseDown occurred " + component + " of the element";
   }
}
```

Related Item: `event` object

contains(*elementObjectReference*)

Returns: Boolean

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+-, Opera+, Chrome+

The `contains()` method reports whether the current object contains another known object within its HTML containment hierarchy. Note that this is not geographical collision detection of overlapping elements, but the determination of whether one element is nested somewhere within another.

The scope of the `contains()` method extends as deeply within the current object's hierarchy as is necessary to locate the object. In essence, the `contains()` method examines all of the elements that are part of an element's `all` array. Therefore, you can use this method as a shortcut replacement for a `for` loop that examines each nested element of a container for the existence of a specific element.

The parameter to the `contains()` method is a reference to an object. If you have only the element's ID as a string to go by, you can use the `document.getElementById()` method to generate a valid reference to the nested element.

Note

An element always contains itself. ■

Example

Using The Evaluator (Chapter 4), see how the `contains()` method responds to the object combinations in each of the following statements as you enter them in the top text box:

```
document.body.contains(document.getElementById("myP"))
document.getElementById("myP").contains(document.getElementById("myEM"))
document.getElementById("myEM").contains(document.getElementById("myEM"))
document.getElementById("myEM").contains(document.getElementById("myP"))
```

Feel free to test other object combinations within this page.

Related Items: `item()`, `document.getElementById()` methods

`createControlRange("*param*")`

Returns: Integer ID

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `createControlRange()` method is used to create a control range for a selection of text. Although the method is implemented for several elements, it is intended solely for the `selection` object and, therefore, should be used only on that object.

Related Item: `selection` object

`detachEvent()`

(See `attachEvent()`)

`dispatchEvent(*eventObject*)`

Returns: Boolean

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `dispatchEvent()` method allows a script to fire an event aimed at any object capable of supporting that event. This is the W3C event model way of generalizing mechanisms that earlier browsers sometimes mimic with object methods such as `click()` and `focus()`.

The process of generating one of these events is similar to the way a script generates a new node and inserts that node somewhere into the DOM. For events, however, the object that is created is an `Event` object, which is generated via the `document.createEvent()` method. An event generated in this manner is simply a specification about an event. Use properties of an event object to supply specifics about the event, such as its coordinates or mouse button. Then dispatch the event to a target object by invoking that target object's `dispatchEvent()` method and passing the newly created `Event` object as the sole parameter.

Interpreting the meaning of the Boolean value that the `dispatchEvent()` method returns is not straightforward. The browser follows the dispatched event through whatever event propagation is in effect for that object and event type (either bubbling or capture). If any of the event listener functions triggered by this dispatched event invokes the `preventDefault()` method, the `dispatchEvent()` method returns `false` to indicate that the event did not trigger the native action of the object; otherwise, the method returns `true`. Notice that this returned value indicates nothing about propagation type or how many event listeners run as a result of dispatching this event.

Caution

Although the `dispatchEvent()` method was implemented in NN6, the browser does not yet provide a way to generate new events from scratch. And if you attempt to redirect an existing event to another object via the `dispatchEvent()` method, the browser is prone to crashing. In other words, Mozilla-based browsers are much better candidates for scripts that use `dispatchEvent()`. ■

Example

Listing 26-25 demonstrates how to fire events programmatically using the W3C DOM `dispatchEvent()` method. Notice the syntax in the `doDispatch()` function for creating and initializing a new mouse event, supported most reliably in Mozilla-based browsers. The behavior is identical to that of Listing 26-26 later in this chapter, which demonstrates the IE5.5+ equivalent: `fireEvent()`.

}

// invoke dispatchEvent() on object whose ID is passed as parameter
function doDispatch(objID, evt)
{
   // create empty mouse event
   var newEvt = document.createEvent("MouseEvents");
   // initialize as click with button ID 3
   newEvt.initMouseEvent("click", true, true, window, 0, 0, 0, 0, 0, false,
        false, false, false, 3, null);
   // send event to element passed as param
   document.getElementById(objID).dispatchEvent(newEvt);
   // don't let button clicks bubble
   evt.stopPropagation();
}
```

Related Item: `fireEvent()` method

doScroll("*scrollAction*")

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `doScroll()` method is used to control the scrolling of an element by triggering its scroll bars. Although a subtle distinction, `doScroll()` doesn't move the scroll bars to a specific position; instead, it simulates a scroll-bar click. The end result is an `onscroll` event being fired, which is what you would expect from a simulated scroll.

The string parameter to `doScroll()` can be one of the following values to indicate what kind of scrolling is to take place: `scrollbarUp`, `scrollbarDown`, `scrollbarLeft`, `scrollbarRight`, `scrollbarPageUp`, `scrollbarPageDown`, `scrollbarPageLeft`, `scrollbarPageRight`, `scrollbarHThumb`, or `scrollbarVThumb`.

dragDrop()

Returns: Boolean

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `dragDrop()` method initiates a mouse drag-and-drop sequence by triggering an `ondragstart` event. The return value is a Boolean that indicates when the user releases the mouse button (`true`).

fireEvent("*eventType*"[, *eventObjectRef*])

Returns: Boolean

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Although some objects have methods that emulate physical events (for example, the `click()` and `focus()` methods), WinIE5.5+ generalizes the mechanism by letting a script direct any valid event to any object. The `fireEvent()` method is the vehicle.

One required parameter is the event type, formatted as a string. IE event types are coded just like the property names for event handlers (for example, `onclick`, `onmouseover`, and so on).

A second, optional parameter is a reference to an existing `event` object. This object can be an event that some user or system action triggers (meaning that the `fireEvent()` method is in a function invoked by an event handler). The existing event can also be an object created by the IE5.5+ `document.createEventObject()` method. In either case, the purpose of providing an existing `event` object is to set the properties of the `event` object that the `fireEvent()` method creates. The event type is defined by the method's first parameter, but if you have other properties to set (for example, coordinates or a keyboard key code), those properties are picked up from the existing object. Here is an example of a sequence that creates a new `mousedown` event, stuffs some values into its properties, and then fires the event at an element on the page:

```
var newEvent = document.createEventObject();
newEvent.clientX = 100;
newEvent.clientY = 30;
newEvent.cancelBubble = false;
newEvent.button = 1;
document.getElementById("myElement").fireEvent("onmousedown", newEvent);
```

Events generated by the `fireEvent()` method are just like regular IE `window.event` objects, and they have several important `event` object properties that the browser presets. It is important that `cancelBubble` is set to `false` and `returnValue` is set to `true` — just like a regular user- or system-induced event. This means that if you want to prevent event bubbling and/or prevent the default action of the event's source element, the event handler functions must set these `event` object properties just like normal event handling in IE.

The `fireEvent()` method returns a Boolean value that the `returnValue` property of the event determines. If the `returnValue` property is set to `false` during event handling, the `fireEvent()` method returns `false`. Under normal processing, the method returns `true`.

The W3C DOM (Level 2) event model includes the `dispatchEvent()` method to accommodate script-generated events (and `Event` object methods to create event objects), which is roughly the W3C equivalent of the `fireEvent()` method.

Example

Listing 26-26 contains script code that shows how to fire events programmatically using the `fireEvent()` method. Three buttons in the example page enable you to direct a click event to each of the three elements that have event handlers defined for them. The events fired this way are artificial, generated via the `createEventObject()` method. For demonstration purposes, the `button` property of these scripted events is set to 3. This property value is assigned to the `event`

object that eventually gets directed to an element. With event bubbling left on, the events sent via `fireEvent()` behave just like the physical clicks on the elements. Similarly, if you disable event bubbling, the first event handler to process the event cancels bubbling, and no further processing of that event occurs. Notice that event bubbling is canceled within the event handlers that process the event. To prevent the clicks of the checkbox and action buttons from triggering the `body` element's `onclick` event handlers, event bubbling is turned off for the buttons right away.

   event.cancelBubble = true;
}
```

Related Item: `dispatchEvent()` method

`focus()`

(See `blur()`)

`getAdjacentText("`*`position`*`")`

Returns: String

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `getAdjacentText()` method enables you to extract copies of plain-text components of an element object (in other words, without any HTML tag information). The sole parameter is one of four case-insensitive string constant values that indicate from where, in relation to the current object, the text should be extracted. The values are:

Parameter Value	Description
`beforeBegin`	Text immediately in front of the element's tag, back to the preceding tag
`afterBegin`	Text that begins inside the element tag, up to the next tag (whether it be a nested element or the element's end tag)
`beforeEnd`	Text immediately in front of the element's end tag, back to the preceding tag (whether it be a nested element or the element's start tag)
`afterEnd`	Text immediately following the element's end tag, forward until the next tag

If the current object has no nested elements, both the `afterBegin` and `beforeEnd` versions return the same as the object's `innerText` property. When the current object is encased immediately within another element (for example, a `td` element inside a `tr` element), there is no text before the element's beginning or after the element's end, so these values are returned as empty strings.

The strings returned from this method are roughly equivalent to values of text fragment nodes in the W3C DOM, but IE5+ treats these data pieces as string data types rather than as text node types. W3C DOM equivalents for the four versions are

```
document.getElementById("objName").previousSibling.nodeValue
document.getElementById("objName").firstChild.nodeValue
document.getElementById("objName").lastChild.nodeValue
document.getElementById("objName").nextSibling.nodeValue
```

Example

Use The Evaluator (see Chapter 4) to examine all four adjacent text possibilities for the `myP` and nested `myEM` elements in that document. Enter each of the following statements in the top text box, and view the results:

```
document.getElementById("myP").getAdjacentText("beforeBegin")
document.getElementById("myP").getAdjacentText("afterBegin")
document.getElementById("myP").getAdjacentText("beforeEnd")
document.getElementById("myP").getAdjacentText("afterEnd")
```

The first and last statements return empty strings because the `myP` element has no text fragments surrounding it. The `afterBegin` version returns the text fragment of the `myP` element up to, but not including, the EM element nested inside. The `beforeEnd` string picks up after the end of the nested EM element and returns all text to the end of `myP`.

Now see what happens with the nested `myEM` element:

```
document.getElementById("myEM").getAdjacentText("beforeBegin")
document.getElementById("myEM").getAdjacentText("afterBegin")
document.getElementById("myEM").getAdjacentText("beforeEnd")
document.getElementById("myEM").getAdjacentText("afterEnd")
```

Because this element has no nested elements, the `afterBegin` and `beforeEnd` strings are identical — the same value as the `innerText` property of the element.

Related Items: `childNodes`, `data`, `firstChild`, `lastChild`, `nextSibling`, `nodeValue`, and `previousSibling` properties

getAttribute("*attributeName*"[, *caseSensitivity*])

Returns: (See text)

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `getAttribute()` method returns the value assigned to a specific attribute of the current object. You can use this method as an alternative to retrieving properties of an object, particularly when your

script presents you the attribute name as a string (in contrast to a fully formed reference to an object and its property). Thus, the following example statements yield the same data:

```
var mult = document.getElementById("mySelect").multiple;
var mult = document.getElementById("mySelect").getAttribute("multiple");
```

Returned value types from `getAttribute()` are either strings (including attribute values assigned as unquoted numeric values) or Booleans (for example, the `multiple` property of a `select` element object).

Note

The W3C DOM Level 2 standard recommends `getAttribute()` and `setAttribute()` for reading and writing element object attribute values, rather than reading and writing those values by way of their corresponding properties. Although using these methods is certainly advisable for XML elements, the same DOM standard sends conflicting signals by defining all kinds of properties for HTML element objects. Browsers, of course, will support access via properties well into the future, so don't feel obligated to change your ways just yet. ■

All browsers that support the `getAttribute()` method require one parameter, which is a string of the attribute name. By default, this parameter is not case sensitive. Note that this has impact on custom attributes that you might assign to HTML or XML elements in your documents. Attribute names are automatically converted to lowercase when they are turned into properties of the object. Therefore, you must avoid reusing attribute names, even if you use different case letters in the source-code assignments.

IE includes an optional extension to the method in the form of a second parameter that enables you to be more specific about the case sensitivity of the first parameter. The default value of the second parameter is `false`, which means that the first parameter is not case sensitive. A value of `true` makes the first parameter case sensitive. This matters only if you use `setAttribute()` to add a parameter to an existing object and if the IE version of that method insists on case sensitivity. The default behavior of `setAttribute()` respects the case of the attribute name. See also the discussion of the `setAttribute()` method later in this chapter with regard to `setAttribute()`'s influence on the IE `attributes` property.

Example

Use The Evaluator (see Chapter 4) to experiment with the `getAttribute()` method for the elements in the page. You can enter the following sample statements in the top text box to view attribute values:

```
document.getElementById("myTable").getAttribute("cellpadding")
document.getElementById("myTable").getAttribute("border")
```

Related Items: `attributes` property; `document.createAttribute()`, `setAttribute()` methods

getAttributeNode("*attributeName*")

Returns: Attribute node object

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

In the W3C DOM, an attribute is an object that inherits all the properties of a `Node` object (see Chapter 25). As its name implies, an attribute object represents a name-value pair of an attribute that

is explicitly defined inside an element's tag. The ability to treat attributes as node objects is far more important when working with XML than HTML, but it is helpful to understand attribute nodes within the context of the W3C DOM object-oriented view of a document. It is important that attribute nodes specifically are not recognized as nodes of a document hierarchy. Therefore, an attribute node is not a child node of the element that defines the attribute.

The nodeness of attributes comes into play when addressing the contents of an object's `attributes` property. The W3C `attributes` property builds on the DOM's formal structure by returning an object known (internally) as a *named node map*. Like an array, the named node map has a `length` property (facilitating `for` loop iteration through the map), plus several methods that allow for inserting, removing, reading, or writing attribute name-value pairs within the node map.

An attribute object inherits all the properties of the `Node` object. Table 26-10 lists the properties of an attribute object.

All of this is a long way to explain the W3C DOM `getAttributeNode()` method, which returns a W3C DOM attribute object. The sole parameter of the method is a case-insensitive string version of the attribute's name. Then you can use any of the properties shown in Table 26-10 to get or set attribute values. Of course, HTML attributes are generally exposed as properties of HTML elements, so it is usually easier to read or write the object's properties directly.

TABLE 26-10

Attribute Object Properties of W3C DOM–Compatible Browsers

`attributes`
`childNodes`
`firstChild`
`lastChild`
`name`
`nextSibling`
`nodeName`
`nodeType`
`nodeValue`
`ownerDocument`
`parentNode`
`previousSibling`
`specified`
`value`

Example

Use The Evaluator (see Chapter 4) to explore the `getAttributeNode()` method. The Results `textarea` element provides several attributes to check out. Because the method returns an object, enter the following statements in the bottom text box so you can view the properties of the attribute node object returned by the method:

```
document.getElementById("myTextArea").getAttributeNode("cols")
document.getElementById("myTextArea").getAttributeNode("rows")
document.getElementById("myTextArea").getAttributeNode("wrap")
document.getElementById("myTextArea").getAttributeNode("style")
```

All (except the last) statements display a list of properties for each attribute node object. The last statement, however, returns nothing because the `style` attribute is not specified for the element.

You can also use The Evaluator to explore the properties of the attribute object returned by the `getAttributeNode()` method. Enter the following statement in the top text box:

```
document.getElementById("myTextArea").getAttributeNode("cols").value
```

Related Items: `attributes` property; `getAttribute()`, `removeAttributeNode()`, `setAttributeNode()` methods

getAttributeNodeNS("*namespaceURI*", "*localName*")

Returns: Attribute node object

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+-, Opera+, Chrome_

This method returns a W3C DOM attribute object. The first parameter of the method is a URI string matching a URI assigned to a label in the document. The second parameter is the local name portion of the attribute you are getting.

Related Items: `attributes`, `namespaceURI`, `localName` properties; `getAttributeNode()`, `setAttributeNodeNS()` methods

getAttributeNS("*namespaceURI*", "*localName*")

Returns: (See text)

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+-, Opera+, Chrome+

This method returns the value assigned to a specific attribute of the current object when that attribute's name is defined by way of an XML namespace definition within the document. The first parameter of the method is a URI string matching a URI assigned to a namespace label in a tag defined earlier in the document. The second parameter is the local name portion of the attribute whose value you are getting.

Returned value types from `getAttributeNS()` are either strings (including attribute values assigned as unquoted numeric values) or Booleans (for example, the `multiple` property of a `select` element object). In the W3C DOM, Netscape, Safari, and Opera, return values are always strings.

Related Items: `attributes`, `namespaceURI`, `localName` properties; `getAttribute()`, `getAttributeNodeNS()`, `setAttributeNodeNS()` methods

getBoundingClientRect()
getClientRects()

Returns: `getBoundingClientRect()` returns a `TextRectangle` object; `getClientRects()` returns an array of `TextRectangle` objects

Compatibility: WinIE5+, MacIE-, NN-, Moz+-, Safari+-, Opera+, Chrome+

Original with IE5+, most modern browsers assign to every content-holding element a rectangle that describes the space that the element occupies on the page. This rectangle is called a *bounding rectangle,* and it is expressed as a TextRectangle object (even when the content is an image or some other kind of object). A `TextRectangle` object has four properties (`top`, `left`, `bottom`, and `right`) that are the pixel coordinates that define the rectangle. You can get the same information from older browsers that do not support the `TextRectangle` object with `offsetTop`, `offsetLeft`, `offsetHeight`, and `offsetWidth`. The `getBoundingClientRect()` method returns a `TextRectangle` object that describes the bounding rectangle of the current object. You can access an individual measure of an object's bounding rectangle, as in the following example:

```
var parTop = document.getElementById("myP").getBoundingClientRect().top;
```

For elements that consist of text, such as paragraphs, the dimensions of individual `TextRectangles` for each line of text in the element influence the dimensions of the bounding rectangle. For example, if a paragraph contains two lines, and the second line extends only halfway across the width of the first line, the width of the second line's `TextRectangle` object is only as wide as the actual text in the second line. But because the first line extends close to the right margin, the width of the encompassing bounding rectangle is governed by that wider, first line `TextRectangle`. Therefore, an element's bounding rectangle is as wide as its widest line and as tall as the sum of the height of all `TextRectangle` objects in the paragraph.

The method `getClientRects()` enables you to obtain a collection of line-by-line `TextRectangle` objects for an element. It returns an array of all `TextRectangle` objects that fall within the current object the moment the method is invoked. Each `TextRectangle` object has its own `top`, `left`, `bottom`, and `right` coordinate properties. You can then, for example, loop through all objects in this array to calculate the pixel width of each line. If you want to find out the aggregate height and/or maximum width of the entire collection, you can use the `getBoundingClientRect()` method as a shortcut.

The length of the collection returned by `getClientRects()` is where you'll see differences between the browsers. WebKit-based browsers and earlier releases of Mozilla-based browsers have only one `TextRectangle` object in the collection returned by `getClientRects()` for each block element found in the argument passed to it. IE and the most recent releases of Mozilla-based browsers will do the same only if a width is specified for a block element. Presto-based browsers always return a collection of one regardless of how many elements, block or not, are involved. All that we've said so far just pertains to an argument that is not identified by a block element (for example, the argument passed to `getClientRects()` in Listing 26-27a is a `span` element). If the argument is a block element (for example a `div`), then the only browser that returns a collection of `TextRectangle` objects for each line is IE. Obviously, this can be very frustrating for scripters. Keep this in mind when looking at Listings 26-27a and 26-27b in the various browsers.

Example

Listing 26-27a employs only the `getClientRects()` method. (We'll look at both methods in Listing 26-27b in a moment.) The element passed to the `getClientRects()` method is a `span` and it contains two paragraphs and an ordered list. The area contained by it is colored blue. There is a button that generates an alert about the length of the collection that is returned by the method.

LISTING 26-27a

Using getClientRects()

HTML: jsb26-27a.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>getClientRects() Method</title>
      <style type="text/css">
         #main
         {
            color:blue;
         }
      </style>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-27a.js"></script>
   </head>
   <body>
      <h1>getClientRects() Method</h1>
      <hr />
      <p>The area we're interested in is colored blue.</p>
      <form>
         <button onclick="howMany();">How many TextRectangle objects
                                   are in the collection?</button>
      </form>
      <span id="main">
         <p>Lorem ipsum dolor sit amet, consectetaur adipisicing

            er expedit distinct.
         </p>
      </span>
   </body>
</html>
```

JavaScript: jsb26-27a.js

```
function howMany()
{
   var clientRects = document.getElementById("main").getClientRects();
   alert("The length of the rectangle returned by getClientRects() is ="
         + clientRects.length + ".");
}
```

Listing 26-27b employs both the `getBoundingClientRect()` and `getClientRects()` methods in a demonstration of how they differ. While the listing works in all major browsers, due to the differences you've already since in the collection returned by the `getClientRects()` method, you'll only really see anything meaningful in IE, and you'll only really want to use it in IE anyway. Keep in mind, though, that you don't have to use the two methods together; there are many things you can do regardless of the browser with just the `getBoundingClientRect()` method.

As with Listing 26-27a, a set of elements is grouped within a `span` element named `main`. The group consists of two paragraphs and an unordered list, all of whose text is colored blue.

Two controls enable you to set the position of an underlying highlight rectangle to any line of your choice. A checkbox enables you to set whether the highlight rectangle should be only as wide as the line or the full width of the bounding rectangle for the entire `span` element.

All the code is located in the `hilite()` function. The `select` and checkbox elements invoke this function. Early in the function, the `getClientRects()` method is invoked for the `main` element to capture a snapshot of all `TextRectangle`s for the entire element. This array comes in handy when the script needs to get the coordinates of a rectangle for a single line, as chosen in the `select` element.

Whenever the user chooses a number from the `select` list, and the value is less than the total number of `TextRectangle` objects in `clientRects`, the function begins calculating the size and location of the underlying yellow highlighter. When the Full Width checkbox is checked, the left and right coordinates are obtained from the `getBoundingClientRect()` method because the entire `span` element's rectangle is the space you're interested in; otherwise, you pull the `left` and `right` properties from the chosen rectangle in the `clientRects` array.

Next comes the assignment of location and dimension values to the `hiliter` object's `style` property. The top and bottom are always pegged to whatever line is selected, so the `clientRects` array is polled for the chosen entry's `top` and `bottom` properties. The previously calculated `left` value is assigned to the `hiliter` object's `pixelLeft` property, whereas the width is calculated by subtracting the `left` from the `right` coordinates. Notice that the `top` and `left` coordinates also take into account any vertical or horizontal scrolling of the entire body of the document. If you resize the window smaller, line wrapping throws off the original line count. However, an invocation of `hilite()` from the `onresize` event handler applies the currently chosen line number to whatever content falls in that line after resizing.

Because the `z-index` style property of the `hiliter` element is set to `-1`, the element always appears beneath the primary content on the page. If the user selects a line number beyond the current number of lines in the main element, the `hiliter` element is hidden.

LISTING 26-27b

Using getBoundingClientRect()

HTML: jsb26-27b.html

```
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>getClientRects() and getBoundClientRect() Methods</title>
      <style type="text/css">
         #main

  }
```

Related Item: `TextRectangle` object (Chapter 33, on the CD-ROM)

getElementsByTagName("*tagName*")

Returns: Array of element objects

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `getElementsByTagName()` method returns an array of all elements contained by the current object whose tags match the tag name supplied as the sole parameter to the method. The tag name parameter must be in the form of a string and is case insensitive. The group of elements returned in the array includes only those elements that are within the containment scope of the current object. Therefore, if you have two table objects in a document, and you invoke the `getElementsByTagName("td")` method on one of them, the list of returned table cell elements is confined to those cells within the current table object. The current element is not included in the returned array.

For MacIE5, WinIE6+, and all other supporting browsers, the method accepts a wildcard character (`"*"`) for matching descendent elements regardless of tag name. The resulting array of elements is nearly identical to what IE4+ returns via the `document.all` collection.

Example

Use The Evaluator (see Chapter 4) to experiment with the `getElementsByTagName()` method. Enter the following statements one at a time in the top text box, and study the results:

```
document.body.getElementsByTagName("div")
document.body.getElementsByTagName("div").length
document.getElementById("myTable").getElementsByTagName("td").length
```

Because the `getElementsByTagName()` method returns an array of objects, you can use one of those returned values as a valid element reference:

```
document.getElementsByTagName("form")[0].getElementsByTagName("input").length
```

Related Items: `getElementByTagNameNS()`, `getElementById()`, `tags()` methods

getElementsByTagNameNS("*namespaceURI*", "*localName*")

Returns: Array of element objects

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

This method returns an array of all elements contained by the current object (within an XML document) as specified in the two parameters. The first parameter of the method is a URI string matching a URI assigned to a label in the document. The second parameter is the local name portion of the attribute whose value you are getting.

Returned value types from `getAttributeNS()` are either strings (including attribute values assigned as unquoted numeric values) or Booleans (for example, the `multiple` property of a `select` element object).

Related Items: `attributes`, `namespaceURI`, `localName` properties; `getElementsByTagNameNS()`, `getElementById()`, `tags()` methods

getExpression("*attributeName*")

Returns: String

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `getExpression()` method returns the text of the expression that was assigned to an element's attribute via the `setExpression()` method. The returned value is not the value of the expression, but the expression itself. If you want to find out the current value of the expression (assuming that the variables used are within the scope of your script), you can use the `eval()` function on the call to `getExpression()`. This action converts the string to a JavaScript expression and returns the evaluated result.

One parameter, a string version of the attribute name, is required.

Example

See Listing 26-32 for the `setExpression()` method. This listing demonstrates the kinds of values returned by `getExpression()`.

Related Items: `document.recalc()`, `removeExpression()`, `setExpression()` methods

getFeature("*feature*", "*version*")

Returns: Object

Compatibility: WinIE-, MacIE-, NN-, Moz1.7.2+, Safari-, Opera+, Chrome-

According to the W3C DOM specification, the `getFeature()` method accepts a scripting feature and version, and returns an object that implements the APIs for the feature. Examples of possible feature parameters to this method are `Core` and `Events`, which correspond to DOM modules.

As recently as Mozilla 1.8.1 (Firefox 2.0), the `getFeature()` method returns an object but the object exposes no API features to the script.

Related Item: `implementation.hasFeature()` method

getUserData("*key*")

Returns: Object

Compatibility: WinIE-, MacIE-, NN6-, Moz1.7.2+, Safari+-, Opera-, Chrome+

The `getUserData()` method enables you to access custom user data that has been associated with a node. A given node can have multiple objects of user data, in which case each one is identified

through a text key. This key is the parameter that you pass into `getUserData()` to obtain a user data object. As of Mozilla 1.8.1 (Firefox 2.0), the method is only partially implemented and, therefore, still not useful.

hasAttribute("*attributeName*")

Returns: Boolean

Compatibility: WinIE+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `hasAttribute()` method returns `true` if the current object has an attribute whose name matches the sole parameter; it returns `false` otherwise.

Related Items: `hasAttributeNS()`, `hasAttributes()` methods

hasAttributeNS("*namespaceURI*", "*localName*")

Returns: Boolean

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `hasAttributeNS()` method returns `true` if the current object has an attribute as identified by the two parameters; it returns `false` otherwise. The first parameter of the method is a URI string matching a URI assigned to a label in the document. The second parameter is the local name portion of the attribute whose value you are getting.

Related Items: `attributes`, `namespaceURI`, `localName` properties; `hasAttribute()`, `hasAttributes()` methods

hasAttributes()

Returns: Boolean

Compatibility: WinIE+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `hasAttributes()` method returns `true` if the current object has any attributes explicitly assigned within the tag; it returns `false` otherwise.

Related Items: `hasAttribute()`, `hasAttributeNS()` methods

hasChildNodes()

Returns: Boolean

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `hasChildNodes()` method returns `true` if the current object has child nodes nested within; it returns `false` otherwise. A child node is not necessarily the same as a child element, so the following two expressions return `true` when the current object has at least one child node:

```
document.getElementById("myObject").hasChildNodes()
document.getElementById("myObject").childNodes.length > 0
```

You cannot use the second expression interchangeably with the following statement (which uses the `children` property):

```
document.getElementById("myObject").children.length > 0
```

You generally use the `hasChildNodes()` method in a conditional expression to make sure such nodes exist before performing operations on them:

```
if (document.getElementById("myObject").hasChildNodes()
{
    // [statements that apply to child nodes]
}
```

Example

Use The Evaluator (see Chapter 4) to experiment with the `hasChildNodes()` method. If you enter the following statement in the top text box

```
document.getElementById("myP").hasChildNodes()
```

the returned value is `true`. You can find out how many nodes there are by getting the `length` of the `childNodes` array:

```
document.getElementById("myP").childNodes.length
```

This expression reveals a total of three nodes: the two text nodes and the `em` element between them. Check out whether the first text node has any children:

```
document.getElementById("myP").childNodes[0].hasChildNodes()
```

The response is `false` because text fragments do not have any nested nodes. But check out the `em` element, which is the second child node of the `myP` element:

```
document.getElementById("myP").childNodes[1].hasChildNodes()
```

The answer is `true` because the `em` element has a text fragment node nested within it. Sure enough, the statement

```
document.getElementById("myP").childNodes[1].childNodes.length
```

yields a node count of `1`. You can also go directly to the `em` element in your references:

```
document.getElementById("myEM").hasChildNodes()
document.getElementById("myEM").childNodes.length
```

If you want to see the properties of the text fragment node inside the `em` element, enter the following in the bottom text box:

```
document.getElementById("myEM").childNodes[0]
```

You can see that the `data` and `nodeValue` properties for the text fragment return the text `"all"`.

Related Items: `childNodes` property; `appendChild()`, `removeChild()`, `replaceChild()` methods.

`insertAdjacentElement("`*`location`*`", `*`elementObject`*`)`

Returns: Object

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari+, Opera+, Chrome+

The `insertAdjacentElement()` method inserts an element object (coming from a variety of sources) into a specific position relative to the current object. Both parameters are required. The first must be one of four possible case-insensitive locations for the insertion, shown in the following table:

Location	Description
`beforeBegin`	Before the current element's start tag
`afterBegin`	After the start tag but before any nested content
`beforeEnd`	Before the end tag but after all other nested content
`afterEnd`	After the end tag

These locations are relative to the current object. The element type of the current object (a block-level or inline element) has great bearing on how the inserted element is rendered. For example, suppose that you create a `b` element (using `document.createElement()`) and assign some inner text to it. You then use `insertAdjacentElement()` in an effort to insert this `b` element before some text in a `p` element. Because a `p` element is a block-level element, the location `beforeBegin` places the new `b` element before the start tag of the `p` element. This means, however, that the bold text appears in a text line above the start of the `p` element because a `<p>` tag begins a new block at the left margin of its container (unless instructed otherwise by style sheets). The resulting HTML looks like the following:

```
<b>The new element.</b><p>The original paragraph element.</p>
```

To make the new `b` element a part of the `p` element — but in front of the existing `p` element's content — use the `afterBegin` location. The resulting HTML looks like the following:

```
<p><b>The new element.</b>The original paragraph element.</p>
```

To complete the demonstration of the four location types, the following is the result of the `beforeEnd` location:

```
<p>The original paragraph element. <b>The new element.</b></p>
```

And this is the result of the `afterEnd` location:

```
<p>The original paragraph element.</p><b>The new element.</b>
```

The object to be inserted is a reference to an element object. The object reference can come from any expression that evaluates to an element object or, more likely, from the result of the `document.createElement()` method. Bear in mind that the object generated by `document.createElement()` initially has no content, and all attribute values are set to default values. Moreover, the object is passed to `insertAdjacentElement()` by reference, which means that there is only one instance of that object. If you attempt to insert that object in two places with two statements, the object is moved from the first location to the second. If you need to copy an existing object so that the original is not moved or otherwise disturbed by this method, use the `cloneNode()` method to specify the `true` parameter to capture all nested content of the node.

Example

Use The Evaluator (see Chapter 4) in WinIE5+ to experiment with the `insertAdjacentElement()` method. The goal of the experiment is to insert a new `h1` element above the `myP` element.

All actions require you to enter a sequence of statements in the top text box. Begin by storing a new element in the global variable `a`:

```
a = document.createElement("h1")
```

Give the new object some text:

```
a.innerText = "New Header"
```

Now insert this element before the start of the `myP` object:

```
myP.insertAdjacentElement("beforeBegin", a)
```

Notice that you have not assigned an `id` property value to the new element. But because the element was inserted by reference, you can modify the inserted object by changing the object stored in the `a` variable:

```
a.style.color = "red"
```

The inserted element is also part of the document hierarchy, so you can access it through hierarchy references such as `myP.previousSibling`.

The parent element of the newly inserted element is the `body`. Thus, you can inspect the current state of the HTML for the rendered page by entering the following statement in the top text box:

```
document.body.innerHTML
```

If you scroll down past the first form, you can find the `<h1>` element that you added along with the `style` attribute.

Related Items: `document.createElement()`, `applyElement()` methods

insertAdjacentHTML("*location*", "*HTMLtext*")
insertAdjacentText("*location*", "*text*")

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera+, Chrome+

These two methods insert HTML or straight text at a location relative to the current element. They are intended for use after a page loads, rather than inserting content while the page loads (in which case you can use `document.write()` wherever you need evaluated content to appear on the page).

The first parameter must be one of four possible case-insensitive locations for the insertion, shown in the following table:

Location	Description
`beforeBegin`	Before the current element's start tag
`afterBegin`	After the start tag but before any nested content
`beforeEnd`	Before the end tag but after all other nested content
`afterEnd`	After the end tag

These locations yield the same results as described in the `insertAdjacentElement()` function discussed earlier in this chapter.

Whether you use `insertAdjacentHTML()` or `insertAdjacentText()` depends on the nature of your content and what you want the browser to do with it. If the content contains HTML tags that you want the browser to interpret and render as though it were part of the page source code, use the `insertAdjacentHTML()` method. All tags become objects in the document's object model. But if you want only to display some text (including HTML tags in their raw form), use `insertAdjacentText()`. The rendering engine does not interpret any tags included in the string passed as the second parameter. Instead, these tags are displayed as characters on the page. This distinction is identical to the one between the `innerHTML` and `innerText` properties.

The difference between `insertAdjacentHTML()` and `insertAdjacentElement()` is the nature of the content that you insert. The former enables you to accumulate the HTML as a string, whereas the latter requires the creation of an element object. Also, the two methods in this section work with IE4+ (including Mac versions), whereas `insertAdjacentElement()` requires the newer object model of WinIE5+.

If the HTML you pass as the second parameter of `insertAdjacentHTML()` contains `<script>` tags, you must set the `defer` attribute in the opening tag. This prevents script statements from executing as you insert them.

Example

Use The Evaluator (see Chapter 4) to experiment with these two methods. The example here demonstrates the result of employing both methods in an attempt to add some HTML to the beginning of the `myP` element.

Begin by assigning a string of HTML code to the global variable `a`:

```
a = "<b id='myB'>Important News!</b>"
```

Because this HTML is to go on the same line as the start of the `myP` paragraph, use the `afterBegin` parameter for the insert method:

```
myP.insertAdjacentHTML("afterBegin", a)
```

Notice that there is no space after the exclamation mark of the inserted HTML. But to prove that the inserted HTML is genuinely part of the document's object model, now you can insert the text of a space after the `b` element whose ID is `myB`:

```
myB.insertAdjacentText("afterEnd", " ")
```

Each time you evaluate the preceding statement (by repeatedly clicking the Evaluate button or pressing Enter with the cursor in the top text box), another space is added.

You should also see what happens when the string to be inserted with `insertAdjacentText()` contains HTML tags. Reload The Evaluator, and enter the following two statements in the top text box, evaluating each one in turn:

```
a = "<b id='myB'>Important News!</b>"
myP.insertAdjacentText("afterBegin", a)
```

The HTML is not interpreted but is displayed as plain text. There is no object named `myB` after executing this latest insert method.

Related Items: `innerText`, `innerHTML`, `outerText`, `outerHTML` properties; `insertAdjacentElement()`, `replaceAdjacentText()` methods

insertBefore(*newChildNodeObject, referenceChildNode*)

Returns: `Node` object

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `insertBefore()` method is the W3C DOM syntax for inserting a new child node into an existing element. Node references for both parameters must be valid `Node` objects (including those that `document.createElement()` generates).

The behavior of this method might seem counterintuitive at times. If you include the second parameter (a reference to an existing child node of the current element — optional in IE), the new child node is inserted before that existing one. But if you omit the second parameter (or its value is `null`), the new child node is inserted as the last child of the current element — in which case the method acts the same as the `appendChild()` method. The true power of this method is summoned when you specify that second parameter; from the point of view of a parent element, you can drop a new child into any spot among its existing children. If an inserted node already exists in the document tree, it will be removed from its previous position.

Bear in mind that the `insertBefore()` method works from a parent element. Internet Explorer provides additional methods, such as `insertAdjacentElement()`, to operate from the perspective of what will become a child element.

Example

Listing 26-28 demonstrates how the `insertBefore()` method can insert child elements (`li`) inside a parent (`ol`) at different locations, depending on the second parameter. A text box enables you to enter your choice of text and/or HTML for insertion at various locations within the `ol` element. If you don't specify a position, the second parameter of `insertBefore()` is passed as `null` — meaning that the new child node is added to the end of the existing children. But choose a spot from the select

list where you want to insert the new item. The value of each `select` list option is an index of one of the first three child nodes of the `ol` element.

LISTING 26-28

Using the insertBefore() Method

HTML: jsb26-28.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>insertBefore() Method</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb26-28.js"></script>
   </head>
   <body>
      <h1>insertBefore() Method</h1>
      <hr />
      <form onsubmit="return false">
         <p>Enter text or HTML for a new list item:
            <input type="text"
                   name="newText" size="40" value="" />
         </p>
         <p>Before which existing item?
            <select name="itemIndex">
               <option value="null">None specified</option>
               <option value="0">1</option>
               <option value="1">2</option>
               <option value="2">3</option>
            </select>
         </p>
         <input type="button" value="Insert Item"
                onclick="doInsert(this.form)" />
      </form>
      <ol id="myUL">
         <li>Originally the First Item</li>
         <li>Originally the Second Item</li>
         <li>Originally the Third Item</li>
      </ol>
   </body>
</html>
```

JavaScript: jsb26-28.js

```
function doInsert(form)
{
   if (form.newText)
   {
      var newChild = document.createElement("LI");
      newChild.innerHTML = form.newText.value;
```

```
        var choice = form.itemIndex.options[form.itemIndex.selectedIndex].value;
        var insertPoint = (isNaN(choice)) ?
           null : document.getElementById("myUL").childNodes[choice];
        document.getElementById("myUL").insertBefore(newChild, insertPoint);
    }
}
```

Related Items: `appendChild()`, `replaceChild()`, `removeChild()`, `insertAdjacentElement()` methods

`isDefaultNamespace("`*`namespaceURI`*`")`

Returns: Boolean

Compatibility: WinIE-, MacIE-, NN6-, Moz1.7.2+, Safari+, Opera+, Chrome+

This method checks whether the specified namespace matches the default namespace of the current node.

`isEqualNode(`*`nodeRef`*`)`
`isSameNode(`*`nodeRef`*`)`

Returns: Integer ID

Compatibility: WinIE-, MacIE-, NN-, Moz1.7.2+, Safari+, Opera+, Chrome+

When it comes to nodes, there is a distinct difference between a node being equal to another node and a node being the same as another node. Equality has a very specific meaning with respect to nodes: Two nodes are considered equal if they have the same values for the `attributes`, `childNodes`, `localname`, `namespaceURI`, `nodeName`, `nodeType`, `nodeValue`, and `prefix` properties. Together, these properties essentially reflect the content of a node. What they don't reflect is the relative position of a node within a document, which means that nodes can be equal and reside in different locations in the node tree. Two nodes are considered the same if ... well, they are the same identical node. The `isEqualNode()` method checks for node equality, whereas `isSameNode()` checks whether two nodes are the same. Both methods expect a node reference as their only parameter. Currently, Opera does not support the `isEqualNode()` method.

`isSupported("`*`feature`*`", "`*`version`*`")`

Returns: Boolean

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `isSupported()` method returns `true` if the current node supports required portions of the specified W3C DOM module and version; it returns `false` otherwise. The first parameter accepts any of the following case-sensitive DOM module name strings: `Core`, `XML`, `HTML`, `Views`, `StyleSheets`, `CSS`, `CSS2`, `Events`, `UIEvents`, `MouseEvents`, `MutationEvents`, `HTMLEvents`, `Range`, and `Traversal`. The second parameter accepts a string representation of the major and minor DOM module version, such as `"2.0"` for DOM Level 2.

Example

Use The Evaluator (see Chapter 4) to experiment with the `isSupported()` method. If you have multiple versions of NN6 or later and Mozilla, try the following (and others) to see how the support for various modules has evolved:

```
document.body.isSupported("CSS", "2.0")
document.body.isSupported("CSS2", "2.0")
document.body.isSupported("Traversal", "2.0")
```

If you have access to Safari, Opera, or Chrome, try the same methods there to see the differences in modules supported compared with Mozilla-based browsers.

item(*index* | "*index*" [, *subIndex*])

Returns: Object

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `item()` method works with most objects that are themselves collections of other objects. In W3C DOM terminology, these kinds of objects are known as *named node lists* (for objects such as nodes and attributes) or *HTML collections* (for objects such as elements of a form). You may call the `item()` method with a single numeric parameter that is the index value of the desired object within the collection. If you know the index number of the item, you can use JavaScript array syntax instead. The following two statements return the same object reference:

```
document.getElementById("myTable").childNodes.item(2)
document.getElementById("myTable").childNodes[2]
```

The method also supports a string of the ID of an object within the collection. (Integer values are required for the `attributes`, `rules`, and `TextRectangle` objects, however.) Additionally, if the collection has more than one object with the same ID (never a good idea except when necessary), a second numeric parameter enables you to select which identically named group you want (using zero-based index values within that subgroup). This obviously does not apply to collections, such as attributes and rules, which have no ID associated with them.

The method returns a reference to the object specified by the parameters.

Example

Use The Evaluator (see Chapter 4) to experiment with the `item()` method. Type the following statements in the top text box, and view the results for each.

W3C and IE5:

```
document.getElementById("myP").childNodes.length
document.getElementById("myP").childNodes.item(0).data
document.getElementById("myP").childNodes.item(1).nodeName
```

W3C, IE4, and IE5:

```
document.forms[1].elements.item(0).type
```

The first approach is helpful when your script is working with a string version of an object's name. If your script already knows the object reference, the second approach is more efficient and compact.

Related Items: All object element properties that return collections (arrays) of other objects

lookupNamespaceURI("*prefix*")
lookupPrefix("*namespaceURI*")

Returns: Namespace or prefix string (see description)

Compatibility: WinIE-, MacIE-, NN-, Moz1.7.2+, Safari+, Opera+, Chrome+

These two methods use one piece of information to look up the other. The `lookupNamespaceURI()` method accepts a prefix as its only parameter and returns a URI string for the node if the prefix matches a previously defined namespace. Operating in the reverse, the `lookupPrefix()` method accepts a namespace URI string and returns a prefix string for the node if the namespace parameter matches a previously defined namespace.

mergeAttributes("*sourceObject*")

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `mergeAttributes()` method is a convenient way to propagate attributes in newly created elements without painstakingly adding attributes one at a time. When you have an object whose attributes can function as a prototype for other elements, those attributes (except for the `id` attribute) can be applied to a newly created element instantaneously. The default action of this method is not to duplicate the `id` or `name` attributes of the element. However, IE5.5+ introduced an extra Boolean parameter, `preserveIDs`, that enables you to duplicate these two attributes by setting the parameter to `false` (`true` is the default).

Example

Listing 26-29 demonstrates the usage of `mergeAttributes()` in the process of replicating the same form input field while assigning a unique ID to each new field. So that you can see the results as you go, we display the HTML for each input field in the field.

The `doMerge()` function begins by generating two new elements: a `p` element and an `input` element. Because these newly created elements have no properties associated with them, a unique ID is assigned to the `input` element through the `uniqueID` property. Attributes from the field in the source code (`field1`) are merged into the new `input` element. Thus, all attributes except `name` and `id` are copied to the new element. The `input` element is inserted into the `p` element, and the `p` element is appended to the document's form element. Finally, the `outerHTML` of the new element is displayed in its field. Notice that except for the `name` and `id` attributes, all others are copied. This includes style sheet attributes and event handlers. To prove that the event handler works in the new elements, you can add a space to any one of them and press Tab to trigger the `onchange` event handler that changes the content to all-uppercase characters.

LISTING 26-29

Using the mergeAttributes() Method

normalize()

Returns: Nothing

Compatibility: WinIE6+, MacIE5+, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

In the course of appending, inserting, removing, and replacing child nodes of an element, it is conceivable that two text nodes can end up adjacent to each other. Although this typically has no effect on the rendering of the content, some XML-centric applications that rely heavily on the document node hierarchy to interpret content properly may not like having two text nodes sitting next to each other. The proper form of a node hierarchy is for a single text node to be bounded by other node types. The `normalize()` method sweeps through the child nodes of the current node object and combines adjacent text nodes into a single text node. The effect obviously impacts the number of child nodes of an element, but it also cleanses the nested node hierarchy.

Example

Use The Evaluator (see Chapter 4) to experiment with the `normalize()` method. The following sequence adds a text node adjacent to one in the `myP` element. A subsequent invocation of the `normalize()` method removes the division between the adjacent text nodes.

Begin by confirming the number of child nodes of the `myP` element:

```
document.getElementById("myP").childNodes.length
```

Three nodes initially inhabit the element. Next, create a text node, and append it as the last child of the `myP` element:

```
a = document.createTextNode("This means you!")
document.getElementById("myP").appendChild(a)
```

With the new text now rendered on the page, the number of child nodes increases to four:

```
document.getElementById("myP").childNodes.length
```

You can see that the last child node of `myP` is the text node you just created:

```
document.getElementById("myP").lastChild.nodeValue
```

But by invoking `normalize()` on `myP`, all adjacent text nodes are accumulated into single nodes:

```
document.getElementById("myP").normalize()
```

You can see that the `myP` element is back to three child nodes, and the last child is a combination of the two previously distinct, but adjacent, text nodes:

```
document.getElementById("myP").childNodes.length
document.getElementById("myP").lastChild.nodeValue
```

Related Items: `document.createTextNode()`, `appendChild()`, `insertBefore()`, `removeChild()`, `replaceChild()` methods

releaseCapture()
setCapture(containerBoolean)

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

You can instruct a single object on a page to capture all mouse events (`onmousedown`, `onmouseup`, `onmousemove`, `onmouseout`, `onmouseover`, `onclick`, and `ondblclick`) via the WinIE-specific `setCapture()` method. A primary scenario for mouse event capture is when some content appears on the page that you wish to leave as the center of user focus — items such as pull-down menus, context menus, or simulated modal window areas. When such items appear onscreen, you want the effect of blocking all mouse events except those that apply to the menu or currently visible pseudowindow. When the region disappears, mouse events can be released so that individual elements (such as buttons and links elsewhere on the page) respond to mouse events.

Event capture does not block the events. Instead, the events are redirected to the object set to capture all mouse events. Events bubble up from that point unless explicitly canceled (see Chapter 32). For example, consider a document that has a `<body>` tag containing an `onclick` event handler that governs the entire document at all times. If you turn on event capture for a `div` somewhere in the document, the click event first goes to the `div`. That `div` might have an `onclick` event handler that looks to process click events when they occur in some of its child elements. If the event handler for the `div` does not also cancel the bubbling of that click event, the `body` element's `onclick` event handler eventually receives and processes the event, even though the `div` initially captured the event.

Deciding which object should capture events is an important design issue to confront. With event capture engaged, all mouse events (no matter where they occur) get funneled to the object set to capture the events. Therefore, if you design an application whose entire interface consists of clicking and dragging positionable elements, you can set one of those elements (or even the `document` object) to perform the capturing. For pop-up regions, however, it is generally more logical and convenient for your coding to assign the capture mechanism to the primary container of the pop-up content (usually, a positioned `div`).

The `setCapture()` method has one optional Boolean parameter. The parameter controls whether mouse events on child elements within the capturing object are under control of the event capture mechanism. The default value (`true`) means that all mouse events targeted at elements within the current object go to the current object rather than to the original target — the most likely way you will use `setCapture()` for things such as pop-up and context menus. But if you specify `false` as the parameter, mouse events occurring in child elements of the capturing container receive their events directly. From there, regular event bubbling upward from the target ensues (see Chapter 32).

You may encounter odd behavior when the region you set up to capture mouse events contains form elements such as text input fields and `select` lists. Because these elements require mouse events to gain focus for interaction, the event capture mechanism inhibits access to these items. To work around this behavior, you can examine the click event's `srcElement` property to see whether the click was on one of these elements and script the focus of that element (or instruct the user to press the Tab key until the element gets focus manually).

After an object is set to capture events, your other code must define which events actually do something and decide whether events should bubble up beyond the capturing element. You need to worry about bubbling only if your design includes mouse event handlers in elements higher up the element containment hierarchy. You may not want those event handlers to fire while event capture is on; in this case, you need to cancel the bubbling of those events in the capturing object.

If your application design requires that the pop-up area be hidden and event handling be returned to normal (such as after the user makes a pop-up menu selection), use the `releaseCapture()` method

in conjunction with hiding the container. Because event capture can be engaged for only one element at a time, you can release capture by invoking the `releaseCapture()` method from the container or from the `document` object.

Event capture is automatically disengaged when the user performs any of the following actions:

- Gives focus to any other window
- Displays any system modal dialog window (for example, alert window)
- Scrolls the page
- Opens a browser context menu (by right-clicking)
- Tabs to give focus to the Address field in the browser window

Therefore, you may want to set the `document` object's `onlosecapture` event handler to hide any container that your script displays in concert with event capture.

Also be aware that even though mouse events may be captured to prevent mouse access to the rest of the page, keyboard events are not captured. Thus, using the event capture mechanism to simulate modal windows is not foolproof: A user can tab to any form element or link in the page and press the spacebar or Enter key to activate that element.

Event capture, as defined in the W3C DOM, operates differently from WinIE event capture. In the W3C DOM, you can instruct the browser to substitute event capture of any kind of event for the normal event bubbling behavior. For example, you can attach an event listener to the `body` element in such a way that it sees all click events aimed at elements contained by the `body` element before the events reach their target elements. (See Chapter 25 and Chapter 32, for more on the W3C DOM event model and how to integrate it into cross-browser applications.)

Example

Listing 26-30 demonstrates the usage of `setCapture()` and `releaseCapture()` in a quick-and-dirty context menu for WinIE5+. The job of the context menu is to present a list of numbering styles for the ordered list of items on the page. Whenever the user brings up the context menu atop the `ol` element, the custom context menu appears. Event capture is turned on in the process to prevent mouse actions elsewhere on the page from interrupting the context menu choice. Even a click of the link set up as the title of the list is inhibited while the context menu is visible. A click anywhere outside the context menu hides the menu. Clicking a choice in the menu changes the `listStyleType` property of the `ol` object and hides the menu. Whenever the context menu is hidden, event capture is turned off so that clicking the page (such as the link) works as normal.

For this design, `onclick`, `onmouseover`, and `onmouseout` event handlers are assigned to the `div` element that contains the context menu. To trigger the display of the context menu, the `ol` element has an `oncontextmenu` event handler. This handler invokes the `showContextMenu()` function. In this function, event capture is assigned to the context menu `div` object. The `div` is also positioned at the location of the click before it is set to be visible. To prevent the system's regular context menu from also appearing, the `event` object's `returnValue` property is set to `false`.

Now that all mouse events on the page go through the `contextMenu div` object, let's examine what happens with different kinds of events triggered by user action. As the user rolls the mouse, a flood of `mouseover` and `mouseout` events fires. The event handlers assigned to the `div` manage these events. But notice that the two event handlers, `highlight()` and `unhighlight()`, perform action only when the `srcElement` property of the event is one of the menu items in the `div`. Because the page has no other `onmouseover` or `onmouseout` event handlers defined for elements up the containment hierarchy, you do not have to cancel event bubbling for these events.

When a user clicks the mouse button, different things happen, depending on whether event capture is enabled. Without event capture, the `click` event bubbles up from wherever it occurred to the `onclick` event handler in the `body` element. (An alert dialog box displays to let you know when the event reaches the `body`.) But with event capture turned on (the context menu is showing), the `handleClick()` event handler takes over to apply the desired choice whenever the click is atop one of the context menu items. For all `click` events handled by this function, the context menu is hidden, and the `click` event is canceled from bubbling up any higher (no alert dialog box appears). This takes place whether the user makes a choice in the context menu or clicks anywhere else on the page. In the latter case, all you need is for the context menu to go away as the real context menu does. For added insurance, the `onlosecapture` event handler hides the context menu when a user performs any of the actions just listed that cancel capture.

LISTING 26-30

Using setCapture() and releaseCapture()

removeAttribute("*attributeName*"[, *caseSensitivity*])

Returns: Boolean (IE), nothing (NN/DOM)

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

If you create an attribute with the `setAttribute()` method, you can eliminate that attribute from the element object via the `removeAttribute()` method. The required parameter is the name of the attribute. Internet Explorer permits you to set and remove attributes such that the attribute names are case sensitive. The default behavior of `removeAttribute()` in IE (the second parameter is a Boolean value) is `false`. Therefore, if you supply a value of `true` for the case-sensitivity parameter in `setAttribute()`, you should set the parameter to `true` in `removeAttribute()` to ensure a proper balance between created and removed attributes.

The W3C DOM (NN/Moz-/WebKit-based) version of the `removeAttribute()` method has a single parameter (a case-insensitive attribute name) and returns no value. The returned value in IE is `true`

if the removal succeeds and `false` if it doesn't succeed (or if the attribute is one that you set in some other manner).

Example

Use The Evaluator (see Chapter 4) to experiment with the `removeAttribute()` method for the elements in the page. See the examples for the `setAttribute()` method later in this chapter, and enter the corresponding `removeAttribute()` statements in the top text box. Interlace statements using `getAttribute()` to verify the presence or absence of each attribute.

Related Items: `attributes` property; `document.createAttribute()`, `getAttribute()`, `setAttribute()` methods

removeAttributeNode(*attributeNode*)
setAttributeNode(*attributeNode*)

Returns: `Attribute` object

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

As discussed in the coverage of the `getAttributeNode()` method earlier in this chapter, the W3C DOM treats a name–value attribute pair as an attribute object. An attribute object is a distinct node within a named node map — a collection of attribute objects belonging to an element. Understanding named node maps and attribute objects is more useful in an XML environment, where attributes can not only contain valuable data, but also are not exposed to the DOM as properties you can access via script. Instead of accessing an object's properties, you work with the actual attributes.

If you want to insert an attribute in the formal W3C methodology, you can use `document.createAttribute()` to generate a new attribute object. Subsequent script statements assign values to the `nodeName` and `nodeValue` properties to give the attribute its traditional name–value pair. You can then insert that new attribute object into the attribute list of an object via the `setAttributeNode()` method. The sole parameter is an attribute object, and the return value is a reference to the newly inserted attribute object.

To remove an attribute node from an element using this syntax, employ the `removeAttributeNode()` method. Again, the sole parameter is an attribute object. If your script knows only the attribute's name, you can use `getAttributeNode()` to obtain a valid reference to the attribute object. The `removeAttributeNode()` method returns a reference to the removed attribute object. That object remains in the browser's memory, but it is not part of the document hierarchy. By capturing this removed attribute object in a variable, you have the flexibility to modify and assign it to another object elsewhere in the document.

In practice, you may rarely, if ever, need to address attributes as nodes. Other methods — notably `getAttribute()`, `removeAttribute()`, and `setAttribute()` — do the job when your scripts have only the name (as a string) of an attribute belonging to an element.

Example

Use The Evaluator (see Chapter 4) to experiment with the `setAttributeNode()` and `removeAttributeNode()` methods for the `p` element in the page. The task is to create and add a `style` attribute to the `p` element. Begin by creating a new attribute and storing it temporarily in the global variable `a`:

```
a = document.createAttribute("style")
```

Assign a value to the `attribute` object:

```
a.nodeValue = "color:red"
```

Now insert the new attribute into the `p` element:

```
document.getElementById("myP").setAttributeNode(a)
```

The paragraph changes color in response to the newly added attribute.

Due to the NN6 bug that won't allow the method to return a reference to the newly inserted attribute node, you can artificially obtain such a reference:

```
b = document.getElementById("myP").getAttributeNode("style")
```

Finally, use the reference to the newly added attribute to remove it from the element:

```
document.getElementById("myP").removeAttributeNode(b)
```

Upon the removal of the attribute, the paragraph resumes its initial color. See the example for the `setAttribute()` method later in this chapter to discover how you can perform this same kind of operation with `setAttribute()`.

Related Items: `attributes` property; `document.createAttribute()`, `getAttribute()`, `getAttributeNode()`, `setAttribute()` methods

removeAttributeNS("*namespaceURI*", "*localName*")

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

This method removes the attribute specified in the two parameters. The first parameter of the method is a URI string matching a URI assigned to a label in the document. The second parameter is the local name portion of the attribute whose value you are removing.

Related Items: `attributes`, `namespaceURI`, `localName` properties; `removeAttribute()`, `getAttributeNS()`, `setAttributeNS()` methods

removeBehavior(*ID*)

Returns: Boolean

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `removeBehavior()` method detaches a behavior from an object. It assumes that the behavior was added to the object via the `addBehavior()` method. The return value of the `addBehavior()` method is a unique identifier for that particular behavior. This identifier is the required parameter for the `removeBehavior()` method. Thus, you can add two behaviors to an object and remove just one of them if you so desire. If the removal succeeds, the `removeBehavior()` method returns `true`; otherwise, it returns `false`.

Example

See Listing 26-19a and Listing 26-19b earlier in this chapter for examples of how to use `addBehavior()` and `removeBehavior()`.

Related Item: `addBehavior()` method

`removeChild(nodeObject)`

Returns: `Node` object reference

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `removeChild()` method erases a child element from the current element. Content associated with the child element is no longer visible on the page, and the object is no longer part of the document object hierarchy.

As destructive as that sounds, the specifications for the deleted object are not necessarily lost to the ether. The `removeChild()` method returns a reference to the removed node. By assigning this value to a variable, you can hold on to that object specification for insertion later in the session. You are free to use this value as a parameter to such methods as `appendChild()`, `replaceChild()`, `swapNode()`, and `insertBefore()`.

Remember that `removeChild()` is invoked from the point of view of a parent element. If you simply want to remove an element, you can do so more directly (in WinIE5+ only) with the `removeNode()` method. The IE `removeNode()` method also allows a node to remove itself, which isn't possible via the `removeChild()` method.

Example

You can see an example of `removeChild()` as part of Listing 26-21 earlier in this chapter.

Related Items: `appendChild()`, `replaceChild()`, `removeNode()` methods

`removeEventListener()`

(See `addEventListener()`)

`removeExpression("propertyName")`

Returns: Boolean

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

If you assign an expression to an object property (including an object's `style` object) via the `setExpression()` method, you can remove it under script control with the `removeExpression()` method. The sole parameter is the name of the property in string form. Property names are case sensitive.

The method returns `true` if the removal succeeds; otherwise, `false` is returned. Be aware that removing an expression does not alter the value that is currently assigned to the property. In other words, you can use `setExpression()` to set a property's value and then remove the expression so that no further changes are made when the document recalculates expressions. If this is your goal, however, you are probably better served by simply setting the property directly via scripting.

Example

You can experiment with all three expression methods in The Evaluator (Chapter 4). The following sequence adds an expression to a style sheet property of the `myP` element on the page and then removes it.

To begin, enter the number 24 in the bottom one-line text box in The Evaluator (but don't press Enter or click the List Properties button). This is the value used in the expression to govern the `fontSize` property of the `myP` object. Next, assign an expression to the `myP` object's `style` object by entering the following statement in the top text box:

```
myP.style.setExpression("fontSize","document.forms[0].↩
inspector.value","JScript")
```

Now you can enter different font sizes in the bottom text box and have the values immediately applied to the `fontSize` property. (Keyboard events in the text box automatically trigger the recalculation.) The default unit is `px`, but you can also append other units (such as `pt`) to the value in the text box to see how different measurement units influence the same numeric value.

Before proceeding to the next step, enter a value other than 16 (the default `fontSize` value). Finally, enter the following statement in the top text box to disconnect the expression from the property:

```
myP.style.removeExpression("fontSize")
```

Notice that although you can no longer adjust the font size from the bottom text box, the most recent value assigned to it sticks to the element. To prove it, enter the following statement in the top text box to see the current value:

```
myP.style.fontSize
```

Related Items: `document.recalc()`, `getExpression()`, `setExpression()` methods

`removeNode(`*`removeChildrenFlag`*`)`

Returns: `Node` object reference

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

You can use the `removeNode()` method to delete the current node from an element hierarchy in WinIE5+. The sole parameter is a Boolean value that directs the method to remove only itself (without its child nodes) or the node and all of its children (value of `true`). The method returns a reference to the node object removed. This removed object is no longer accessible to the DOM. But the returned value contains all properties of the object as it existed before you removed it (including properties such as `outerHTML` and explicitly set style sheet rules). Thus, you can use this value as a parameter to insert the node elsewhere in the document.

Although the W3C DOM does not have a `removeNode()` method, the cross-browser method whose behavior most closely resembles `removeNode()` is the `removeChild()` method. The scope of the `removeChild()` method is one level up the object hierarchy from the object you use for the `removeNode()` method.

Example

Examine Listing 26-21 for the `appendChild()` method to understand the difference between `removeChild()` and `removeNode()`. In the `restore()` function, you can replace this statement

```
mainObj.removeChild(oneChild);
```

in IE5+ with

```
oneChild.removeNode(true);
```

The difference is subtle, but it is important to understand. See Listing 26-31 later in this chapter for another example of the `removeNode()` method.

Related Items: `Node` object; `appendChild()`, `cloneChild()`, `removeChild()`, `replaceChild()`, `replaceNode()` methods

`replaceAdjacentText("location", "text")`

Returns: String

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `replaceAdjacentText()` method enables you to replace one chunk of document text with another in a specific position relative to the current object. Be aware that this method works only for plain text and not HTML tags. The returned value is the string of the text that you replace.

Both parameters are required. The first must be one of four possible case-insensitive locations for the insertion, shown in the following table:

Location	Description
`beforeBegin`	Before the current element's start tag
`afterBegin`	After the start tag but before any nested content
`beforeEnd`	Before the end tag but after all other nested content
`afterEnd`	After the end tag

This method is best used with inline (rather than block) elements when specifying the `beforeBegin` and `afterEnd` parameters. For example, if you attempt to use `replaceAdjacentText()` with `beforeBegin` on the second of two consecutive paragraph elements, the replacement text is inserted into the end of the first paragraph. You can think of the `replaceAdjacentText()` method in terms of text fragment nodes. The method replaces the text fragment node (given any one of the four position parameters) with new text. Replacing the text of a simple element with either the `afterBegin` or `beforeEnd` locations is the same as assigning that text to the object's `innerText` property.

Example

Use The Evaluator (see Chapter 4) to experiment with the `replaceAdjacentText()` method. Enter each of the following statements in the top text box, and watch the results in the `myP` element (and its nested `myEM` element) below the solid rule:

```
document.getElementById("myEM").replaceAdjacentText("afterBegin", "twenty")
```

Notice that the `myEM` element's new text picks up the behavior of the element. In the meantime, the replaced text (`all`) is returned by the method and displayed in the Results box:

```
document.getElementById("myEM").replaceAdjacentText("beforeBegin", "We need")
```

All characters of the text fragment, including spaces, are replaced. Therefore, you may need to supply a trailing space, as shown here, if the fragment you replace has a space:

```
document.getElementById("myP").replaceAdjacentText("beforeEnd", "good people.")
```

This is another way to replace the text fragment following the `myEM` element, but it is also relative to the surrounding `myP` element. If you now attempt to replace text after the end of the `myP` block-level element

```
document.getElementById("myP").replaceAdjacentText("afterEnd", "Hooray!")
```

the text fragment is inserted after the end of the `myP` element's tag set. The fragment is just kind of floating in the DOM as an unlabeled text node.

Related Items: `innerText`, `outerText` properties; `getAdjacentText()`, `insertAdjacentHTML()`, `insertAdjacentText()` methods

`replaceChild(`*`newNodeObject, oldNodeObject`*`)`

Returns: `Node` object reference

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `replaceChild()` method enables you to swap an existing child node object for a new node object. Parameters for the `replaceChild()` method are node object references, and they must be in the order of the new object followed by the object you want to replace. The old object must be an immediate child node of the parent used to invoke the method, and the new object must also be a legal child element within the document containment hierarchy.

The method returns a reference to the child object that you replaced with the new object. This reference can be used as a parameter to any of the node-oriented insertion or replacement methods.

Remember that `replaceChild()` is invoked from the point of view of a parent element. If you simply want to change an element, you can do so more directly in WinIE5+ with the `swapNode()` or `replaceNode()` method.

Example

You can see an example of `replaceChild()` as part of Listing 26-21 (for the `appendChild` property) earlier in this chapter.

Related Items: `appendChild()`, `removeChild()`, `replaceNode()`, `swapNode()` methods

`replaceNode("`*`newNodeObject`*`")`

Returns: `Node` object reference

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `replaceNode()` method is related to the `replaceChild()` method, but you invoke this method on the actual node you want to replace (instead of the object's parent). The sole parameter is a reference to a valid node object, which you can generate via the `document.createElement()` method or copy from an existing node. The value returned from the method is a reference to the

object that you replace. Thus, you can preserve a copy of the replaced node by storing the results in a variable for use later.

If the node you replace contains other nodes, the `replaceNode()` method removes all contained nodes of the original from the document. Therefore, if you want to change a wrapper node but want to maintain the original children, your script must capture the children and put them back into the new node as shown in the following example.

Example

Listing 26-31 demonstrates three node-related methods: `removeNode()`, `replaceNode()`, and `swapNode()`. These methods work in WinIE5+ only.

The page rendered from Listing 26-31 begins with a `ul` type list of four items. Four buttons control various aspects of the node structure of this list element. The first button invokes the `replace()` function, which changes the `ul` type to `ol`. To do this, the function must temporarily tuck away all child nodes of the original `ul` element so that they can be added back into the new `ol` element. At the same time, the old `ul` node is stored in a global variable (`oldNode`) for restoration in another function.

To replace the `ul` node with an `ol`, the `replace()` function creates a new, empty `ol` element and assigns the `myOL` ID to it. Next, the children (`li` elements) are stored en masse as an array in the variable innards. The child nodes are then inserted into the empty `ol` element, using the `insert-Before()` method. Notice that as each child element from the `innards` array is inserted into the `ol` element, the child element is removed from the `innards` array. That's why the loop to insert the child nodes is a `while` loop that constantly inserts the first item of the `innards` array to the new element. Finally, the `replaceNode()` method puts the new node in the old node's place, and the old node (just the `ul` element) is stored in `oldNode`.

The `restore()` function operates in the inverse direction of the `replace()` function. The same juggling of nested child nodes is required.

The third button invokes the `swap()` function, whose script exchanges the first and last nodes. The `swapNode()` method, like the others in this discussion, operates from the point of view of the node. Therefore, the method is attached to one of the swapped nodes, and the other node is specified as a parameter. Because of the nature of the `ol` element, the number sequence remains fixed, but the text of the `li` node swaps.

To demonstrate the `removeNode()` method, the fourth function removes the last child node of the list. Each call to `removeNode()` passes the `true` parameter to guarantee that the text nodes nested inside each `li` node are also removed. Experiment with this method by setting the parameter to `false` (the default). Notice how the parent-child relationship changes when you remove the `li` node.

```

JavaScript: jsb26-31.js

```
// store original node between changes
var oldNode;

// replace UL node with OL
function replace()
{
   if (document.getElementById("myUL"))
   {
      var newNode = document.createElement("OL");
      newNode.id = "myOL";
      var innards = document.getElementById("myUL").children;
      while (innards.length > 0)
      {
         newNode.insertBefore(innards[0]);
      }
      oldNode = document.getElementById("myUL").replaceNode(newNode);
   }
}

// restore OL to UL
function restore()
{
```

```
    if (document.getElementById("myOL") && oldNode)
    {
       var innards = document.getElementById("myOL").children;
       while (innards.length > 0)
       {
          oldNode.insertBefore(innards[0]);
       }
       document.getElementById("myOL").replaceNode(oldNode);
    }
 }

 // swap first and last nodes
 function swap()
 {
    if (document.getElementById("myUL"))
    {
       document.getElementById("myUL").firstChild.swapNode(
          document.getElementById("myUL").lastChild);
    }
    if (document.getElementById("myOL"))
    {
       document.getElementById("myOL").firstChild.swapNode(
          document.getElementById("myOL").lastChild);
    }
 }

 // remove last node
 function remove()
 {
    if (document.getElementById("myUL"))
    {
       document.getElementById("myUL").lastChild.removeNode(true);
    }
    if (document.getElementById("myOL"))
    {
       document.getElementById("myOL").lastChild.removeNode(true);
    }
 }
```

You can accomplish the same functionality shown in Listing 26-31 in a cross-browser fashion using the W3C DOM. In place of the `removeNode()` and `replaceNode()` methods, use `removeChild()` and `replaceChild()` methods to shift the point of view (and object references) to the parent of the `ul` and `ol` objects: the `document.body`. Also, you need to change the `document.all` references to `document.getElementById()`.

Related Items: `removeChild()`, `removeNode()`, `replaceChild()`, `swapNode()` methods

scrollIntoView(*topAlignFlag*)

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN7+, Moz+, Safari 2.02, Opera+, Chrome+

The `scrollIntoView()` method scrolls the page (vertically and/or horizontally as needed) such that the current object is visible within the window or frame that contains it. A single parameter, a Boolean value, controls the location of the element within the viewable space. A value of `true` (the default) causes the element to be displayed so that its top is aligned with the top of the window or frame (provided that the document beneath it is long enough to allow this amount of scrolling). But a value of `false` causes the bottom of the element to align with the bottom of the viewable area. In most cases, you want the former so that the beginning of a page section is at the top of the viewable area. But if you don't want a user to see content below a certain element when you jump to the new view, use the `false` parameter.

For form elements, you must use the typical form element reference (`document.formName.elementName.scrollIntoView()`) unless you also specify an ID attribute for the element (`document.getElementById("elementID").scrollIntoView()`).

Example

Use The Evaluator (see Chapter 4) to experiment with the `scrollIntoView()` method. Resize the browser window height so that you can see only the top text box and the Results text area. Enter each of the following statements in the top text box, and see where the `myP` element comes into view:

```
myP.scrollIntoView()
myP.scrollIntoView(false)
```

Expand the height of the browser window until you can see part of the table lower on the page. If you enter

```
myTable.scrollIntoView(false)
```

in the top text box, the page scrolls to bring the bottom of the table to the bottom of the window. But if you use the default parameter (`true` or empty)

```
myTable.scrollIntoView()
```

the page scrolls as far as it can in an effort to align the top of the element as closely as possible to the top of the window. The page cannot scroll beyond its normal scrolling maximum (although if the element is a positioned element, you can use dynamic positioning to place it wherever you want — including off the page). Also, if you shrink the window and try to scroll the top of the table to the top of the window, be aware that the `table` element contains a `caption` element, so the caption is flush with the top of the window.

Related Items: `window.scroll()`, `window.scrollBy()`, `window.scrollTo()` methods

setActive()

Returns: Nothing

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `setActive()` method lets a script designate an element object as the active element. However, unlike in the `focus()` method, the window does not scroll the active element into view. Any `onFocus` event handler defined for the element fires when `setActive()` is invoked without the browser's giving the element focus.

Example

Use The Evaluator (see Chapter 4) to compare the `setActive()` and `focus()` methods. With the page scrolled to the top and the window sized so that you cannot see the sample checkbox near the bottom of the page, enter the following statement in the top text box:

```
document.getElementById("myCheckbox").setActive()
```

Scroll down to see that the checkbox has operational focus (press the spacebar to see). Now scroll back to the top, and enter the following:

```
document.getElementById("myCheckbox").focus()
```

This time, the checkbox gets focus, and the page automatically scrolls the object into view.

Related Item: `focus()` method

setAttribute("*attributeName*", *value*[, *caseSensitivity*])

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `setAttribute()` method assigns a new value to an existing attribute of the current object or inserts an entirely new attribute name–value pair among the attributes of the current object. This method represents an alternative syntax to setting a property of the object directly.

Note

The W3C DOM Level 2 standard recommends `getAttribute()` and `setAttribute()` for reading and writing element object attribute values, rather than reading and writing those values by way of their corresponding properties. Although using these methods is certainly advisable for XML elements, the same DOM standard sends conflicting signals by defining all kinds of properties for HTML element objects. Browsers, of course, will support access via properties well into the future, so don't feel obligated to change your ways just yet. ■

The first two parameters of `setAttribute()` are required. The first is the name of the attribute. The default behavior of this method respects the case of the attribute name. Therefore, if you use `setAttribute()` to adjust the value of an existing attribute in default mode, the first parameter must match the case of the attribute as known by the object model for the current document. Remember that all names of all attributes assigned as inline source-code attributes are automatically converted to lowercase letters.

A value you assign to the attribute is the second parameter. For cross-browser compatibility, the value should be either a string or Boolean data type.

IE provides an optional third parameter to control the case-sensitivity issue for the attribute name. The default value (`true`) has a different impact on your object depending on whether you use `setAttribute()` to assign a new attribute or reassign an existing one. In the former case, the third parameter as `true` means that the attribute name assigned to the object observes the case of the first parameter. In the latter case, the third parameter as `true` means that the attribute isn't reassigned unless the first parameter matches the case of the attribute currently associated with the object. Instead, a new attribute with a different case sequence is created.

Attempting to manage the case sensitivity of newly created attributes is fraught with peril, especially if you try to reuse names but with different case sequences. We strongly recommend using default case-sensitivity controls for `setAttribute()` and `getAttribute()`.

See also the W3C DOM facilities for treating attributes as node objects in the discussions of the `getAttributeNode()` and `removeAttributeNode()` methods earlier in this chapter.

Example

Use The Evaluator (see Chapter 4) to experiment with the `setAttribute()` method for the elements in the page. Setting attributes can have immediate impact on the layout of the page (just as setting an object's properties can). Enter the following sample statements in the top text box to view attribute values.

```
document.getElementById("myTable").setAttribute("width", "80%")
document.getElementById("myTable").setAttribute("border", "5")
```

Related Items: `attributes` property; `document.createAttribute()`, `getAttribute()`, `getAttributeNode()`, `removeAttribute()`, `removeAttributeNode()`, `setAttributeNode()` methods

`setAttributeNode()`

(See `removeAttributeNode()`)

`setAttributeNodeNS("`*`attributeNode`*`")`

Returns: `Attribute` object

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

This method inserts or replaces an attribute in the current element. The sole parameter is an attribute object, and the return value is a reference to the newly inserted attribute object. When the method is invoked, the browser looks for a pairing of local name and namespace URI between the nodes. If there is a match, the node replaces the matched node; otherwise, the node is inserted.

Related Items: `attributes`, `namespaceURI`, `localName` properties; `removeAttributeNS()`, `getAttributeNS()`, and `setAttributeNS()` methods

`setAttributeNS("`*`namespaceURI`*`", "`*`qualifiedName`*`", "`*`value`*`")`

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

This method inserts or replaces an attribute in the current element, as specified in the three parameters. The first parameter of the method is a URI string matching a URI assigned to a label in the document. The second parameter is the local name portion of the attribute whose value you are getting. If a match is found among these parameters, the value in the third parameter is assigned to the existing attribute; otherwise, the value is inserted as a new attribute.

Related Items: `attributes`, `namespaceURI`, `localName` properties; `removeAttributeNS()`, `getAttributeNS()`, and `setAttributeNodeNS()` methods

setCapture(*containerBoolean*)

(See releaseCapture())

setExpression("*propertyName*", "*expression*",["*language*"])

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Use the setExpression() method to assign the result of an executable expression to the value of an element object property. This method can assign values to both HTML element objects and style objects that belong to them.

The setExpression() method is a scripted way of assigning expressions to attributes. But you can also assign expressions directly to style sheet definitions in the HTML tag of an element using the expression() syntax, as in the following example:

```
<p style="width:expression(document.body.style.width * 0.75)">
```

The setExpression() method requires three parameters. The first parameter is the name of the property (in string form) to which you assign the expression. Property names are case sensitive. The second parameter is a string form of the expression to be evaluated to supply a value for the property. Expressions can refer to global variables or properties of other objects in the same document (provided that the property is anything other than an array). An expression may also contain math operators.

Pay close attention to the data type of the evaluated value of the expression. The value must be a valid data type for the property. For example, the URL of the body background image must be a string. But for numeric values, you can generally use number and string types interchangeably because the values are converted to the proper type for the property. Even for expressions that evaluate to numbers, encase the expression inside quotes. It may not be necessary in all cases, but if you get into the habit of using quotes, you'll have fewer problems for strings or complex expressions that require them.

You are not limited to using JavaScript as the language for the expression because you can also specify the scripting language of the expression in the optional third parameter. Acceptable parameter values for the language are

```
JScript
JavaScript
VBScript
```

For all intents and purposes, JScript and JavaScript are the same. Both languages are ECMA-262 compatible. JScript is the default value for the language parameter.

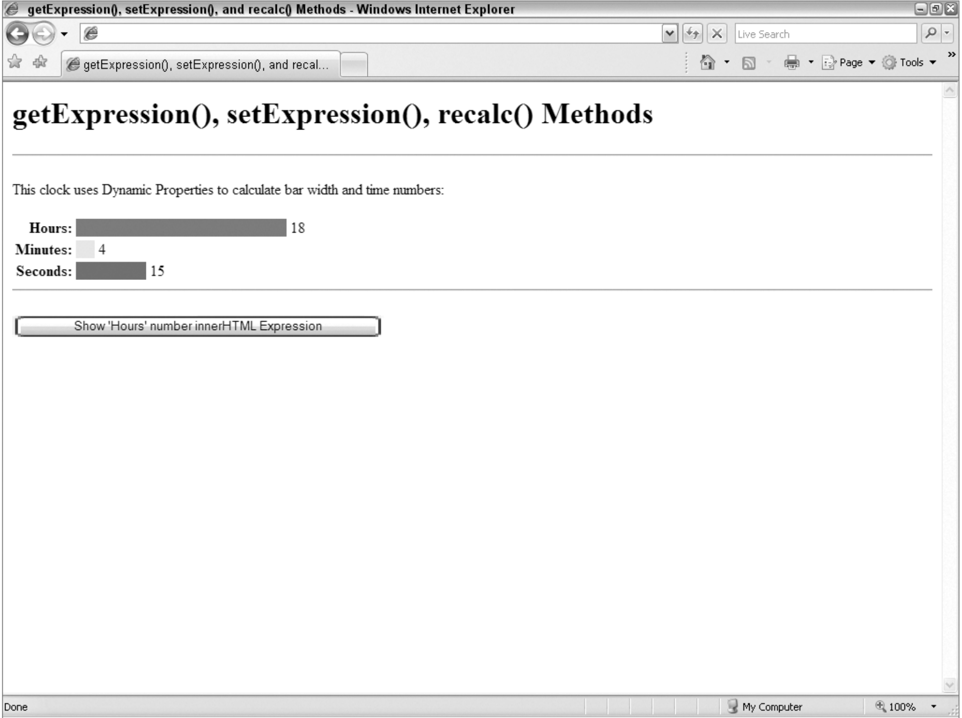
One reason to use setExpression() for dynamic properties is to let the property always respond to the current conditions on the page. For example, if you set a property that is dependent on the current width of the body, you want a recalculation that is applied to the property if the user resizes the window. The browser automatically responds to many events and updates any dynamic properties. In essence, the browser recalculates the expressions and applies the new values to the property. Keyboard events in particular trigger this kind of automatic recalculation for you. But if your scripts perform actions on their own (in other words, not triggered by events), your scripts need to force the recalculation of the expressions. The document.recalc() method takes care of this, but you must invoke it to force the recalculation of dynamic properties in these cases.

Example

Listing 26-32 shows the `setExpression()`, `recalc()`, and `getExpression()` methods at work in a DHTML-based clock. Figure 26-1 shows the clock. As time clicks by, the bars for hours, minutes, and seconds adjust their widths to reflect the current time. At the same time, the `innerHTML` of `span` elements to the right of each bar display the current numeric value for the bar.

FIGURE 26-1

A bar-graph clock created with dynamic expressions



The dynamically calculated values in this example are based on the creation of a new `Date` object over and over again to get the current time from the client computer clock. It is from the `Date` object (stored in the variable called `now`) that the hour, minute, and second values are retrieved. Some other calculations are involved so that a value for one of these time components is converted to a pixel value for the width of the bars. The bars are divided into 24 (for the hours) and 60 (for the minutes and seconds) parts, so the scale for the two types differs. For the 60-increment bars in this application, each increment is set to 5 pixels (stored in `shortWidth`); the 24-increment bars are 2.5 times the `shortWidth`.

As the document loads, the three `span` elements for the colored bars are given no width, which means that they assume the default width of zero. But after the page loads, the `onload` event handler invokes the `init()` function, which sets the initial values for each bar's width and the text (`innerHTML`) of the three labeled spans. After these initial values are set, the `init()` function invokes the `updateClock()` function.

In the `updateClock()` function, a new `Date` object is created for the current instant. The `document.recalc()` method is called, instructing the browser to recalculate the expressions that were set in the `init()` function and assign the new values to the properties. To keep the clock ticking, the `setTimeout()` method is set to invoke this same `updateClock()` function in 1 second.

To see what the `getExpression()` method does, you can click the button on the page. It simply displays the returned value for one of the attributes that you assign using `setExpression()`.

      ".");
}
```

Related Items: `document.recalc()`, `removeExpression()`, `setExpression()` methods

setUserData("*key*", *dataObj*, *dataHandler*)

Returns: Object

Compatibility: WinIE-, MacIE-, NN-, Moz1.7.2+, Safari+, Opera-, Chrome+

The `setUserData()` method is designed to allow for the addition of user data to a node. This user data comes in the form of an object and is associated with a node through a string key. By requiring a key for an object of user data, the `setUserData()` method allows you to set multiple pieces of data (objects) on a single node. The last parameter to the method is an event handler function reference that is called whenever the data object is cloned, imported, deleted, renamed, or adopted.

Although some support for the `setUserData()` method was added in Moz1.7.2, the method still isn't supported to the degree that you can actually use it, as of Moz1.8.1.

swapNode(*otherNodeObject*)

Returns: `Node` object reference

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `swapNode()` method exchanges the positions of two nodes within an element hierarchy. Contents of both nodes are preserved in their entirety during the exchange. The single parameter must be a valid node object (perhaps created with `document.createElement()` or copied from an existing node). A return value is a reference to the object whose `swapNode()` method was invoked.

Example

See Listing 26-31 (the `replaceNode()` method) for an example of the `swapNode()` method in action.

Related Items: `removeChild()`, `removeNode()`, `replaceChild()`, `replaceNode()` methods

tags("*tagName*")

Returns: Array of element objects

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera+, Chrome+

The `tags()` method does not belong to every element, but it is a method of every collection of objects (such as `all`, `forms`, and `elements`). The method is best thought of as a kind of filter for the elements that belong to the current collection. For example, to get an array of all `p` elements inside a document, use this expression:

```
document.all.tags("P")
```

You must pass a parameter string consisting of the tag name you wish to extract from the collection. The tag name is case insensitive.

The return value is an array of references to the objects within the current collection whose tags match the parameter. If there are no matches, the returned array has a length of zero. If you need cross-browser compatibility, use the `getElementsByTagName()` method described earlier in this chapter, and pass a wildcard value of `"*"`.

Example

Use The Evaluator (see Chapter 4) to experiment with the `tags()` method. Enter the following statements one at a time in the top text box, and study the results:

```
document.all.tags("div")
document.all.tags("div").length
myTable.all.tags("td").length
```

Because the `tags()` method returns an array of objects, you can use one of those returned values as a valid element reference:

```
document.all.tags("form")[1].elements.tags("input").length
```

The browsers that support tags do not all support it for the same HTML elements. For example, WebKit-based browsers do not support `tags` as part of `table`.

Related Item: `getElementsByTagName()` method

`toString("`*`param`*`")`

Returns: String

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `toString()` method returns a string representation of the element object, which unfortunately can mean different things to different browsers. Don't expect entirely consistent results across browsers, especially when you consider that IE simply returns a generic `"[object]"` string.

`urns("`*`behaviorURN`*`")`

Returns: Array of element objects

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, opera-, Chrome-

The `urns()` method does not belong to every element, but it is a method of every collection of objects. You must pass a parameter string consisting of the URN (Uniform Resource Name) of a behavior resource (most typically `.htc`) assigned to one or more elements of the collection. The parameter does not include the extension of the filename. If there is no matching behavior URN for the specified parameter, the `urns()` method returns an array of zero length. This method is related to the `behaviorUrns` property, which contains an array of behavior URNs assigned to a single element object.

Example

In case the `urns()` method is reconnected in the future, you can add a button and function to Listing 26-19b that reveals whether the `makeHot.htc` behavior is attached to the `myP` element. Such a function looks like this:

```
function behaviorAttached()
{
   if (document.all.urns("makeHot"))
   {
      alert("There is at least one element set to \'makeHot\'.");
   }
}
```

Related Item: `behaviorUrns` property

Event handlers

onactivate
ondeactivate

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onactivate` and `ondeactivate` event handlers are similar to the `onfocus` and `onblur` event handlers, respectively, as well as to the IE5.5+ `onfocusin` and `onfocusout` events. Starting with IE5.5+, it is possible to manage the activation of an element and the focus of an element separately. The `onactivate` and `ondeactivate` events correspond to the activation of an element, whereas `onfocusin` and `onfocusout` deal with focus. In many cases, activation and focus go hand in hand, but not always.

If an element receives activation, the `onactivate` event fires for that element just before the activation takes hold; conversely, just before the element loses activation, events fire in the sequence `onbeforedeactivate`, `ondeactivate`, `onblur`. Only elements that by their nature can accept activation (for example, links and form input controls) or that have a `tabindex` attribute set can become the active element (and, therefore, fire these events).

WinIE5.5+ maintains the original `onfocus` and `onblur` event handlers. But because the behaviors are so close to those of the `onactivate` and `ondeactivate` events, we don't recommend mixing the old and new event handler names in your coding style. If you script exclusively for WinIE5.5+, which is unlikely in this day and age, you can use the newer terminology throughout. And if you truly want to track the focus of an element in IE, consider using `onfocusin` and `onfocusout` instead.

Example

You can modify Listing 26-34 later in this chapter by substituting `onactivate` for `onfocus` and `ondeactivate` for `onblur`.

Use The Evaluator (see Chapter 4) to experiment with the `onbeforedeactivate` event handler. To begin, set the `myP` element so it can accept focus:

```
myP.tabIndex = 1
```

If you repeatedly press the Tab key, the `myP` paragraph will eventually receive focus — indicated by the dotted rectangle around it. To see how you can prevent the element from losing focus, assign an anonymous function to the `onbeforedeactivate` event handler, as shown in the following statement:

```
myP.onbeforedeactivate = new Function("event.returnValue=false")
```

Now you can press Tab all you like or click other focusable elements all you like, and the `myP` element will not lose focus until you reload the page (which clears away the event handler). Please do not do this on your pages unless you want to infuriate and alienate your site visitors.

Related Items: `onblur`, `onfocus`, `onfocusin`, `onfocusout` event handlers

onafterupdate
onbeforeupdate

Compatibility: WinIE4+, MacIE5+, NN-, Moz-, Safari-, Opera-, Chrome-

The `onafterupdate` and `onbeforeupdate` event handlers fire on a bound data object in IE whenever the data in the object is being updated. The `onbeforeupdate` event is fired just before the update occurs, whereas `onafterupdate` is fired after the data has been successfully updated.

onbeforecopy

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari1.3+, Opera-, Chrome+

The `onbeforecopy` event handler fires before the actual copy action takes place whenever the user initiates a content copy action via the Edit menu (including the Ctrl+C, for Windows, and Command+C, for Mac, keyboard shortcuts) or the right-click context menu. In all browsers, if the user copies with a keyboard shortcut, the copy operation will be completed. If the user accesses the Copy command via the Edit or context menu different browsers behave differently. In WebKit-based browsers, the menu displays, the user selects copy and then the `onbeforecopy` event fires. The `onbeforecopy` event fires before either menu can display in IE. In practice, the event may fire twice even though you expect it only once. Just because the `onbeforecopy` event fires, it does not guarantee that a user will complete the copy operation (for example, the context menu may close before the user makes a selection).

Unlike paste-related events, the `onbeforecopy` event handler does not work with form input elements. Just about any other HTML element is fair game, however.

Example

In Listing 26-33, the function invoked by the "Latin" paragraph element's `onbeforecopy` event handler merely issues an alert. If your audience is limited in their browser use, you could use the `onbeforecopy` event handler to preprocess information prior to an actual copy action.

LISTING 26-33

The onbeforecopy Event Handler

HTML: jsb26-33.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>onbeforecopy event handler</title>
      <style type="text/css">
         .keyword
```

```
        {
           color: blue; font-weight:bold;
        }
     </style>
     <script type="text/javascript" src="../jsb-global.js"></script>
     <script type="text/javascript" src="jsb26-33.js"></script>
   </head>
   <body>
     <h1>onbeforecopy event handler</h1>
     <hr />
     <p>Select one or more characters in the Latin paragraph.
        then execute a copy command:
        <ul>
           <li>edit menu</li>
           <li>context menu</li>
           <li>ctrl-c (on Windows)</li>
           <li>command-c (on Mac)</li>
        </ul>
        Browsers that support <span class="keyword">onbeforecopy</span>,
        do not behave consistently. You may not be able to use all
        of the copy commands normally available to you. Test all the
        different ways to copy text and see what happens.
     </p>
     <p>
        Browsers that do not support <span class="keyword">onbeforecopy</span>
        will still allow you to copy -- you just won't see an alert.
     </p>
     <p id="myp" onbeforecopy="beforeCopy()">lorem ipsum dolor sit amet,
        consectetaur adipisicing elit, sed do eiusmod tempor incididunt ut

        exercitation ullamco laboris nisi ut aliquip ex commodo consequat.</p>
     <form>
        <p>paste results here:<br />
           <textarea name="output" cols="60" rows="5"></textarea>
        </p>
     </form>
   </body>
</html>
```

JavaScript: jsb26-33.js

```
function beforeCopy()
{
   alert("onbeforecopy is supported by your browser");
}
```

Related Items: onbeforecut, oncopy event handlers

onbeforecut

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari 1.3+, Opera-, Chrome+

The `onbeforecut` event handler fires before the actual cut action takes place whenever the user initiates a content cut via the Edit menu (including the Ctrl+X keyboard shortcut) or the right-click context menu. If you add the `onbeforecut` event handler to an HTML element, the context menu usually disables the Cut menu item. But assigning a JavaScript call to this event handler brings the Cut menu item to life. If the user accesses the Cut command via the Edit or context menu, different browsers behave differently. In WebKit-based browsers, the menu displays, the user selects cut and then the `onbeforecut` event fires. In IE the `onbeforecut` event fires before either menu displays. In practice, the event may fire twice even though you expect it only once. Just because the `onbeforecut` event fires, it does not guarantee that a user will complete the cut operation (for example, the context menu may close before the user makes a selection).

Example

You can use the `onbeforecut` event handler to preprocess information prior to an actual cut action. You can try this by editing a copy of Listing 26-33, changing the `onbeforecopy` event handler to `onbeforecut`.

Related Items: `onbeforecopy`, `oncut` event handlers

onbeforedeactivate

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-

(See `onactivate` event handler)

onbeforeeditfocus

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onbeforeeditfocus` event handler is triggered whenever you edit an element on a page in an environment such as Microsoft's DHTML Editing ActiveX control or with the editable page content feature of IE5.5+. This discussion focuses on the latter scenario because it is entirely within the scope of client-side JavaScript. The `onbeforeeditfocus` event fires just before the element receives its focus. (There may be no onscreen feedback that editing is turned on unless you script it yourself.) The event fires each time a user clicks the element, even if the element just received edit focus elsewhere in the same element.

Example

Use The Evaluator (see Chapter 4) to explore the `onbeforeeditfocus` in WinIE5.5+. In the following sequence, you assign an anonymous function to the `onbeforeeditfocus` event handler of the `myP` element. The function turns the text color of the element to red when the event handler fires:

```
document.getElementById("myP").onbeforeeditfocus = new
Function("document.getElementById('myP').style.color='red'")
```

Now turn on content editing for the `myP` element:

```
document.getElementById("myP").contentEditable = true
```

Now if you click inside the `myP` element on the page to edit its content, the text turns red before you begin editing. In a page scripted for this kind of user interface, you would include some control that turns off editing and changes the color to normal.

Related Items: `document.designMode`, `contentEditable`, `isContentEditable` properties

onbeforepaste

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari 1.3+, Opera-, Chrome+

Like `onbeforecopy` and `onbeforecut`, the `onbeforepaste` event occurs differently in different browsers. In WebKit-based browsers, the menu displays, the user selects paste and then the `onbeforepaste` event fires. In IE, the `onbeforepaste` event fires just prior to the display of either the context or menu-bar Edit menu when the current object is selected (or has a selection within it). The primary value of this event comes when you use scripts to control the copy-and-paste process of a complex object. Such an object may have multiple kinds of data associated with it, but your script captures only one of the data types. Or you may want to put some related data about the copied item (for example, the `id` property of the element) into the clipboard. By using the `onbeforepaste` event handler to set the `event.returnValue` property to `false`, you guarantee that the pasted item is enabled in the context or Edit menu (provided that the clipboard is holding some content). A handler invoked by `onpaste` should then apply the specific data subset from the clipboard to the currently selected item.

Example

See Listing 26-44 for the `onpaste` event handler (later in this chapter) to see how the `onbeforepaste` and `onpaste` event handlers work together.

Related Items: `oncopy`, `oncut`, `onpaste` event handlers

onbeforeupdate

(See `onafterupdate`)

onblur

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `onblur` event fires when an element that has focus is about to lose focus because some other element is about to receive focus. For example, a text input element fires the `onblur` event when a user tabs from that element to the next one inside a form. The `onblur` event of the first element fires before the `onfocus` event of the next element.

The availability of the `onblur` event has expanded with succeeding generations of script-capable browsers. In the earlier versions, blur and focus were largely confined to text-oriented input elements (including the `select` element). These are safe to use with all scriptable browser versions. The `window` object received the `onblur` event handler starting with NN3 and IE4. IE4 also extended the event handler to more form elements, predominantly on the Windows operating system because that OS has a user interface clue (the dotted rectangle) when items such as buttons and links receive focus (so that you may act upon them by pressing the spacebar). For IE5+, the `onblur` event handler is available to virtually every HTML element. For most of those elements, however, blur and focus are not possible unless you assign a value to the `tabindex` attribute of the element's tag. For example, if you assign `tabindex="1"` inside a `<p>` tag, the user can bring focus to that paragraph (highlighted with the dotted rectangle in Windows in some of the browsers) by clicking the paragraph or pressing the Tab key until that item receives focus in sequence.

If you plan to use the `onblur` event handler on window or text-oriented input elements, be aware that there might be some unexpected and undesirable consequences of scripting for the event. For

example, in IE, a `window` object that has focus loses focus (and triggers the `onblur` event) if the user brings focus to any element on the page (or even clicks a blank area on the page). Similarly, the interaction between `onblur`, `onfocus`, and the `alert()` dialog box can be problematic with text input elements. This is why we generally recommend using the `onchange` event handler to trigger form validation routines. If you should employ both the `onblur` and `onchange` event handler for the same element, the `onchange` event fires before `onblur`. For more details about using this event handler for data validation, see Chapter 46 on the CD-ROM.

WinIE5.5+ added the `ondeactivate` event handler, which fires immediately before the `onblur` event handler. Both the `onblur` and `ondeactivate` events can be blocked if the `onbeforedeactivate` event handler function sets `event.returnValue` to `false`.

Example

More often than not, a page author uses the `onblur` event handler to exert extreme control over the user, such as preventing a user from exiting a text box unless that user types something in the box. This is not a web-friendly practice, and it is one that we discourage because there are intelligent ways to ensure that a field has something typed into it before a form is submitted (see Chapter 46 on the CD-ROM). Listing 26-34 simply demonstrates the impact of the `tabindex` attribute with respect to the `onblur` and `onfocus` events. Notice that as you press the Tab key, only the second paragraph issues the events, even though all three paragraphs have event handlers assigned to them.

}
```

Related Items: `blur()`, `focus()` methods; `ondeactivate`, `onbeforedeactivate`, `onfocus`, `onactivate` event handlers

oncellchange

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `oncellchange` event handler is part of the data binding of IE and fires when data changes in the data provider, which is usually a bound control. When responding to this event, you can analyze the `dataFld` property to find out which field in the recordset has changed.

onclick

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `onclick` event fires when a user presses down (with the primary mouse button) and releases the button with the pointer atop the element (both the down and up strokes must be within the rectangle of the same element). The event also fires with non-mouse-click equivalents in operating systems such as Windows. For example, you can use the keyboard to give focus to a clickable object and then press the spacebar or Enter key to perform the same action as clicking the element. In IE, if the element object supports the `click()` method, the `onclick` event fires with the invocation of that method (notice that this does not apply to Navigator or other browsers).

The `onclick` event is closely related to other mouse events. The other related events are `onmousedown`, `onmouseup`, and `ondblclick`. The `onmousedown` event fires when the user makes contact with the mouse switch on the downstroke of a click action. Next comes the `onmouseup` event (when the contact breaks). Only then does the `onclick` event fire — provided that the `onmousedown` and `onmouseup` events have fired in the same object. See the discussions on the `onmousedown` and `onmouseup` events later in this chapter for examples of their usage.

Interaction with the ondblclick event is simple: The onclick event fires (after the first click), followed by the ondblclick event (after the second click). See the discussion of the ondblclick event handler later in this chapter for more about the interaction of these two event handlers.

When used with objects that have intrinsic actions when users click them (namely, links and areas), the onclick event handler can perform all of the actions — including navigating to the destination normally assigned to the href attribute of the element. For example, to be compatible with all scriptable browsers, you can make an image clickable if you surround its tag with an <a> link tag. This lets the onclick event of that tag substitute for the missing onclick event handler of earlier <img> tags. If you assign an onclick event handler without special protection, the event handler will execute, and the intrinsic action of the element will be carried out. Therefore, you need to block the intrinsic action. To accomplish this, the event handler must evaluate to the statement return false. You can do this in two ways. The first is to append a return false statement to the script statement assigned to the event handler:

```
<a href="#" onclick="yourFunction(); return false"><img...></a>
```

As an alternative, you can let the function invoked by the event handler supply the false part of the return false statement, as shown in the following sequence:

```
function yourFunction()
{
   // [statements that do something here]
   return false;
}
...
<a href="#" onclick="return yourFunction()"><img...></a>
```

Either methodology is acceptable. A third option is to not use the onclick event handler at all but assign a javascript: pseudo-URL to the href attribute (see the Link object in Chapter 30).

The event model in IE4+ provides one more way to prevent the intrinsic action of an object from firing when a user clicks it. If the onclick event handler function sets the returnValue property of the event object to false, the intrinsic action is canceled. Simply include the following statement in the function invoked by the event handler:

```
event.returnValue = false;
```

The event model of the W3C DOM has a different approach to canceling the default action. In the event handler function for an event, invoke the eventObj.cancelDefault() method.

A common mistake made by scripting beginners is to use a submit type input button as a button intended to perform some script action rather than submitting a form. The typical scenario is an input element of type submit assigned an onclick event handler to perform some local action. The submit input button has an intrinsic behavior, just like links and areas. Although you can block the intrinsic behavior, as just described, you should use an input element of type button.

If you are experiencing difficulty with an implementation of the onclick event handler (such as trying to find out which mouse button was used for the click), it may be that the operating system or default browser behavior is getting in the way of your scripting. But you can usually get what you need via the onmousedown event handler. (The onmouseup event may not fire when you use the secondary mouse button to click an object.) Use the onclick event handler whenever possible to capture user clicks, because this event behaves most like users are accustomed to in their daily computing work. But fall back on onmousedown in an emergency.

Example

The `onclick` event handler is one of the simplest to grasp and use. Listing 26-35 demonstrates its interaction with the `ondblclick` event handler and shows you how to prevent a link's intrinsic action from activating when combined with `click` events. As you click and/or double-click the link, the text in the `span` element displays a message associated with each event. Notice that if you double-click, the `click` event fires first, with the first message immediately replaced by the second. For demonstration purposes, we show both backward-compatible ways of canceling the link's intrinsic action. In practice, decide on one style and stick with it.

LISTING 26-35

Using onclick and ondblclick Event Handlers

   </head>
   <body>
      <h1>onclick and ondblclick Event Handlers</h1>
      <hr />
      <a href="#" onclick="showClick();return false"
         ondblclick="return showDblClick()">A sample link.</a>
      (Click type: <span id="clickType"></span>)
   </body>
</html>
```

JavaScript: jsb26-35.js

```
var timeout;
function clearOutput()
{
   document.getElementById("clickType").innerHTML = "";
}
function showClick()
{
   document.getElementById("clickType").innerHTML = "single";
   clearTimeout(timeout);
   timeout = setTimeout("clearOutput()", 3000);
}
function showDblClick()
{
   document.getElementById("clickType").innerHTML = "double";
   clearTimeout(timeout);
   timeout = setTimeout("clearOutput()", 3000);
   return false;
}
```

Related Items: `click()` method; `oncontextmenu`, `ondblclick`, `onmousedown`, `onmouseup` event handlers

oncontextmenu

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari+, Opera-, Chrome+

The `oncontextmenu` event fires when the user clicks an object with the secondary (usually the right) mouse button. The only click-related events that fire with the secondary button are `onmousedown` and `oncontextmenu`.

To block the intrinsic application menu display of the `oncontextmenu` event, use any of the event cancellation methodologies available in for your browser (as just described in the `onclick` event handler description: two variations of evaluating the event handler to `return false`; assigning `false` to the `event.returnValue` property). It is not uncommon to wish to block the context menu from appearing so that users are somewhat inhibited from downloading copies of images or viewing the source code of a frame. Be aware, however, that if a user turns Active Scripting off in WinIE5+, the event handler cannot prevent the context menu from appearing.

Another possibility for this event is to trigger the display of a custom context menu constructed with other DHTML facilities. In this case, you must also disable the intrinsic context menu so that both menus do not display at the same time.

Example

See Listing 26-30 earlier in this chapter for an example of using the `oncontextmenu` event handler with a custom context menu.

Related Items: `releaseCapture()`, `setCapture()` methods

oncontrolselect

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `oncontrolselect` event fires just before a user makes a selection on an editable element while the page is in edit mode. It's important to note that it is the element itself that is selected to trigger this event, not the content within the element.

Related Items: `onresizeend`, `onresizestart` event handlers

oncopy
oncut

Compatibility: WinIE5+, MacIE4+, NN-, Moz+, Safari1.3+, Opera-, Chrome+

The `oncopy` and `oncut` events fire immediately after the user or script initiates a copy or cut edit action on the current object. Each event is preceded by its associated before event, which fires before any Edit or context menu appears (or before the copy or cut action, if initiated by keyboard shortcut).

Use these event handlers to provide edit functionality to elements that don't normally allow copying or cutting. In such circumstances, you need to enable the Copy or Cut menu items in the context or Edit menu by setting the `event.returnValue` for the `onbeforecopy` or `onbeforecut` event handlers to `false`. Then your `oncopy` or `oncut` event handlers must manually stuff a value into the clipboard by way of the `setdata()` method of the IE `clipboardData` object. If you use the `setdata()` method in your `oncopy` or `oncut` event handler, you must also set the

`event.returnValue` property to `false` in the handler function to prevent the default copy or cut action from wiping out your clipboard contents.

Because you are in charge of what data is stored in the clipboard, you are not limited to a direct copy of the data. For example, you might wish to store the value of the `src` property of an image object so that the user can paste it elsewhere on the page.

In the case of the `oncut` event handler, your script is also responsible for cutting the element or selected content from the page. To eliminate all of the content of an element, you can set the element's `innerHTML` or `innerText` property to an empty string. For a selection, use the `selection.createRange()` method to generate a `TextRange` object whose contents you can manipulate through the `TextRange` object's methods.

Example

Listing 26-36 shows both the `onbeforecut` and `oncut` event handlers in action (as well as `onbeforepaste` and `onpaste`). Notice that the `handleCut()` function not only stuffs the selected word into the IE `clipboardData` object, but also erases the selected text from the table cell element from where it came. If you replace the `onbeforecut` and `oncut` event handlers with `onbeforecopy` and `oncopy` (and change `handleCut()` to not eliminate the inner text of the event source element), the operation works with copy and paste instead of cut and paste. We demonstrate this later in the chapter in Listing 26-44.

LISTING 26-36

Cutting and Pasting under Script Control

         event.returnValue = false;
      }
}
```

Related Items: `onbeforecopy`, `onbeforecut`, `onbeforepaste`, and `onpaste` event handlers

ondataavailable
ondatasetchanged
ondatasetcomplete

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

These three events are part of the data binding of IE and are fired to help reflect the state of data that is being transmitted. The `ondataavailable` event fires when data is transmitted from the data source, whereas the `ondatasetcomplete` event indicates that the recordset has completely downloaded from the data source. The `ondatasetchanged` event is fired when the recordset of a data source has somehow changed.

ondblclick

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `ondblclick` event fires after the second click of a double-click sequence. The timing between clicks depends on the client's mouse control panel settings. The `onclick` event also fires, but only after the first of the two clicks.

In general, it is rarely a good design to have an element perform one task when the mouse is single-clicked and a different task if double-clicked. With the event sequence employed in modern browsers, this isn't practical anyway (the `onclick` event always fires, even when the user double-clicks). But it is not uncommon to have the mouse down action perform some helper action. You see this in most icon-based file systems: If you click a file icon, it is highlighted at mouse down to select the item; you can double-click the item to launch it. In either case, one event's action does not impede the other nor confuse the user.

Example

See Listing 26-35 (for the `onclick` event handler) to see the `ondblclick` event in action.

Related Items: `onclick`, `onmousedown`, `onmouseup` event handlers

`ondrag, ondragend, ondragstart`

Compatibility: WinIE5+, MacIE-, NN-, Moz+, Safari 1.3+, Opera-, Chrome+

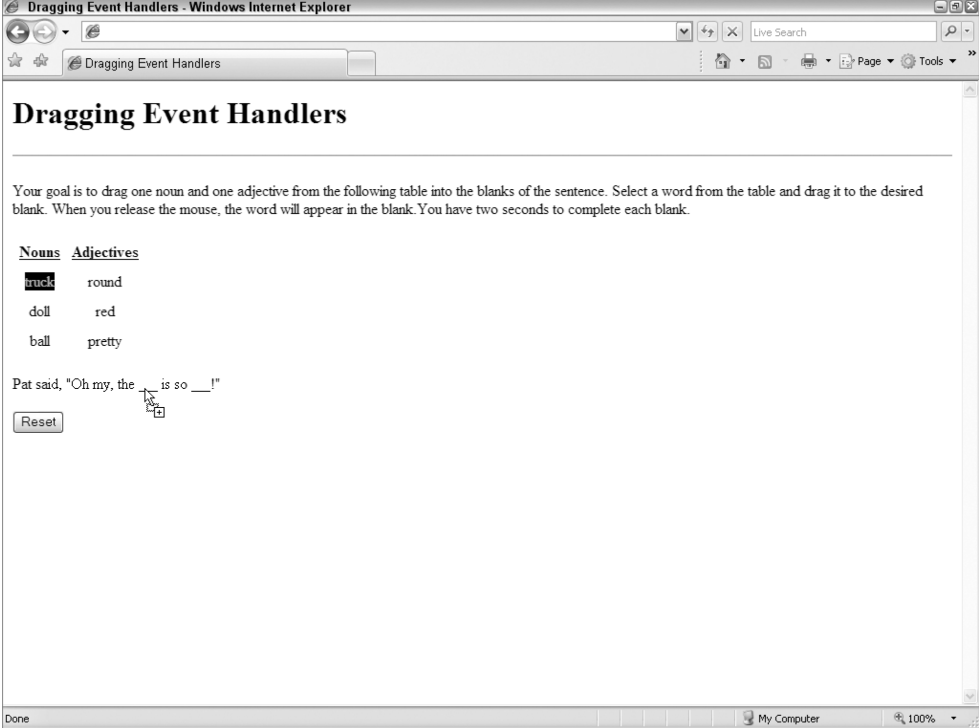
The `ondrag` event fires after the `ondragstart` event and continues firing repeatedly while the user drags a selection or object onscreen. Unlike the `onmousemove` event, which fires only as the cursor moves onscreen, the `ondrag` event continues to fire even when the cursor is stationary. In most browsers, users can drag objects to other browser windows or other applications. The event fires while the dragging extends beyond the browser window.

Because the event fires regardless of what is underneath the dragged object, you can use it in a game or training environment in which the user has only a fixed amount of time to complete a dragging operation (for example, matching similar pairs of objects). If the browser accommodates downloadable cursors, the `ondrag` event could cycle the cursor through a series of cursor versions to resemble an animated cursor.

Understanding the sequence of drag-related events during a user drag operation can be helpful if your scripts need to micromanage the actions (usually not necessary for basic drag-and-drop operations). Consider the drag-and-drop operation shown in Figure 26-2.

FIGURE 26-2

A typical drag-and-drop operation



It helps to imagine that the cells of the table with draggable content are named like spreadsheet cells: truck is cell A1; round is B1; doll is A2; and so on. During the drag operation, many objects are the targets of a variety of drag-related events. Table 26-11 lists the event sequence and the event targets.

In practice, some of the events shown in Table 26-11 may not fire. Much has to do with how many event handlers you trap that need to execute scripts along the way. The other major factor is the physical speed at which the user performs the drag-and-drop operation (which interacts with the CPU processing speed). The kinds of events that are most likely to be skipped are the `ondragenter` and `ondragleave` events, and perhaps some `ondragover` events if the user flies over an object before its `ondragover` event has a chance to fire.

Despite this uncertainty about drag-related event reliability, you can count on several important ones to fire all the time. The `ondragstart`, `ondrop` (if over a drop target), and `ondragend` events — as well some interstitial `ondrag` events — will definitely fire in the course of dragging onscreen. All but `ondrop` direct their events to the source element, whereas `ondrop` fires on the target.

Example

Listing 26-37 shows several drag-related event handlers in action. The page resembles the example in Listing 26-36, but the scripting behind the page is quite different. In this example, the user is encouraged to select individual words from the Nouns and Adjectives columns and drag them to the blanks of the sentence. To beef up the demonstration, Listing 26-37 shows you how to pass the equivalent of array data from a drag source to a drag target. At the same time, the user has a fixed amount of time (2 seconds) to complete each drag operation.

The `ondragstart` and `ondrag` event handlers are placed in the `<body>` tag because those events bubble up from any element that the user tries to drag. The scripts invoked by these event handlers filter the events so that the desired action is triggered only by the hot elements inside the table. This approach to event handlers prevents you from having to duplicate event handlers for each table cell.

The `ondragstart` event handler invokes `setupDrag()`. This function cancels the `ondragstart` event except when the target element (the one about to be dragged) is one of the `td` elements inside the table. To make this application smarter about what kind of word is dragged to which blank, it passes not only the word's text, but also some extra information about the word. This lets another event handler verify that a noun has been dragged to the first blank, whereas an adjective has been dragged to the second blank. To help with this effort, class names are assigned to the `td` elements to distinguish the words from the Nouns column from the words of the Adjectives column. The `setupDrag()` function generates an array consisting of the `innerText` of the event's source element plus the element's class name. But the `event.dataTransfer` object cannot store array data types, so the `Array.join()` method converts the array to a string with a colon separating the entries. This string, then, is stuffed into the `event.dataTransfer` object. The object is instructed to render the cursor display during the drag-and-drop operation so that when the cursor is atop a drop target, the cursor is the copy style. Finally, the `setupDrag()` function is the first to execute in the drag operation, so a timer is set to the current clock time to time the drag operation.

The `ondrag` event handler (in the `body`) captures the `ondrag` events that are generated by whichever table cell element is the source element for the action. Each time the event fires (which is a lot during the action), the `timeIt()` function is invoked to compare the current time against the reference time (global `timer`) set when the drag starts. If the time exceeds 2 seconds (2,000 milliseconds), an alert dialog box notifies the user. To close the alert dialog box, the user must unclick the mouse button to end the drag operation.

TABLE 26-11

Events and Their Targets during a Typical Drag-and-Drop Operation

Event	Target	Discussion
`ondragstart`	cell `A1`	The very first event that fires during a drag-and-drop operation.
`ondrag`	cell `A1`	Fires continually on this target throughout the entire operation. Other events get interspersed, however.
`ondragenter`	cell `A1`	Even though the cursor hasn't moved from cell A1 yet, the `ondragenter` event fires upon first movement within the source element.
`ondragover`	cell `A1`	Fires continually on whatever element the cursor rests on at that instant. If the user simply holds the mouse button down and does not move the cursor during a drag, the `ondrag` and `ondragover` events fire continually, alternating between the two.
`(repetition)`	cell `A1`	`ondrag` and `ondragover` events fire alternately while the cursor remains atop cell A1.
`ondragenter`	`table`	The `table` element, represented by the border and/or cell padding, receives the `ondragenter` event when the cursor touches its space.
`ondragleave`	cell `A1`	Notice that the `ondragleave` event fires after the `ondragenter` event fires on another element.
`ondrag`	cell `A1`	Still firing away.
`ondragover`	`table`	The source element for this event shifts to the table because that's what the cursor is over at this instant. If the cursor doesn't move from this spot, the `ondrag` (cell A1) and `ondragover` (table) events continue to fire in turn.
`ondragenter`	cell `B1`	The drag is progressing from the `table` border space to cell B1.
`ondragleave`	`table`	The `table` element receives the `ondragleave` event when the cursor exits its space.
`ondrag`	cell `A1`	The `ondrag` event continues to fire on the cell A1 object.
`ondragover`	cell `B1`	The cursor is atop cell B1 now, so the `ondragover` event fires for that object. Fires multiple times (depending on the speed of the computer and the user's drag action), alternating with the previous `ondrag` event.
		More of the same as the cursor progresses from cell B1 through the `table` border again to cell B2, the `table` again, cell B3, and the outermost edge of the `table`.
`ondragenter`	`body`	Dragging is free of the `table` and is floating free on the bare `body` element.
`ondragleave`	`table`	Yes, you just left the `table`.
`ondrag`	cell `A1`	Still alive and receiving this event.

Event	Target	Discussion
ondragover	body	That's where the cursor is now. Fires multiple times (depending on the speed of the computer and the user's drag action), alternating with the previous ondrag event.
ondragenter	blank1	The cursor reaches the span element whose ID is blank1, where the empty underline is.
ondragleave	body	Just left the body for the blank.
ondrag	cell A1	Still kicking.
ondragover	blank1	That's where the cursor is now. Fires multiple times (depending on the speed of the computer and the user's drag action), alternating with the previous ondrag event.
ondrop	blank1	The span element gets the notification of a recent drop.
ondragend	cell A1	The original source element gets the final word that dragging is complete. This event fires even if the drag does not succeed because the drag does not end on a drop target.

To turn the blank span elements into drop targets, their ondragenter, ondragover, and ondrop event handlers must set event.returnValue to false; also, the event.dataTransfer .dropEffect property should be set to the desired effect (copy, in this case). These event handlers are placed in the p element that contains the two span elements, again for simplicity. Notice, however, that the cancelDefault() functions do their work only if the target element is one of the span elements whose ID begins with blank.

As the user releases the mouse button, the ondrop event handler invokes the handleDrop() function. This function retrieves the string data from event.dataTransfer and restores it to an array data type (using the String.split() method). A little bit of testing makes sure that the word type (noun or adjective) is associated with the desired blank. If so, the source element's text is set to the drop target's innerText property; otherwise, an error message is assembled to help the user know what went wrong.

         {
            if (passedData[1] == "adjective")
            {
               event.dataTransfer.dropEffect = "copy";
               event.srcElement.innerText = passedData[0];
            }
            else
            {
               errMsg = "You can't put a noun into the adjective placeholder.";
            }
         }
         if (errMsg)
         {
            alert(errMsg);
         }
      }
}

function cancelDefault()
{
   if (event.srcElement.id.indexOf("blank") == 0)
   {
      event.dataTransfer.dropEffect = "copy";
      event.returnValue = false;
   }
}
```

One event handler not shown in Listing 26-37 is `ondragend`. You can use this event to display the elapsed time for each successful drag operation. Because the event fires on the drag source element, you can implement it in the `<body>` tag and filter events similar to the way the `ondragstart` or `ondrag` event handlers filter events for the `td` element.

Related Items: `event.dataTransfer` object; `ondragenter`, `ondragleave`, `ondragover`, `ondrop` event handlers

ondragenter
ondragleave
ondragover

Compatibility: WinIE5+, MacIE-, NN-, Moz+, Safari 1.3+, Opera-, Chrome+

These events fire during a drag operation. When the cursor enters the rectangular space of an element on the page, the `ondragenter` event fires on that element. Immediately thereafter, the `ondragleave` event fires on the element from which the cursor came. Although this may seem to occur out of sequence from the physical action, the events always fire in this order. Depending on the speed of the client computer's CPU and the speed of the user's dragging action, one or the other of these events may not fire — especially if the physical action outstrips the computer's capability to fire the events in time.

The `ondragover` event fires continually while a dragged cursor is atop an element. In the course of dragging from one point on the page to another, the `ondragover` event target changes with the element beneath the cursor. If no other drag-related events are firing (the mouse button is still down in the drag operation, but the cursor is not moving), the `ondrag` and `ondragover` events fire continually, alternating between the two.

You should have the `ondragover` event handler of a drop target element set the `event.returnValue` property to `false`. See the discussion of the `ondrag` event handler earlier in this chapter for more details on the sequence of drag-related events.

Example

Listing 26-38 shows the `ondragenter` and `ondragleave` event handlers in use. The simple page displays (via the status bar) the time of entry to one element of the page. When the dragged cursor leaves the element, the `ondragleave` event handler hides the status-bar message. No drop target is defined for this page, so when you drag the item, the cursor remains the no-drop cursor.

ondragstart

(See `ondrag`)

ondrop

Compatibility: WinIE5+, MacIE-, NN-, Moz+, Safari 1.3+, Opera-, Chrome+

The `ondrop` event fires on the drop target element as soon as the user releases the mouse button at the end of a drag-and-drop operation. For IE, Microsoft recommends that you denote a drop target by applying the `ondragenter`, `ondragover`, and `ondrop` event handlers to the target element. In each of those event handlers, you should set the `dataTransfer.dropEffect` to the transfer effect you wish to portray in the drag-and-drop operation (signified by a different cursor for each type). These settings should match the `dataTransfer.effectAllowed` property that is usually set in the `ondragstart` event handler. Each of the three drop-related handlers should also override the default event behavior by setting the `event.returnValue` property to `false`. See the discussion of the `ondrag` event handler earlier in this chapter for more details on the sequence of drag-related events.

Example

See Listing 26-37 of the `ondrag` event handler to see how to apply the `ondrop` event handler in a typical drag-and-drop scenario.

onerrorupdate

Compatibility: WinIE4+, MacIE5+, NN-, Moz-, Safari-, Opera-, Chrome-

The `onerrorupdate` event handler is part of the data binding of IE and fires when an error occurs while updating the data in the data source object.

onfilterchange

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onfilterchange` event fires whenever an object's visual filter switches to a new state or a transition completes (a transition may be extended over time). Only objects that accommodate filters and transitions in IE (primarily block elements and form controls) receive the event.

A common usage of the `onfilterchange` event is to trigger the next transition within a sequence of transition activities. This may include an infinite loop transition, for which the object receiving the event toggles between two transition states. If you don't want to get into a loop of that kind, place the different sets of content in their own positionable elements, and use the `onfilterchange` event handler in one to trigger the transition in the other.

Example

Listing 26-39 demonstrates how the `onfilterchange` event handler can trigger a second transition effect after another one completes. The `onload` event handler triggers the first effect. Although the `onfilterchange` event handler works with most of the same objects in IE4 as IE5, the filter object transition properties are not reflected in a convenient form. The syntax shown in Listing 26-39 uses the more modern ActiveX filter control found in IE5.5+ (described in Chapter 38).

Related Item: `filter` object

onfocus

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `onfocus` event fires when an element receives focus, usually following some other object's losing focus. (The element losing focus receives the `onblur` event before the current object receives the `onfocus` event.) For example, a text input element fires the `onfocus` event when a user tabs to that element while navigating through a form via the keyboard. Clicking an element also gives that element focus, as does making the browser the frontmost application on the client desktop.

The availability of the `onfocus` event has expanded with succeeding generations of script-capable browsers. In earlier versions, blur and focus were largely confined to text-oriented input elements such as the `select` element. The `window` object received the `onfocus` event handler starting with NN3 and IE4. IE4 also extended the event handler to more form elements, predominantly on the Windows operating system because that OS has a user interface clue (the dotted rectangle) when items such as buttons and links receive focus (so that users may act on them by pressing the spacebar). For IE5+, the `onfocus` event handler is available to virtually every HTML element. For most of those elements, however, you cannot use blur and focus unless you assign a value to the `tabindex` attribute of the element's tag. For example, if you assign `tabindex="1"` inside a `<p>` tag, the user can bring focus to that paragraph (highlighted with the dotted rectangle in Windows) by clicking the paragraph or pressing the Tab key until that item receives focus in sequence.

WinIE5.5 adds the `onfocusin` event handler, which fires immediately before the `onfocus` event handler. You can use one or the other, but there is little need to include both event handlers for the same object unless you wish to block an item temporarily from receiving focus. To prevent an object from receiving focus in IE5.5+, include an `event.returnValue=false` statement in the `onfocusin` event handler for the same object. In other browsers, you can usually get away with assigning `onfocus="this.blur()"` as an event handler for elements such as form controls. However, this is not a foolproof way to prevent a user from changing a control's setting. Unfortunately, there are few reliable alternatives short of disabling the control.

Example

See Listing 26-34 earlier in this chapter for an example of the `onfocus` and `onblur` event handlers.

Related Items: `onactivate`, `onblur`, `ondeactivate`, `onfocusin`, `onfocusout` event handlers

onfocusin
onfocusout

Compatibility: WinIE6+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onfocusin` and `onfocusout` events fire to indicate that an element is about to receive focus or has just lost focus. These events are closely related to `onactivate` and `ondeactivate` except that in IE5.5+ activation and focus can be distinguished from each other. For example, if you set an element as the active element through `setActive()`, the element becomes active, but it does not gain the input focus. However, if you set the focus of an element with a call to `focus()`, the element is activated and gains input focus.

Related Items: `onactivate`, `onblur`, `ondeactivate`, `onfocus` event handlers

onhelp

Compatibility: WinIE4+, MacIE5+, NN-, Moz-, Safari-, Opera-, Chrome-

The `onhelp` event handler fires in Windows whenever an element of the document has focus and the user presses the F1 function key on a Windows PC. As of MacIE5, the event fires only on the window (in other words, event handler specified in the `<body>` tag) and does so via the dedicated Help key on a Mac keyboard. Browser Help menu choices do not activate this event. To prevent the browser's Help window from appearing, the event handler must evaluate to `return false` (for IE4+) or set the `event.returnValue` property to `false` (IE5+). Because the event handler can be associated with individual elements of a document in the Windows version, you can create a context-sensitive help system. However, if the focus is in the Address field of the browser window, you cannot intercept the event. Instead, the browser's Help window appears.

***elementObject*.onhelp**

Example

Listing 26-40 is a rudimentary example of a context-sensitive help system that displays help messages tailored to the kind of text input required by different text boxes. When the user gives focus to either of the text boxes, a small legend appears to remind the user that help is available by a press of the F1 help key. MacIE5 provides only generic help.

Related Items: `window.showHelp()`, `window.showModalDialog()` methods

onkeydown
onkeypress
onkeyup

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

When someone presses and releases a keyboard key, a sequence of three events fires in quick succession. The `onkeydown` event fires when the key makes its first contact. This is followed immediately by the `onkeypress` event. When contact is broken by the key release, the `onkeyup` event fires.

If you hold a character key down until it begins autorepeating, the `onkeydown` and `onkeypress` events fire with each repetition of the character.

The sequence of events can be crucial in some keyboard event handling. Consider the scenario that wants the focus of a series of text boxes to advance automatically after the user enters a fixed number of characters (for example, date, month, and two-digit year). By the time the `onkeyup` event fires, the character associated with the key-press action is already added to the box and you can accurately determine the length of text in the box, as shown in this simple example:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Simple entry form</title>
      <script type="text/javascript">
         function jumpNext(fromFld, toFld)
         {
            if (fromFld.value.length == 2)
            {
               document.dateForm.elements[toFld].focus();
               document.dateForm.elements[toFld].select();
            }
         }
      </script>
   </head>
   <body>
      <form name="dateForm">
         Month: <input name="month" type="text" size="3" value=""
                      onkeyup="jumpNext(this, 'day')" maxlength="2" />
         Day: <input name ="day" type="text" size="3" value=""
                    onkeyup ="jumpNext(this, 'year')" maxlength="2" />
         Year: <input name="year" type="text" size="3" value=""
                     onkeyup ="jumpNext(this, 'month')" maxlength="2" />
      </form>
   </body>
</html>
```

These three events do not fire for all keys of the typical PC keyboard on all browser versions that support keyboard events. The only keys that you can rely on supporting the events in all browsers shown in the preceding compatibility chart are the alphanumeric keys represented by ASCII values, including the spacebar and Enter (Return on the Mac), but excluding all function keys, arrow keys, and other navigation keys. Modifier keys, such as Shift, Ctrl (PC), Alt (PC), Command (Mac), and Option (Mac), generate some events on their own (depending on browser and version). However, functions invoked by other key events can always inspect the pressed states of these modifier keys.

Caution

The `onkeydown` event handler works in Mozilla-based browsers only starting with Mozilla 1.4 (and Netscape 7.1). ■

Scripting keyboard events almost always entails examining which key is pressed so that some processing or validation can be performed on that key press. This is where the situation gets very complex if you are writing for cross-browser implementation. In some cases, even writing just for Internet

Explorer gets tricky because nonalphanumeric keys generate only the `onkeydown` and `onkeyup` events.

In fact, to comprehend keyboard events fully, you need to make a distinction between *key codes* and *character codes*. Every PC keyboard key has a key code associated with it. This key code is always the same regardless of what other keys you press at the same time. Only the alphanumeric keys (letters, numbers, spacebar, and so on), however, generate character codes. The code represents the typed character produced by that key. The value might change if you press a modifier key. For example, if you press the A key by itself, it generates a lowercase *a* character (character code 97); if you also hold down the Shift key, that same key produces an uppercase *A* character (character code 65). The key code for that key (65 for Western-language keyboards) remains the same no matter what.

That brings us, then, to where these different codes are made available to scripts. In all cases, the code information is conveyed as one or two properties of the browser's `event` object. IE's `event` object has only one such property: `keyCode`. It contains key codes for `onkeydown` and `onkeyup` events but character codes for `onkeypress` events. The NN6+/Moz event object, on the other hand, contains two separate properties: `charCode` and `keyCode`. You can find more details and examples about these `event` object properties in Chapter 32.

The bottom-line script consideration is to use either `onkeydown` or `onkeyup` event handlers when you want to look for nonalphanumeric key events (for example, function keys, arrow and page-navigation keys, and so on). To process characters as they appear in text boxes, use the `onkeypress` event handler. You can experiment with these events and codes in Listing 26-41, as well as in examples from Chapter 32.

Common keyboard event tasks

WinIE4+ enables you to modify the character that a user who is editing a text box enters. The `onkeypress` event handler can modify the `event.keyCode` property and allow the event to continue (in other words, don't evaluate to `return false` or set the `event.returnValue` property to `false`). The following IE function (invoked by an `onkeypress` event handler) makes sure that text entered in a text box is all uppercase, even if you type it as lowercase:

```
function assureUpper()
{
   if (event.keyCode >= 97 && event.keyCode <= 122)
   {
      event.keyCode = event.keyCode - 32;
   }
}
```

Doing this might confuse (or frustrate) users, so think carefully before implementing such a plan.

To prevent a key press from becoming a typed character in a text box, the `onkeypress` event handler prevents the default action of the event. For example, the following HTML page shows how to inspect a text box's entry for numbers only:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Keyboard Capture</title>
      <script type="text/javascript">
```

```
            function checkIt(evt)
            {
               var charCode = (evt.charCode) ?
                     evt.charCode : ((evt.which) ? evt.which : evt.keyCode);
                  if (charCode > 31 && (charCode < 48 || charCode > 57))
                  {
                     alert("Please make sure entries are numbers only.");
                     return false;
                  }
               return true;
            }
         </script>
      </head>
      <body>
         <form>
            Enter any positive integer:
            <input type="text" name="numeric" onkeypress="return checkIt(event)">
         </form>
      </body>
   </html>
```

Whenever a user enters a non-number, the user receives a warning, and the character is not appended to the text box's text.

Keyboard events also enable you to script the submission of a form when a user presses the Enter (Return on the Mac) key within a text box. The ASCII value of the Enter/Return key is 13. Therefore, you can examine each key press in a text box and submit the form whenever value 13 arrives, as shown in the following function:

```
function checkForEnter(evt)
{
   evt = (evt) ? evt : event;
   var charCode = (evt.charCode) ?
         evt.charCode : ((evt.which) ? evt.which : evt.keyCode);

      if (charCode == 13)
         {
         document.forms[0].submit();
         return false;
         }
      return true;
}
```

By assigning the `checkForEnter()` function to each box's `onkeypress` event handler, you suddenly add some extra power to a typical HTML form.

You can intercept Ctrl+keyboard combinations (letters only) in HTML pages most effectively in IE, but only if the browser itself does not use the combination. In other words, you cannot redirect Ctrl+key combinations that the browser uses for its own control. The `onkeypress keyCode` value for Ctrl+key combinations ranges from 1 through 26 for letters A through Z (except for those used by the browser, in which case no keyboard event fires).

Example

Listing 26-41 is a working laboratory that you can use to better understand the way keyboard event codes and modifier keys work in IE5+ and W3C browsers. The actual code of the listing is less important than watching the page while you use it. For every key or key combination that you press, the page shows the `keyCode` value for the `onkeydown`, `onkeypress`, and `onkeyup` events. If you hold down one or more modifier keys while performing the key press, the modifier-key name is highlighted for each of the three events. Note that when run in NN6+/Moz-based browsers/WebKit-based browsers, the `keyCode` value is not the character code. In older browsers, you may need to click the page for the `document` object to recognize the keyboard events.

The best way to watch what goes on during keyboard events is to press and hold a key to see the key codes for the `onkeydown` and `onkeypress` events. Then release the key to see the code for the `onkeyup` event. Notice, for instance, that if you press the A key without any modifier key, the `onkeydown` event key code is 65 (A), but the `onkeypress` key code in IE (and the `charCode` property in NN6+/Moz-based browsers/WebKit-based browsers) is 97 (a). If you then repeat the exercise but hold the Shift key down, all three events generate the 65 (A) key code (and the Shift modifier labels are highlighted). Releasing the Shift key causes the `onkeyup` event to show the key code for the Shift key.

In another experiment, press any of the four arrow keys. No key code is passed for the `onkeypress` event because those keys don't generate those events. They do, however, generate `onkeydown` and `onkeyup` events.

Spend some time with this lab, and try all kinds of keys and key combinations until you understand the way the events and key codes work.

Related Item: `String.fromCharCode()` method

onlayoutcomplete

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onlayoutcomplete` event handler fires when a print or print-preview layout operation completes on the current layout rectangle (`LayoutRect` object). This event is primarily used as the basis for overflowing content from one page to another during printing. In response to the `onlayoutcomplete` event, the `contentOverflow` property can be inspected to determine whether page content has indeed overflowed the current layout rectangle.

onlosecapture

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onlosecapture` event handler fires whenever an object that has event capture turned on no longer has that capture. Event capture is automatically disengaged when the user performs any of the following actions:

- Gives focus to any other window
- Displays any system modal dialog box (for example, alert window)
- Scrolls the page
- Opens a browser context menu (right-clicking)
- Tabs to give focus to the Address field in the browser window

A function associated with the `onlosecapture` event handler should perform any cleanup of the environment due to an object's no longer capturing mouse events.

Example

See Listing 26-30 earlier in this chapter for an example of how to use `onlosecapture` with an event-capturing scenario for displaying a context menu. The `onlosecapture` event handler hides the context menu when the user performs any action that causes the menu to lose mouse capture.

Related Items: `releaseCapture()`, `setCapture()` methods

onmousedown
onmouseup

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `onmousedown` event handler fires when the user presses any button on a mouse. The `onmouseup` event handler fires when the user releases the mouse button, provided that the object receiving the event also received an `onmousedown` event. When a user performs a typical click of the mouse button atop an object, mouse events occur in the following sequence: `onmousedown`, `onmouseup`, and `onclick`. But if the user presses the mouse atop an object and then slides the cursor away from the object, only the `onmousedown` event fires.

These events enable authors and designers to add more applicationlike behavior to images that act as action or icon buttons. If you notice the way most buttons work, the appearance of the button changes while you press the mouse button and reverts to its original style when you release the mouse button (or you drag the cursor out of the button). These events enable you to emulate that behavior.

The event object created with every mouse button action has a property that reveals which mouse button the user pressed. NN4's event model called that property the `which` property. IE4+ and NN6+/Moz-based browsers/WebKit-based browsers call it the `button` property (but with different values for the buttons). It is most reliable to test for the mouse button number on either the `onmousedown` or `onmouseup` event rather than on `onclick`. The `onclick` event object does not always contain the button information.

Example

To demonstrate a likely scenario of changing button images in response to rolling atop an image, pressing down on it, releasing the mouse button, and rolling away from the image, Listing 26-42 presents a pair of small navigation buttons (left- and right-arrow buttons). Images are preloaded into the browser cache as the page loads so that response to the user is instantaneous the first time the user calls upon new versions of the images.

   return false;
}
```

Related Item: `onclick` event handler

onmouseenter
onmouseleave

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

WinIE5.5 introduced the `onmouseenter` and `onmouseleave` event handlers. Both event handlers operate just like the `onmouseover` and `onmouseout` event handlers, respectively. Microsoft simply offers an alternative terminology. The old and new events continue to fire in IE5.5+. The old ones fire just before the new ones for each act of moving the cursor atop, and exiting from atop, the object. If you are scripting exclusively for IE5.5+, you should use the new terminology; otherwise, stay with the older versions.

Example

You can modify Listing 26-43 with the IE5.5 syntax by substituting `onmouseenter` for `onmouseover` and `onmouseleave` for `onmouseout`. The effect is the same.

Related Items: `onmouseover`, `onmouseout` event handlers

onmousemove

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `onmousemove` event handler fires whenever the cursor is atop the current object and the mouse is moved, even by a single pixel. You do not have to press the mouse button for the event to fire, although the event is most commonly used in element dragging — especially in NN/FF3.4-/Opera, where no `ondrag` event handler is available.

Even though the granularity of this event can be at the pixel level, you should not use the number of event firings as a measurement device. Depending on the speed of cursor motion and the performance of the client computer, the event may not fire at every pixel location.

In IE4+ and W3C DOM-compatible browsers, you can assign the `onmousemove` event handler to any element (although you can drag only with positioned elements). When designing a page that encourages users to drag multiple items on a page, it is most common to assign the `onmousemove` event handler to the `document` object and let all such events bubble up to the document for processing.

Example

See Chapter 43 and Chapter 59 on the CD-ROM for examples of using mouse events to control element dragging on a page.

Related Items: `ondrag`, `onmousedown`, `onmouseup` event handlers

onmouseout
onmouseover

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `onmouseover` event fires for an object whenever the cursor rolls into the rectangular space of the object on the screen. The `onmouseout` event handler fires when you move the cursor outside the object's rectangle. These events most commonly display explanatory text about an object in the window's status bar and effect image swapping (so-called mouse rollovers). Use the `onmouseover` event handler to change the state to a highlighted version; use the `onmouseout` event handler to restore the image or status bar to its normal setting.

Although these two events have been in object models of scriptable browsers since the beginning, they were not available to most objects in earlier browsers. IE4+ and W3C DOM-compatible browsers provide support for these events on every element that occupies space onscreen. IE5.5+ includes an additional pair of event handlers — `onmouseenter` and `onmouseleave` — that duplicates the `onmouseover` and `onmouseout` events but with different terminology. The old event handlers fire just before the new versions.

Note

The `onmouseout` event handler commonly fails to fire if the event is associated with an element that is near a frame or window edge and the user moves the cursor quickly outside the current frame. ■

Example

Listing 26-43 uses the U.S. Pledge of Allegiance with four links to demonstrate how to use the `onmouseover` and `onmouseout` event handlers. Notice that for each link, the handler runs a general-purpose function that sets the window's status message. The function returns a `true` value, which the event handler call evaluates to replicate the required `return true` statement needed for setting the status bar. In one status message, we supply a URL in parentheses to let you evaluate how helpful you think it is for users.

         onmouseout="return setStatus('')">flag</a>
      of the
      <a href="javascript:emulate()"
         onmouseover="return setStatus('View info about the U.S. government')"
         onmouseout="return setStatus('')">United States of America</a>,
      and to the Republic for which it stands, one nation
      <a href="javascript:emulate()"
         onmouseover="return setStatus('Read about the history of this phrase↩
            in the Pledge')"
         onmouseout="return setStatus('')">under God</a>,
      indivisible, with liberty and justice for all.
   </body>
</html>
```

JavaScript: jsb26-43.js

```
function setStatus(msg)
{
   window.status = msg;
   return true;
}

// destination of all link HREFs
function emulate()
{
   alert("Not going there in this demo.");
}
```

Related Items: `onmouseenter`, `onmouseleave`, `onmousemove` event handlers

onmousewheel

Compatibility: WinIE6+, MacIE-, NN-, Moz+, Safari+, Opera+, Chrome+

The `onmousewheel` event handler fires in response to the user's rotating the mouse wheel. When responding to the `onmousewheel` event, you can check the `wheelDelta` property to find out how far the mouse wheel has been rotated. The `wheelDelta` property expresses mouse wheel rotations in multiples of 120, with positive values indicating a rotation away from the user and negative values corresponding to a rotation toward the user. The W3C equivalent is `DOMMouseScroll`.

Related Item: `onmousemove` event handler

onmove

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Not to be confused with `onmousemove`, the `onmove` event has nothing to do with the mouse. Instead, the `onmove` event is fired whenever a positionable *element* is moved. For example, if a `div` element is created as an absolutely positioned moveable element, you can track its movement by responding to the `onmove` event. The `offsetLeft` and `offsetTop` properties can be used within this event handler to determine the exact location of the element as it is moving.

Related Items: `onmoveend`, `onmovestart` event handlers

onmoveend
onmovestart

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onmovestart` and `onmoveend` event handlers fire in response to a positionable element's being moved on a page. More specifically, the `onmovestart` event is triggered when an element first starts moving and the `onmoveend` event fires when the element stops moving. In between the `onmovestart` and `onmoveend` events firing, multiple `onmove` events may be sent out to indicate the movement of the element.

Related Item: `onmove` event handler

onpaste

Compatibility: WinIE5+, MacIE-, NN-, Moz+, Safari 1.3+, Opera-, Chrome+

The `onpaste` event fires immediately after the user or script initiates a paste edit action on the current object. The event is preceded by the `onbeforepaste` event, which fires prior to any edit or context menu that appears (or before the paste action if initiated by keyboard shortcut).

Use this event handler to provide edit functionality to elements that don't normally allow pasting. In such circumstances, you need to enable the Paste menu item in the context or Edit menu by setting the `event.returnValue` for the `onbeforepaste` event handler to `false`. Then your `onpaste` event handler must manually retrieve data from the clipboard (by way of the `getData()` method of the IE `clipboardData` object) and handle the insertion into the current object.

Because you are in charge of what data is stored in the clipboard, you are not limited to a direct copy of the data. For example, you might wish to store the value of the `src` property of an image object so that you can paste it elsewhere on the page.

Example

Listing 26-44 demonstrates how to use the `onbeforepaste` and `onpaste` event handlers (in conjunction with `onbeforecopy` and `oncopy`) to let scripts control the data-transfer process during a copy-and-paste user operation. A table contains words to be copied (one column of nouns, one column of adjectives) and then pasted into blanks in a paragraph. The `onbeforecopy` and `oncopy` event handlers are assigned to the `table` element because the events from the `td` elements bubble up to the `table` container and there is less HTML code to contend with.

Inside the paragraph, two `span` elements contain underscored blanks. To paste text into the blanks, the user must first select at least one character of the blanks. (See Listing 26-37, which gives a drag-and-drop version of this application.) The `onbeforepaste` event handler in the paragraph (which gets the event as it bubbles up from either `span`) sets the `event.returnValue` property to `false`, thus allowing the Paste item to appear in the context and Edit menus (not a normal occurrence in HTML body content).

At paste time, the `innerHTML` property of the target `span` is set to the text data stored in the clipboard. The `event.returnValue` property is set to `false` here as well to prevent normal system pasting from interfering with the controlled version.

}
```

Related Items: `oncopy`, `oncut`, `onbeforepaste` event handlers

onpropertychange

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onpropertychange` event fires in WinIE5+ whenever a script modifies an object's property. This includes changes to the properties of an object's style. Changing properties by way of the `setAttribute()` method also triggers this event.

A script can inspect the nature of the property change because the `event.propertyName` property contains the name (as a string) of the property that was just changed. In the case of a change to an object's `style` object, the `event.propertyName` value begins with `"style."` as in `style.backgroundcolor`.

You can use this event handler to localize any object-specific postprocessing of changes to an object's properties. Rather than include the postprocessing statements inside the function that makes the changes, you can make that function generalized (perhaps to modify properties of multiple objects).

Example

Listing 26-45 shows how you can respond programmatically to an object's properties being changed. The page generated by the listing contains four radio buttons that alter the `innerHTML` and `style.color` properties of a paragraph. The paragraph's `onpropertychange` event handler invokes the `showChange()` function, which extracts information about the event and displays the data in the status bar of the window. Notice that the property name includes `style.` when you modify the style sheet property.

   msg += " object has changed to \"" + newValue + "\".";
   alert(msg);
}
```

Related Items: `style` property; `setAttribute()` method

onreadystatechange

Compatibility: WinIE4+, MacIE-, NN7+, Moz1.0.1+, Safari 1.2+, Opera+, Chrome+

The `onreadystatechange` event handler fires whenever the ready state of an object changes. See details about these states in the discussion of the `readyState` property earlier in this chapter (and notice the limits for IE4). The change of state does not guarantee that an object is in fact ready for script statements to access its properties. Always check the `readyState` property of the object in any script that the `onreadystatechange` event handler invokes.

This event fires for objects that are capable of loading data: `applet`, `document`, `frame`, `frameset`, `iframe`, `img`, `link`, `object`, `script`, and XML objects. The event doesn't fire for other types of objects unless a Microsoft DHTML behavior is associated with the object. The `onreadystatechange` event does not bubble; neither can you cancel it.

Related Item: `readyState` property

onresize

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `onresize` event handler fires whenever an object is resized in response to a variety of user or scripted actions. Most elements include this event handler, provided that the object has dimensional style attributes (for example, height, width, or position) assigned to it.

The `onresize` event does not bubble. Resizing the browser window or frame does not cause the window's `onload` event handler to fire.

Example

If you want to capture the user's resizing of the browser window (or frame), you can assign a function to the `onresize` event handler either via script

```
window.onresize = handleResize;
```

or by an HTML attribute of the `body` element:

```
<body onresize="handleResize()">
```

Related Item: `window.resize()` method

onresizeend
onresizestart

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onresizeend` and `onresizestart` event handlers fire only on a resizable object in Windows edit mode.

Related Item: `oncontrolselect` event handler

onrowenter
onrowexit

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onrowenter` and `onrowexit` events fire in response to changes in the current row of recordset data in IE data binding. More specifically, `onrowenter` is triggered when the data for the current row of data has changed and new data is available on the data source object. The `onrowexit` event is triggered when the current row is changing, meaning that another row of data is being selected; the event is fired just before the row changes.

Related Items: `onrowsdelete`, `onrowsinserted` event handlers

onrowsdelete
onrowsinserted

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onrowsdelete` event fires when one or more rows of data are about to be deleted from the recordset in IE data binding. Conversely, the `onrowsinserted` event is triggered when one or more rows of data have been inserted into the recordset.

Related Items: `onrowenter`, `onrowexit` event handlers

onscroll

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera_, Chrome+

The `onscroll` event handler fires whenever the scroll box within a scroll bar of an element is repositioned. In simpler terms, when the user clicks and drags the scroll box with the mouse, the `onscroll` event is fired. That's not the only action that triggers the event, however. An `onscroll` event is also fired in response to the user's clicking the scroll arrow, clicking the scroll bar, or pressing any of the following keys: Home, End, Space, Page Up, or Page Down. A call to the `doScroll()` method also triggers the event, as does the user's holding down the Up Arrow or Down Arrow key.

Related Item: `doScroll()` method

onselectstart

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari 1.3+, Opera-, Chrome+

The `onselectstart` event handler fires when a user begins to select content on the page. Selected content can be inline text, images, or text within an editable text box. If the user selects more than one object, the event fires in the first object affected by the selection.

Example

Use the page from Listing 26-46 to see how the `onselectstart` event handler works when a user selects across multiple elements on a page. As the user begins a selection anywhere on the page, the ID of the object receiving the event appears in the status bar. Notice that the event doesn't fire until you actually make a selection. When no other element is under the cursor, the `body` element fires the event.

CHAPTER 27

Window and Frame Objects

IN THIS CHAPTER

Scripting communication among multiple frames

Creating and managing new windows

Controlling the size, position, and appearance of the browser window

Details of window, frame, frameset, and iframe objects

A quick look at the basic document object model diagram in Chapter 25, "Document Object Model Essentials," (refer to Figure 25-1) reveals that the `window` object is the outermost global container of all document-related objects that you script with JavaScript. All HTML and JavaScript activity takes place inside a window. That window may be a standard Windows, Mac, or XWindows application-style window, complete with scroll bars, toolbars, and other chrome; you can also generate windows that have only some of a typical window's chrome. A frame is also a window, even though a frame doesn't have many accoutrements beyond scroll bars. The `window` object is where everything begins when JavaScript references objects. Modern browsers treat the frameset as a special kind of `window` object, so it is also covered in this chapter.

Of all the objects associated with browser scripting, the `window` and window-related objects have by far the most object-specific terminology associated with them. This necessitates a rather long chapter to keep the whole discussion in one place.

Window Terminology

The `window` object is often a source of confusion when you first learn about the document object model. A number of synonyms for `window` objects muck up the works: `top`, `self`, `parent`, and `frame`. Aggravating the situation is the fact that these terms are also properties of a `window` object. Under some conditions, a window is its own parent, but if you define a frameset with two frames, you have only one parent among a total of three `window` objects. It doesn't take long before the whole subject can make your head hurt.

If you do not use frames in your web applications, these headaches never appear. But if frames are part of your design plan, you should get to know how frames affect the object model.

Frames

The application of frames has become a religious issue among web designers: Some swear by them; others swear at them. We believe, after careful consideration, that there can be compelling reasons to use frames at times. Historically, any humungous document with a hierarchy, or that depends on a file system, might be a good candidate. For example, if you have a document that requires considerable scrolling to get through, you may want to maintain a static set of navigation controls that are visible at all times. By placing those controls — be they links or image maps — in a separate frame, you have made the controls available for immediate access, regardless of the scrolled condition of the main document. However, you could use an Ajax framework to provide such navigational controls instead of using HTML frames. Be aware that creating bookmarks and printing documents in frames can range anywhere from impossible to difficult. Frames can be a problem for folks with disabilities. Most web designers provide an alternative flat HTML document with links for those types of situations.

Creating frames

The task of defining frames in a document remains the same whether or not you're using JavaScript. The simplest framesetting document consists of tags that are devoted to setting up the frameset, as follows:

```
<html>
    <head>
      <title>My Frameset</title>
    </head>
<frameset>
    <frame name="Frame1" src="document1.html">
    <frame name="Frame2" src="document2.html">
</frameset>
</html>
```

The preceding HTML document, which the user never sees, defines the frameset for the entire browser window. Each frame must have a URL reference (specified by the `src` attribute) for a document to load into that frame. Assigning a name to each frame with the `name` attribute greatly simplifies the scripting of frame content.

The frame object model

Perhaps the key to successful frame scripting is understanding that the object model in the browser's memory at any given instant is determined by the HTML tags in the currently loaded documents. All canned object model graphics in this book, such as Figure 27-1, do not reflect the precise object model for your document or document set.

For a single, frameless document, the object model starts with just one `window` object, which contains one document, as shown in Figure 27-1. In this simple structure, the `window` object is the starting point for all references to any loaded object. Because the window is always there — it must be there for a document to load into — a reference to any object in the document can omit a reference to the current window.

In a simple two-framed frameset model (see Figure 27-2), the browser treats the container of the initial, framesetting, document as the parent window. The only visible evidence that the document exists is the framesetting document's title in the browser window title bar.

FIGURE 27-1

The simplest window-document relationship.

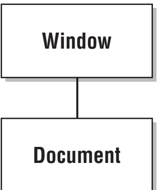

FIGURE 27-2

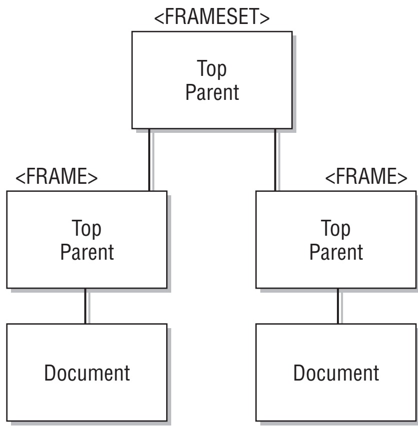
The parent and frames are part of the object model.

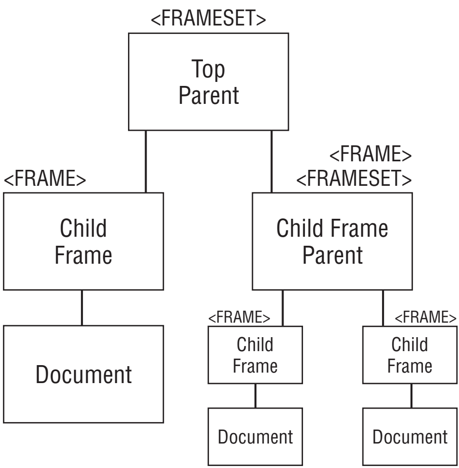


Each `<frame>` tag inside the `<frameset>` tag set creates another `window` object into which a document is loaded. Each of those frames, then, has a `document` object associated with it. From the point of view of a given document, it has a single window container, just as in the model shown in Figure 27-1. And although the `parent` object is not visible to the user, it remains in the object model in memory. The presence of the parent often makes it a convenient repository for variable data that needs to be shared by multiple child frames, or that must persist between loading different documents inside a child frame.

In even more complex arrangements, as shown in Figure 27-3, a child frame itself may load a framesetting document. In this situation, the difference between the `parent` and `top` objects starts to come into focus. The top window is the only one in common with all frames in Figure 27-3. As you see in a moment, when frames need to communicate with other frames (and their documents), you must fashion references to the distant object via the `window` object that they all have in common.

FIGURE 27-3

Three generations of window objects.



Referencing frames

The purpose of an object reference is to help JavaScript locate the desired object in the object model currently held in memory. A reference is a road map for the browser to follow so that it can track down, say, the value of a particular text field in a particular document. Therefore, when you construct a reference, think about where the script appears in the object model and how the reference can help the browser determine where it should go to find the distant object. In a two-generation scenario, such as the one shown in Figure 27-2, three intergenerational references are possible:

- Parent-to-child
- Child-to-parent
- Child-to-child

Assuming that you need to access an object, function, or variable in the relative's frame, the following are the corresponding reference structures: `frameName.objFuncVarName`, `parent.objFuncVarName`. and `parent.frameName.objFuncVarName`.

The rule is this: Whenever a reference must point to another frame, begin the reference with the `window` object that the two destinations have in common. To demonstrate that rule on the complex model in Figure 27-3, if the left child frame's document needs to reference the document at the bottom right of the map, the reference structure is

```
top.frameName.frameName.document. ...
```

Follow the map from the top `window` object, down through two frames, to the final document. JavaScript has to take this route, so your reference must help it along.

Top versus parent

After seeing the previous object maps and reference examples, you may be wondering, Why not use top as the leading object in all transframe references? From an object model point of view, you'll have no problem doing that: A parent in a two-generation scenario is also the top window. What you can't count on, however, is your framesetting document's always being the top window object in someone's browser. Take the instance where a web site loads other web sites into one of its frames. At that instant, the top window object belongs to someone else. If you always specify top in references intended just for your parent window, your references won't work, and will probably lead to script errors for the user. Our advice, then, is to use parent in references whenever you mean one generation above the current document.

Preventing framing

You can use your knowledge of top and parent references to prevent your pages from being displayed inside another web site's frameset. Your top-level document must check whether it is loaded into its own top, or parent, window. When a document is in its own top window, a reference to the top property of the current window is equal to a reference to the current window (the window synonym self seems most grammatically fitting here). If the two values are not equal, you can script your document to reload itself as a top-level document. When it is critical that your document be a top-level document, include the script in Listing 27-1 in the head portion of your document:

LISTING 27-1

Preventing a Document from Getting Framed

```
<script type="text/javascript">
   if (top != self)
   {
      top.location = location;
   }
</script>
```

Your document may appear momentarily inside the other site's frameset, but then the slate is wiped clean, and your top-level document rules the browser window.

Ensuring framing

When you design a web application around a frameset, you may want to make sure that a page always loads the complete frameset. Consider the possibility that a visitor adds only one of your frames to a bookmarks list. On the next visit, only the bookmarked page appears in the browser, without your frameset, which may contain valuable navigation aids to the site.

A script can make sure that a page always loads into its frameset by comparing the URLs of the top and self windows. If the URLs are the same, it means that the page needs to load the frameset. Listing 27-2 shows the simplest version of this technique, which loads a fixed frameset. For a more complete implementation that passes a parameter to the frameset so that it opens a specific page in one of the frames, see the location.search property in Chapter 28, "Location and History Objects."

LISTING 27-2

Forcing a Frameset to Load

```
<script type="text/javascript">
   if (top.location.href == window.location.href)
   {
      top.location.href = " myFrameset.html";
   }
</script>
```

Switching from frames to frameless

Some sites load themselves in a frameset by default, and offer users the option of getting rid of the frames. Modern browsers let you modify a frameset's `cols` or `rows` properties on the fly to simulate adding or removing frames from the current view (see the `frameset` element object later in this chapter). Legacy browsers, on the other hand, don't allow you to change the makeup of a frameset dynamically after it has loaded, but you can load the content page of the frameset into the main window. The workaround for older browsers is to include a button or link whose action loads that document into the `top` window object:

```
top.location.href = "mainBody.html";
```

A switch back to the frame version entails nothing more complicated than loading the framesetting document.

Inheritance versus containment

Scripters who have experience in object-oriented programming environments probably expect frames to inherit properties, methods, functions, and variables, defined in a parent object. That's not the case with scriptable browsers. You can, however, still access those parent items when you make a call to the item with a complete reference to the parent. For example, if you want to define a deferred function in the framesetting parent document that all frames can share, the scripts in the frames refer to that function with this reference:

```
parent.myFunc()
```

You can pass arguments to such functions and expect returned values.

Frame synchronization

A pesky problem for some scripters' plans is that including immediate scripts in the framesetting document is dangerous. Such scripts tend to rely on the presence of documents in the frames being created by this framesetting document. But if the frames have not yet been created, and their documents have not yet loaded, the immediate scripts will likely crash and burn.

One way to guard against this problem is to trigger all such scripts from the frameset's `onload` event handler. In theory, this handler won't trigger until all documents have successfully loaded into the child frames defined by the frameset. At the same time, be careful with `onload` event handlers in the

documents that go into a frameset's frames. If one of those scripts relies on the presence of a document in another frame (one of its brothers or sisters), you're doomed to eventual failure. Anything coming from a slow network or server to a slow modem can get in the way of other documents loading into frames in the ideal order.

One way to work around these problems is to create a Boolean variable in the parent document to act as a flag for the successful loading of subsidiary frames. When a document loads into a frame, its `onload` event handler can set that flag to `true` to indicate that the document has loaded. Any script that relies on a page being loaded should use an `if` construction to test the value of that flag before proceeding.

It is best to construct the code so that the parent's `onload` event handler triggers all the scripts that you want to run after loading. You should also test your pages thoroughly for any residual effects that may accrue if someone resizes a window or clicks Reload.

Blank frames

Often, you may find it desirable to create a frame in a frameset, but not put any document in it until the user has interacted with various controls or other user interface elements in other frames. Most modern browsers have a somewhat empty document in one of their internal URLs (`about:blank`). However, this URL is not guaranteed to be available on all browsers. If you need a blank frame, let your framesetting document write a generic HTML document to the frame directly from the `src` attribute for the frame, as shown in the skeletal code in Listing 27-3. Loading an empty HTML document requires no additional transactions.

LISTING 27-3

Creating a Blank Frame

```
<html>
   <head>
      <script type="text/javascript">
      <! —
         function blank()
         {
            return "<html></html>";
         }
      // — >
      </script>
   </head>
   <frameset>
      <frame name="Frame1" src="someURL.html">
      <frame name="Frame2" src="javascript:parent.blank()">
   </frameset>
</html>
```

Viewing frame source code

Studying other scripters' work is a major tool for learning JavaScript (or any programming language). With most scriptable browsers, you can easily view the source code for any frame, including those

frames whose content is generated entirely, or in part, by JavaScript. Click the desired frame to activate it (a subtle border may appear just inside the frame on some browser versions, but don't be alarmed if the border doesn't appear). Then select Frame Source (or equivalent) from the View menu (or from the right-click submenu). You can also print or save a selected frame.

Frames versus frame element objects

With the expansion of object models that expose every HTML element to scripting, a terminology conflict comes into play. Everything that you have read about frames thus far in the chapter refers to the original object model, where a frame is just another kind of window with a slightly different referencing approach. That still holds true, even in the latest browsers.

But when the object model also exposes HTML elements, the notion of the `frame` element object is somewhat distinct from the frame object of the original model. The `frame` element object represents an object whose properties are dominated by the attributes you set inside the `<frame>` tag. This provides access to settings, such as the frame border and scrollability — the kinds of properties that are not exposed to the original frame object.

References to the frame and `frame` element objects are also different. You've seen plenty of examples of how to reference an old-fashioned frame earlier in this chapter. But access to a `frame` element object is either via the element's `id` attribute or through the child node relationship of the enclosing `frameset` element (you cannot use the `parentNode` property to back your way out of the current document to the `frame` element that encloses the document). The strategy we prefer is assigning an `id` attribute to `<frame>` tags and accessing the `frame` element object by way of the `document` object that lives in the parent (or top) of the frameset hierarchy. Therefore, to access the `frameBorder` property of a `frame` element object from a script living in any frame of a frameset, the syntax is

```
parent.document.all.frame1ID.frameBorder
```

or (for IE5+/Moz/W3C)

```
parent.document.getElementById("frame1ID").frameBorder
```

When the reference goes through the `frame` element object, you can still reach the document object in that frame via the element object's `contentWindow` or `contentDocument` properties (see the `frame` element object later in this chapter).

Syntax

Creating a window:

```
var windowObject = window.open([parameters]);
```

Accessing window properties or methods:

```
window.property | method([parameters])

self.property | method([parameters])

windowObject.property | method([parameters])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

About this object

The `window` object has the unique position of being at the top of the object hierarchy, encompassing even the almighty `document` object. This exalted position gives the `window` object a number of properties and behaviors unlike those of any other object.

Chief among its unique characteristics is that because everything takes place in a window, you can usually omit the `window` object from object references. You've seen this behavior in previous chapters when we invoked document methods, such as `document.write()`. The complete reference is `window.document.write()`. But because the activity was taking place in the window that held the document running the script, that window was assumed to be part of the reference. For single-frame windows, this concept is simple enough to grasp.

As previously stated, among the list of properties for the `window` object is one called `self`. This property is synonymous with the `window` object itself (which is why it shows up in hierarchy diagrams as an object). Having a property of an object that is the same name as the object may sound confusing, but this situation is not that uncommon in object-oriented environments. We discuss the reasons why you may want to use the `self` property as the window's object reference in the `self` property description that follows.

As indicated earlier in the syntax definition, you don't always have to create a `window` object specifically in JavaScript code. Your browser usually opens a window after you start it up. That window is a valid `window` object, even if the window is blank. Therefore, after a user loads your page into the browser, the `window` object part of that document is automatically created for your script to access as it pleases.

One conceptual trap to avoid is believing that a `window` object's event handler or custom property assignments outlive the document whose scripts make the assignments. Except for some obvious physical properties of a window, each new document that loads into the window starts with a clean slate of window properties and event handlers.

Your script's control over an existing (already open) window's user interface elements varies widely with the browser and browser version for which your application is intended. Before the version 4 browsers, the only change you could make to an open window was to the status line at the bottom of the browser window. Version 4 browsers added the ability to control such properties as the size, location, and (with signed scripts in Navigator and Mozilla) the presence of chrome elements (toolbars and scroll bars, for example) on the fly. Many of these properties can be changed beyond specific safe limits only if you cryptographically sign the scripts (see Chapter 49, "Security and Netscape Signed Scripts," on the CD-ROM) and/or the user grants permission for your scripts to make those modifications.

Window properties are far more flexible on all browsers when your scripts generate a new window (with the `window.open()` method): You can influence the size, toolbar, or other view options of a

window. Recent browser versions provide even more options for new windows, including the position of the window and whether the window should display a title bar. Again, if an option can conceivably be used to deceive a user (for example, silently hiding one window that monitors activity in another window), signed scripts and/or user permission are necessary.

The `window` object is also the level at which a script asks the browser to display any of three styles of dialog boxes (a plain alert dialog box, an OK/Cancel confirmation dialog box, or a prompt for user text entry). Although dialog boxes are extremely helpful for cobbling together debugging tools for your own use (see Chapter 48, "Debugging Scripts," on the CD-ROM), they can be very disruptive to visitors who navigate through web sites. Because most JavaScript dialog boxes are modal (that is, you cannot do anything else in the browser until you dismiss the dialog box), use them sparingly, if at all. Remember that some users may create macros on their computers to visit sites unattended. Should such an automated visitor to your site encounter a modal dialog box, it is trapped on your page until a human intervenes.

All dialog boxes generated by JavaScript identify themselves as being generated by JavaScript. This is primarily a security feature to prevent deceitful scripts from creating system- or application-style dialog boxes that convince visitors to enter private information. It should also discourage dialog box usage in web-page design. And that's good, because dialog boxes tend to annoy users.

With the exception of the IE- and Safari-specific modal, and IE-specific modeless, dialog boxes (see the `window.showModalDialog()` and `window.showModeless()` methods), JavaScript dialog boxes are not particularly flexible in letting you fill them with text or graphic elements beyond the basics. In fact, you can't even change the text of the dialog-box buttons or add buttons. With Dynamic HTML (DHTML)-capable browsers, you can use positioned `div` or `iframe` elements to simulate dialog-box behavior in a cross-browser way.

With respect to the W3C DOM, the window is outside the scope of the standard through DOM Level 2. The closest that the standard comes to acknowledging a window at all is the `document.defaultView` property, which evaluates to the `window` object in today's browsers (predominantly Mozilla). But the formal DOM standard specifies no properties or methods for this view object.

Properties

appCore
components[]
content
controllers[]
prompter
sidebar

Values: (See text) Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera-, Chrome-

NN6+/Mozilla provide scriptable access to numerous services that are part of the xpconnect package (*xp* stands for *cross-platform*), which is part of the larger NPAPI (Netscape Plugin Application Programming Interface). The xpconnect services allow scripts to work with COM objects and the mozilla.org XUL (XML-based User Interface Language) facilities — lengthy subjects that extend well beyond the scope of this book. You can begin to explore this subject within the context of Mozilla-based browsers and scripting at `http://www.mozilla.org/scriptable/`.

clientInformation

Value: navigator object Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari 1.2+, Opera-, Chrome+

In an effort to provide scriptable access to browser-level properties while avoiding reference to the Navigator browser brand, Microsoft created the clientInformation property. Its value is identical to that of the navigator object — an object name that is also available in IE. Although Safari 1.2 adopted usage of the clientInformation property, you should use the navigator object for cross-browser applications. (See Chapter 42, "The Navigator and Other Environment Objects," on the CD-ROM.)

Related Item: navigator object

clipboardData

Value: Object Read/Write

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Use the clipboardData object to transfer data for such actions as cutting, copying, and pasting under script control. The object contains data of one or more data types associated with a transfer operation. Use this property only when editing processes via the Edit menu (or keyboard equivalents) or the context menu controlled by script — typically in concert with edit-related event handlers.

Working with the clipboardData object requires knowing about its three methods, shown in Table 27-1. Familiarity with the edit-related event handlers (before and after versions of cut, copy, and paste) is also helpful (see Chapter 26).

TABLE 27-1

window.clipboardData Object Methods

Method	Returns	Description
clearData([*format*])	Nothing	Removes data from the clipboard. If no format parameter is supplied, all data is cleared. Data formats can be one or more of the following strings: Text, URL, File, HTML, Image.
getData(*format*)	String	Retrieves data of the specified format from the clipboard. The format is one of the following strings: Text, URL, File, HTML, Image. The clipboard is not emptied when you get the data so that the data can be retrieved in several sequential operations.
setData(*format*, *data*)	Boolean	Stores string data in the clipboard. The format is one of the following strings: Text, URL, File, HTML, Image. For nontext data formats, the data must be a string that specifies the path or URL to the content. Returns true if the transfer to the clipboard is successful.

You cannot use the clipboardData object to transfer data between pages that originate from different domains or arrive via different protocols (http versus https).

Example

See Listings 26-36 and 26-44 in Chapter 26, "Generic HTML Element Objects," to see how the `clipboardData` object is used with a variety of edit-related event handlers.

Related Items: `event.dataTransfer` property; `onbeforecopy`, `onBeforeCut`, `onbeforepaste`, `oncopy`, `oncut`, `onpaste` event handlers

closed

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

When you create a subwindow with the `window.open()` method, you may need to access object properties from that subwindow, such as setting the value of a text field. Access to the subwindow is via the `window` object reference that is returned by the `window.open()` method, as in the following code fragment:

```
var newWind = window.open("someURL.html","subWind");
...
newWind.document.entryForm.ZIP.value = "00000";
```

In this example, the `newWind` variable is not linked live to the window, but is only a reference to that window. If the user should close the window, the `newWind` variable still contains the reference to the now-missing window. Thus, any script reference to an object in that missing window will likely cause a script error. What you need to know before accessing items in a subwindow is whether the window is still open.

The `closed` property returns `true` if the `window` object has been closed, either by script or by the user. Any time you have a script statement that can be triggered after the user has an opportunity to close the window, test for the `closed` property before executing that statement.

Example

Listing 27-4 is a basic window-opening and window-closing example. The script begins by initializing a global variable, `newWind`, which is used to hold the object reference to the second window. This value needs to be global so that other functions can reference the window for tasks, such as closing.

For this example, the new window contains some HTML code written dynamically to it, rather than loading an existing HTML file into it. Therefore, the URL parameter of the `window.open()` method is left as an empty string. Next comes a brief delay to allow Internet Explorer (especially versions 3 and 4) to catch up with opening the window, so that content can be written to it. The delay (using the `setTimeout()` method described later in this chapter) invokes the `finishNewWindow()` function, which uses the global `newWind` variable to reference the window for writing. The `document.close()` method closes writing to the document — a different kind of close from a window close. A separate function, `closeWindow()`, is responsible for closing the subwindow.

As a final test, an `if` condition looks at two conditions: (1) whether the `window` object has ever been initialized with a value other than `null` (in case you click the window-closing button before ever having created the new window) and (2) whether the window's `closed` property is `null` or `false`. If either condition is true, the `close()` method is sent to the second window.

Note

This is a simple example, so the property assignment event-handling technique employed uses the more modern approach of binding events, using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. This modern, cross-browser event-handling technique is explained in detail in Chapter 32, "Event Objects." The event-handling technique employed throughout most of the code in this chapter and much of the book is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events, as we do in this example. ■

LISTING 27-4

Checking Before Closing a Window

```
HTML: jsb27-04.html

<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>window.closed Property</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb27-04.js"></script>
   </head>
   <body>
      <h1>window.closed Property</h1>
      <hr />
      <p>The new window might open behind this window.</p>
      <form id="newWinForm" name="newWinForm">
         <input id="openNewWin" name="openNewWin" type="button"
                value="Open Window" />
         <br />
         <input id="closeNewWin" name="closeNewWin" type="button"
                value="Close it if Still Open" />
      </form>
   </body>
</html>

JavaScript: jsb27-04.js

// initialize when the page has loaded
addEvent(window, "load", initialize);

// global variables
   var oNewWinForm;
   var oOpenNewWin;
   var oCloseNewWin;

// initialize global var for new window object
// so it can be accessed by all functions on the page
var newWind;
```

continued

LISTING 27-4 *(continued)*

```
function initialize ()
{
   // get IE4+ or W3C DOM reference for an ID
   if (document.getElementById)
   {
      oNewWinForm = document.getElementById("newWinForm");
      oOpenNewWin = document.getElementById("openNewWin");
      oCloseNewWin = document.getElementById("closeNewWin");
   }
   else
   {
      oNewWinForm = document.newWinForm;
      oOpenNewWin = document.oNewWinForm.openNewWin;
      oCloseNewWin = document.oNewWinForm.closeNewWin;
   }
   addEvent(oOpenNewWin, 'click', newWindow);
   addEvent(oCloseNewWin, 'click', closeWindow);
}

// make the new window and put some stuff in it
function newWindow()
{
   newWind = window.open("","subwindow","height=200,width=200");
   setTimeout("finishNewWindow()", 100);
}
function finishNewWindow()
{
   var output = "";
   output += "<html><body><h1>A Sub-window</h1>";
   output += "<form><input type='button' value='Close Main Window'";
   output +="onclick='window.opener.close()'></form></body></html>";
   newWind.document.write(output);
   newWind.document.close();
}

// close subwindow
function closeWindow()
{
   if (newWind && !newWind.closed)
   {
      newWind.close();
   }
   else
   {
      alert("The window is no longer open");
   }
}
```

To complete the example of the window opening and closing, notice that the subwindow is given a button whose `onclick` event handler (bound in the `initialization()` function) closes the main window/tab. In some modern browsers, the user is presented with an alert asking to confirm the closure of the main browser window/tab. Other browsers simply ignore the request with, in some cases, a warning in the error console. Safari closes the main window/tab without any warning.

components

(See `appCore`)

controllers

(See `appCore`)

crypto
pkcs11

Values: Object references Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera-, Chrome-

The `crypto` and `pkcs11` properties return references to browser objects that are relevant to internal public-key cryptography mechanisms. These subjects are beyond the scope of this book, but you can read more about Netscape's efforts on this front at `http://www.mozilla.org/projects/security/`.

defaultStatus

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome-

After a document is loaded into a window or frame, the status bar's message field can display a string that is visible any time the mouse pointer is not atop an object that takes precedence over the status bar (such as a link object or an image map). The `window.defaultStatus` property is normally an empty string, but you can set this property at any time. Any setting of this property will be temporarily overridden when a user moves the mouse pointer on top of a link object (see `window.status` property for information about customizing this temporary status-bar message).

Probably the most common time to set the `window.defaultStatus` property is when a document loads into a window. You can do this as an immediate script statement that executes from the `head` or `body` portion of the document or as part of a document's `onload` event handler.

Example

Unless you plan to change the default status-bar text while a user spends time at your web page, the best time to set the property is when the document loads. In Listing 27-5, notice that we also read this property to reset the status bar in an `onmouseout` event handler. Setting the `status` property to empty also resets the status bar to the `defaultStatus` setting. When testing, remember that even though modern browsers support the `status` property, some of them do not display scripted status-bar text associated with links, in order to prevent link spoofing.

LISTING 27-5

Setting the Default Status Message

```
<!DOCTYPE html>
<html>
   <head>
     <meta http-equiv="content-type" content="text/html;charset=utf-8">
     <title>window.defaultStatus property</title>
     <script type="text/javascript">
        window.defaultStatus = "Welcome to my Web site.";
     </script>
   </head>
   <body>
     <h1>window.defaultStatus property</h1>
     <hr />
     <p><a href="http://www.microsoft.com"
         onmouseover="window.status = 'Visit Microsoft\'s Home page.'; return true;"
         onmouseout="window.status = '';return true;">Microsoft</a>
     </p>
     <p><a href="http://mozilla.org"
         onmouseover="window.status = 'Visit Mozilla\'s Home page.'; return true;"
         onmouseout="window.status = window.defaultStatus;return true;">Mozilla</a>
     </p>
   </body>
</html>
```

If you need to display single or double quotes in the status bar (as in both links in Listing 27-5), use escape sequences (`\'` and `\"`) as part of the strings being assigned to these properties.

Related Item: `window.status` property

dialogArguments

Value: Varies Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera-, Chrome+

The `dialogArguments` property is available only in a window that is generated by the `showModalDialog()` or the IE-specific `showModelessDialog()` methods. Those methods allow a parameter to be passed to the dialog-box window, and the `dialogArguments` property lets the dialog box window's scripts access that parameter value. The value can be in the form of a string, number, or JavaScript array (convenient for passing multiple values).

Example

See Listing 27-36 for the `window.showModalDialog()` method, to see how arguments can be passed to a dialog box and retrieved via the `dialogArguments` property.

Related Items: `window.showModalDialog()`, `window.showModelessDialog()` methods

dialogHeight
dialogWidth

Value: String Read/Write

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Scripts in a document located inside a modal or IE-specific modeless dialog box (generated by `showModalDialog()` or `showModelessDialog()`) can read or modify the height and width of the dialog-box window via the `dialogHeight` and `dialogWidth` properties. Scripts can access these properties from the main window only for modeless dialog boxes, which remain visible while the user can control the main window contents.

Values for these properties are strings and include the unit of measure, the pixel (`px`).

Example

Dialog boxes sometimes provide a button or icon that reveals more details or more complex settings for advanced users. You can create a function that handles the toggle between two sizes. The following function assumes that the document in the dialog box has a button whose label also toggles between Show Details and Hide Details. The button's `onclick` event handler invokes the function as `toggleDetails(this)`:

```
function toggleDetails(btn)
{
   if (dialogHeight == "200px")
   {
      dialogHeight = "350px";
      btn.value = "Hide Details";
   }
   else
   {
      dialogHeight = "200px";
      btn.value = "Show Details";
   }
}
```

In practice, you also have to toggle the `display` style sheet property of the extra material between `none` and `block` to make sure that the dialog box does not display scroll bars in the smaller dialog-box version.

Related Items: `window.dialogLeft`, `window.dialogTop` properties

dialogLeft
dialogTop

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

Scripts in a document located inside a modal or IE-specific modeless dialog box (generated by `showModalDialog()` or `showModelessDialog()`) can read or modify the left and top coordinates of the dialog-box window via the `dialogLeft` and `dialogTop` properties. Scripts can access these

properties from the main window only for modeless dialog boxes, which remain visible while the user can control the main window contents.

Values for these properties are strings and include the unit of measure, the pixel (`px`). If you attempt to change these values so that any part of the dialog-box window would be outside the video monitor, the browser overrides the settings to keep the entire window visible.

Example

Although usually not a good idea because of the potentially jarring effect on a user, you can reposition a dialog-box window that has been resized by script (or by the user if you let the dialog box be resizable). The following statements in a dialog-box window document's script re-center the dialog-box window:

```
dialogLeft = (screen.availWidth/2) - (parseInt(dialogWidth)/2) + "px";
dialogHeight = (screen.availHeight/2) - (parseInt(dialogHeight)/2) + "px";
```

Note that the `parseInt()` functions are used to read the numeric portion of the `dialogWidth` and `dialogHeight` properties so that the values can be used for arithmetic.

Related Items: `window.dialogHeight`, `window.dialogTopWidth` properties

directories
locationbar
menubar
personalbar
scrollbars
statusbar
toolbar

Value: Object Read/Write (with signed scripts)

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari-, Opera-, Chrome-

Beyond the rectangle of the content region of a window (where your documents appear), the Netscape browser window displays an amalgam of bars and other features known collectively as *chrome*. All browsers can elect to remove these chrome items when creating a new window (as part of the third parameter of the `window.open()` method), but until signed scripts were available in Navigator 4, these items could not be turned on and off in the main browser window, or in any existing window.

Navigator 4 promoted these elements to first-class objects contained by the `window` object. Navigator 6 added one more feature, called the *directories bar* — a framelike device that can be opened or hidden from the left edge of the browser window. At the same time, however, NN6+/Mozilla browsers no longer permit hiding and showing the browser window's scroll bars. Chrome objects have but one property: `visible`. Reading this Boolean value (possible without signed scripts) lets you inspect the visitor's browser window for the elements currently engaged.

Changing the visibility of these items on the fly alters the relationship between the inner and outer dimensions of the browser window. If you must carefully size a window to display content, you should adjust the chrome elements before sizing the window. But before you start changing chrome visibility before the eyes of your page visitors, weigh the decision carefully. Experienced users have fine-tuned the look of their browser windows to just the way they like them. If you mess with that look, you may anger your visitors. Fortunately, changes you make to a chrome element's visibility are not stored to the user's preferences. However, the changes you make survive an unloading of the

page. If you change the settings, be sure that you first save the initial settings and restore them with an `onunload` event handler.

Tip

The Macintosh menu bar is not part of the browser's window chrome. Therefore, its visibility cannot be adjusted from a script. ■

Example

In Listing 27-6, you can experiment with the look of a browser window with any of the chrome elements turned on or off. To run this script, you must either sign the scripts or turn on codebase principals (see Chapter 49, "Security and Netscape Signed Scripts," on the CD-ROM). Java must also be enabled to use the signed script statements.

As the page loads, it stores the current state of each chrome element. One button for each chrome element triggers the `toggleBar()` function. This function inverts the visible property for the chrome object passed as a parameter to the function. Finally, the Restore button returns the visibility properties to their original settings. Notice that the `restore()` function is also called by the `onunload` event handler for the document.

}
```

Related Item: `window.open()` method

document

Value: Object Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

We list the `document` property here primarily for completeness. Each `window` object contains a single `document` object. The value of the `document` property is the `document` object, which is not a displayable value. Instead, you use the `document` property as you build references to properties and methods of the document and to other objects contained by the document, such as a form and its elements. To load a different document into a window, use the `location` object (see Chapter 28, "Location and History Objects"). The `document` object is described in detail in Chapter 29, "Document and Body Objects."

Related Item: `document` object

event
Event

Value: Object Read/Write

Compatibility: WinIE4+, MacIE4+, NN+, Moz+, Safari 1+, Opera+, Chrome+

IE4+ treats the `event` object as a property of the `window` object. The W3C DOM passes an instance of the `Event` object as an argument to event handler functions. The connection with the `window` object is relatively inconsequential because all action involving the `event` object occurs in event handler functions. The only difference is that the object can be treated as a more global object when one event handler function invokes another. Instead of having to pass the `event` object parameter to the next function, functions can access the `event` object directly (with or without the `window.` prefix in the reference).

For complete details about the `event` object in all browsers, see Chapter 32, "Event Objects."

Related Item: `event` object

external

Value: Object Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz+, Safari-, Opera-, Chrome-

The `external` property is useful only when the browser window is a component in another application. The property provides a gateway between the current browser window and the application that acts as a host to the browser window component.

With WinIE4+ acting as a component to the host operating system, the `external` property can be used to access several methods that influence behaviors outside the browser. Perhaps the three most useful methods to regular web-page scripters are `AddDesktopComponent()`, `AddFavorite()`, and `NavigateAndFind()`. The first two methods display the same kind of alert dialog box that users get after making these choices from the browser or desktop menus, so that you won't be able to sneak your web site onto desktops or Favorites listings without the visitor's approval. IE7 and Firefox2+ allow `AddSearchProvider()` for installing search plug-ins. As with the first two methods, an alert is displayed asking the user permission to install the search plug-in. You can find information about OpenSearch and the format for the XML file passed to the method at `http://www.opensearch.org/Specifications/OpenSearch/1.1`. Table 27-2 describes the parameters for these methods.

TABLE 27-2

Popular window.external Object Methods

Method	Description
`AddDesktopComponent("URL", "type"[, left, top, width, height])`	Adds a web site or image to the Active Desktop (if turned on in the user's copy of Windows). The `type` parameter value is either `website` or `image`. Dimensional parameters (optional) are all integer values.
`AddFavorite("URL"[, "title"])`	Adds the specified URL to the user's Favorites list. The optional title string parameter is how the URL should be listed in the menu (if missing, the URL appears in the list).
`AddSearchProvider("URL")`	Adds the search provider, specified in the URL with an `OpenSearchDescription` XML file.
`NavigateAndFind("URL", "findString", "target")`	Navigates to the URL in the first parameter and opens the page in the target frame (an empty string opens in the current frame). The `findString` is text to be searched for on that page and highlighted when the page loads.

Example

The first example asks the user whether it is okay to add a web site to the Active Desktop. If Active Desktop is not enabled, the user is given the choice of enabling it at this point:

```
external.AddDesktopComponent("http://www.nytimes.com","website", 200,
      100, 400, 400);
```

In the next example, the user is asked to approve the addition of a URL to the Favorites list. The user can follow the normal procedure for filing the item in a folder in the list:

```
external.AddFavorite("http://www.dannyg.com/support/update13.html",
   "JSBible 6 Support Center");
```

The final example assumes that a user makes a choice from a `select` list of items. The `onchange` event handler of the `select` list invokes the following function to navigate to a fictitious page and locate listings for a chosen sports team on the page:

```
function locate(list)
{
   var choice = list.options[list.selectedIndex].value;
   external.NavigateAndFind("http://www.collegesports.net/scores.html",
      choice, "scores");
}
```

frameElement

Values: `frame` or `iframe` object reference   Read-Only

Compatibility: WinIE5.5+, MacIE-, NN7+, Moz1.0.1+, Safari 1.2+, Opera+, Chrome+

If the current window exists as a result of a `<frame>` or `<iframe>` tag, the window's `frameElement` property returns a reference to the hosting element. As is made clear in the discussion about the `frame` element object later in this chapter, a reference to a `frame` or `iframe` element object provides access to the properties that echo the attributes of the HTML element object. For a window that is not part of a frameset, the `frameElement` property returns `null`.

The convenience of this property becomes apparent when a single document is loaded into multiple framesets. A script in the document can still refer to the containing `frame` element, even when the ID of the element changes from one frameset to another. The `frameset` element is also accessible via the `parentElement` property of the `frameElement` property:

```
var frameSetObj = self.frameElement.parentElement;
```

A reference to the `frameset` element opens possibilities for adjusting frame sizes.

Related Items: `frame`, `iframe` objects

frames

Value: Array Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

In a multiframe window, the top or parent window contains any number of separate frames, each of which acts as a full-fledged `window` object. The `frames` property (note the plural use of the word as a property name) plays a role when a statement must reference an object located in a different frame. For example, if a button in one frame is scripted to load a document in another frame, the button's event handler must be able to tell JavaScript precisely where to display the new HTML document. The `frames` property assists in that task.

To use the `frames` property to communicate from one frame to another, it should be part of a reference that begins with the `parent` or `top` property. This lets JavaScript make the proper journey through the hierarchy of all currently loaded objects to reach the desired object. To find out how many frames are currently active in a window, use this expression:

```
parent.frames.length
```

This expression returns a number indicating how many frames the parent window defines. This value does not, however, count further nested frames, should a third generation of frame be defined in the environment. In other words, no single property exists that you can use to determine the total number of frames in the browser window if multiple generations of frames are present.

The browser stores information about all visible frames in a numbered (indexed) array, with the first frame (that is, the topmost `<frame>` tag defined in the framesetting document) as number `0`:

```
parent.frames[0]
```

Therefore, if the window shows three frames (whose indexes are `frames[0]`, `frames[1]`, and `frames[2]`, respectively), the reference for retrieving the `title` property of the document in the second frame is

```
parent.frames[1].document.title
```

This reference is a road map that starts at the parent window and extends to the second frame's document and its `title` property. Other than the number of frames defined in a parent window and each

frame's name (`top.frames[i].name`), no values from the frame definitions are directly available from the frame object via scripting until you get to IE4 and NN6/Moz/W3C (see the `frame` element object later in this chapter). In these browsers, individual `frame` element objects have several properties that reveal `<frame>` tag attributes.

Using index values for frame references is not always the safest tactic, however, because your frameset design may change over time, in which case the index values will also change. Instead, you should take advantage of the `name` attribute of the `<frame>` tag, and assign a unique, descriptive name to each frame. A value you assign to the `name` attribute is also the name that you use for `target` attributes of links in order to force a linked page to load in a frame other than the one containing the link. You can use a frame's name as an alternative to the indexed reference. For example, in Listing 27-7, two frames are assigned distinctive names. To access the title of a document in the `JustAKid2` frame, the complete object reference is

```
parent.JustAKid2.document.title
```

with the frame name (case sensitive) substituting for the `frames[1]` array reference. Or, in keeping with JavaScript flexibility, you can use the object name in the array index position:

```
parent.frames["JustAKid2"].document.title
```

The supreme advantage to using frame names in references is that no matter how the frameset structure may change over time, a reference to a named frame will always find that frame, even though its index value (that is, its position in the frameset) may change.

Example

Listing 27-7 and Listing 27-8 demonstrate how JavaScript treats values of frame references from objects inside a frame. The same document is loaded into each frame. A script in that document extracts information about the current frame and the entire frameset.

LISTING 27-7

Framesetting Document for Listing 27-8

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
<title>window.frames property</title>
   </head>
   <frameset cols="50%,50%">
      <frame name="JustAKid1" src="jsb27-08.html" />
      <frame name="JustAKid2" src="jsb27-08.html" />
   </frameset>
</html>
```

A call to determine the number (length) of frames returns `0`, from the point of view of the current frame referenced. That's because each frame here is a window that has no nested frames within it. But add the `parent` property to the reference, and the scope zooms out to take into account all frames generated by the parent window's document.

LISTING 27-8

Showing Various Window Properties

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Window Revealer II</title>
      <script type="text/javascript">
         function gatherWindowData()
         {
            var msg = "";
            msg += "<p><b>From the point of view of this frame:</b><br />";
            msg += "window.frames.length: " + window.frames.length + "<br />";
            msg += "window.name: " + window.name + "</p>";
            msg += "<p><b>From the point of view of the framesetting ↩
                          document:</b><br />";
            msg += "parent.frames.length: " + parent.frames.length + "<br />";
            msg += "parent.frames[0].name: " + parent.frames[0].name + "</p>";
            return msg;
         }
      </script>
   </head>
   <body>
      <script type="text/javascript">
         document.write(gatherWindowData());
      </script>
   </body>
</html>
```

The last statement in the example shows how to use the array syntax (brackets) to refer to a specific frame. All array indexes start with `0` for the first entry. Because the document asks for the name of the first frame (`parent.frames[0]`), the response is `JustAKid1` for both frames.

Related Items: `frame`, `frameset` objects; `window.parent`, `window.top` properties

fullScreen

Values: Boolean Read-Only

Compatibility: WinIE-, MacIE-, NN7.1+, Moz1.4+, Safari-, Opera-, Chrome-

The intent of the `fullScreen` property is to indicate whether the browser is in full-screen mode, which can be set in Mozilla browsers through the Full Screen command in the View menu. Unfortunately, the property isn't reliable (as of Mozilla 1.8.1) and always returns `false`, regardless of the browser's actual full-screen setting.

history

Value: Object Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

(See the discussion of the `history` object in Chapter 28, “Location and History Objects.”)

innerHeight
innerWidth
outerHeight
outerWidth

Value: Integer Read/Write (see text)

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari+, Opera+, Chrome+

NN4+/Moz/WebKit- and Presto-based browers let scripts adjust the height and width of any window, including the main browser window, by setting properties. This adjustment can be helpful if your page shows itself best with the browser window sized to a particular height and width. Rather than relying on the user to size the browser window for optimum viewing of your page, you can dictate the size of the window (although the user can always resize the main window manually). And because you can examine the operating system of the visitor via the `navigator` object (see Chapter 42), you can size a window to adjust for the differences in font and form element rendering on different platforms.

Supporting browsers provide two different points of reference for measuring the height and width of a window: inner and outer. Both are measured in pixels. The inner measurements are that of the active document area of a window (sometimes known as a window’s content region). If the optimum display of your document depends on the document display area being a certain number of pixels high and/or wide, the `innerHeight` and `innerWidth` properties are the ones to set.

By contrast, the outer measurements reference the outside boundary of the entire window, including whatever chrome is showing in the window: scroll bars, status bar, and so on. Setting the `outerHeight` and `outerWidth` is generally done in concert with a reading of `screen` object properties (see Chapter 42). Perhaps the most common use of the outer properties is to set the browser window to fill the available screen area of the visitor’s monitor.

A more efficient way of modifying both outer dimensions of a window is with the `window.resizeTo()` method, which is also available in IE4+. The method takes pixel width and height (as integer values) as parameters, thus accomplishing a window resizing in one statement. Be aware that resizing a window does not adjust the location of a window. Therefore, just because you set the outer dimensions of a window to the available space returned by the `screen` object, you can’t count on the window suddenly filling the available space on the monitor. Application of the `window.moveTo()` method is necessary to ensure that the top-left corner of the window is at screen coordinates `0,0`.

Despite the freedom that these properties afford the page author, Netscape and Mozilla-based browsers have built in a minimum size limitation for scripts that are not cryptographically signed. You cannot set these properties such that the outer height and width of the window is smaller than 100 pixels on a side. This limitation is to prevent an unsigned script from setting up a small or nearly invisible window that monitors activity in other windows. With signed scripts, however, windows can be made smaller than 100×100 pixels, with the user’s permission. IE4+ maintains a smaller minimum size to prevent resizing a window to zero size.

Caution

Users may dislike your scripts messing with their browser window sizes and positions. NN7+/Moz/WebKit- and Presto-based browsers do not allow scripts to resize windows unless the script is signed. ■

Example

In Listing 27-9, several buttons let you see the results of setting the `innerHeight`, `innerWidth`, `outerHeight`, and `outerWidth` properties. Safari ignores scripted adjustments to these properties, whereas Mozilla users can set preferences that prevent scripts from moving and resizing windows.

`location`

Value: Object Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

(See the discussion of the `location` object in Chapter 28, "Location and History Objects.")

`locationbar`

(See `directories`)

name

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

All `window` objects can have names assigned to them. Names are particularly useful for working with frames, because a good naming scheme for a multiframe environment can help you determine precisely which frame you're working with in references coming from other frames.

The main browser window, however, has no name attached to it by default. Its value is an empty string. There aren't many reasons to assign a name to the window, because JavaScript and HTML provide plenty of other ways to refer to the `window` object (the `top` property, the `_top` constant for `target` attributes, and the `opener` property from subwindows).

If you want to attach a name to the main window, you can do so by setting the `window.name` property at any time. But be aware that because this is one window property whose life extends beyond the loading and unloading of any given document, chances are that your scripts would use the reference in only one document or frameset. Unless you restore the default empty string, your programmed window name will be present for any other document that loads later. Our suggestion in this regard is to assign a name in a window's or frameset's `onload` event handler and then reset it to empty in a corresponding `onunload` event handler:

```
<body onload="self.name = 'Main'" onunload="self.name = ''">
```

You can see an example of this application in Listing 27-15, where setting a parent window name is helpful for learning the relationships between parent and child windows.

Related Items: `top` property; `window.open()`, `window.sizeToContent()` methods

navigator

Value: Object Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Although the `navigator` object appears as a property of the `window` object only in modern browsers, this object has been around since the very beginning (see Chapter 42). In previous browsers, the `navigator` object was referenced as a stand-alone object. And because you can omit any reference to the `window` object for a `window` object's properties, you can use the same windowless reference syntax for compatibility across all scriptable browsers (at least for the `navigator` object properties that exist across all browsers). That's the way we recommend referring to the `navigator` object.

Example

This book is littered with examples of using the `navigator` object, primarily for performing browser detection. You can find examples of specific `navigator` object properties in Chapter 42.

Related Item: `navigator` object

netscape

Value: Object Read-Only

Compatibility: WinIE-, MacIE-, NN3+, Moz+, Safari-, Opera-, Chrome-

Given its name, you might think that the `netscape` property somehow works in tandem with the `navigator` property, but this is not the case. The `netscape` property is unique to NN/Moz browsers and provides access to functionality that is specific to the Netscape family of browsers, such as the privilege manager.

Example

The `netscape` property is commonly used as a means of accessing the NN/Moz-specific `PrivilegeManager` object to enable or disable security privileges. Following is an example of how this access is carried out:

```
netscape.security.PrivilegeManager.enablePrivilege("UniversalBrowserRead");
```

offscreenBuffering

Value: Boolean or string Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari 1.2+, Opera-, Chrome+

IE4+/Safari 1.2+ by default initially render a page in a buffer (a chunk of memory) before it is blasted to the video screen. You can control this behavior explicitly by modifying the `window.offscreenBuffering` property.

The default value of the property is the string `auto.` You can also assign Boolean `true` or `false` to the property to override the normal automatic handling of this behavior.

Example

If you want to turn off buffering for an entire page, include the following statement at the beginning of your script statements:

```
window.offscreenBuffering = false;
```

onerror

Value: Function Read/Write

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari-, Opera-, Chrome-

The `onerror` property is an exception to this book's rule of not describing event handlers as properties within object reference sections. The reason is that the `onerror` event brings along some special properties that are useful to control by setting the event handler property in scripts.

Modern browsers (IE5+, NN4+, and W3C) are designed to prevent script errors from being intrusive if a user encounters a script error while loading or interacting with a page. But even the subtle hints about problems (messages or icons in the status bar) can be confusing for users who have no idea what JavaScript is. JavaScript lets you turn off the display of script error windows or messages as someone executes a script on your page. The question is: When should you turn off these messages?

Script errors generally mean that something is wrong with your script. The error may be the result of a coding mistake or, conceivably, a bug in JavaScript (perhaps on a platform version of the browser that you haven't been able to test). If such errors occur, often the script won't continue to do what you intended. Hiding the script error from yourself during development would be foolhardy, because you'd never know whether unseen errors are lurking in your code. It can be equally dangerous to turn off error dialog boxes for users who may believe that the page is operating normally, when in fact it's not. Some data values may not be calculated or displayed correctly.

That said, we can see some limited instances of when you may want to keep such dialog-box windows from appearing. For example, if you know for a fact that a platform-specific bug trips the error message without harming the execution of the script, you may want to prevent that error alert dialog box from appearing in the files posted to your web site. You should do this only after extensive testing to ensure that the script ultimately behaves correctly, even with the bug or error.

Note

IE fires the `onerror` event handler only for runtime errors. This means that if you have a syntactical error in your script that trips the browser as the page loads, the `onerror` event doesn't fire, and you cannot trap that error message. Moreover, if the user has the IE script debugger installed, any code you use to prevent browser error messages from appearing will not work. ■

When the browser starts, the `window.onerror` property is `<undefined>`. In this state, all errors are reported via the normal JavaScript error window or message. To turn off error alerts, set the `window.onerror` property to invoke a function that does absolutely nothing:

```
function doNothing() { return true; }
window.onerror = doNothing;
```

To restore the error messages, reload the page.

You can, however, also assign a custom function to the `window.onerror` property. This function then handles errors in a more friendly way under your script control. Whenever error messages are turned on (the default behavior), a script error (or Java applet or class exception) invokes the function assigned to the `onerror` property, passing three parameters:

- Error message
- URL of the document causing the error
- Line number of the error

You can essentially trap for all errors and handle them with your own interface (or no user notification at all). The last statement of this function must be `return true` if you do not want the JavaScript script error message to appear.

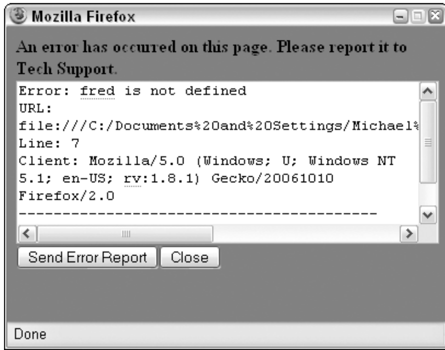
If you are using the NPAPI to communicate with a Java applet directly from your scripts, you can use the same scheme to handle any exception that Java may throw. A Java exception is not necessarily a mistake kind of error: Some methods assume that the Java code will trap for exceptions to handle special cases — for example, reacting to a user's denial of access when prompted by a signed script dialog box. See Chapter 47, "Scripting Java Applets and Plug-Ins" (on the CD-ROM), for an example of trapping for a specific Java exception. Also, see Chapter 21, "Control Stuctures and Exception Handling," for JavaScript exception handling introduced for W3C DOM–compatible browsers.

Example

In Listing 27-10, one button triggers a script that contains an error. We added an error-handling function to process the error so that it opens a separate window and fills in a `textarea` form element (see Figure 27-4). A Submit button is also provided to mail the bug information to a support center email address — an example of how to handle the occurrence of a bug in your scripts.

FIGURE 27-4

An example of a self-reporting error window.



LISTING 27-10

Controlling Script Errors

HTML: jsb27-10.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Error Dialog Control</title>
      <script type="text/javascript" src="jsb27-10.js"></script>
   </head>
   <body>
      <h1>Error Dialog Control</h1>
      <hr />
      <form name="myform">
         <input type="button" value="Cause an Error" onclick="goWrong()" />
         <p><input type="button" value="Turn Off Error Dialogs"
                   onclick="errOff()" />
            <input type="button" value="Turn On Error Dialogs"
                   onclick="errOn()" />
         </p>
      </form>
   </body>
</html>
```

JavaScript: jsb27-10.js

```
// function with invalid variable value
function goWrong()
{
   var x = fred;
```

```
}
// turn off error dialogs
function errOff()
{
   window.onerror = doNothing;
}
// turn on error dialogs with hard reload
function errOn()
{
   window.onerror = handleError;
}

// assign default error handler
window.onerror = handleError;

// error handler when errors are turned off...prevents error dialog
function doNothing() { return true; }

function handleError(msg, URL, lineNum)
{
   var errWind = window.open("","errors","height=270,width=400");
   var wintxt = "<html><body bgcolor=red>";
   wintxt += "<b>An error has occurred on this page. "
          + "Please report it to Tech Support.</b>";
   wintxt += "<form method=POST enctype='text/plain' "
          + "action=mailTo:support4@dannyg.com >";
   wintxt += "<textarea name='errMsg' cols=45 rows=8 wrap=VIRTUAL>";
   wintxt += "Error: "
          + msg + "\n";
   wintxt += "URL: "
          + URL + "\n";
   wintxt += "Line: "
          + lineNum + "\n";
   wintxt += "Client: "
          + navigator.userAgent + "\n";
   wintxt += "-----------------------------------------\n";
   wintxt += "Please describe what you were doing when the error occurred:";
   wintxt += "</textarea><br />";
   wintxt += "<input type=SUBMIT value='Send Error Report'>";
   wintxt += "<input type=button value='Close' onclick='self.close()'>";
   wintxt += "</form></body></html>";
   errWind.document.write(wintxt);
   errWind.document.close();
   return true;
}
```

We provide a button that performs a hard reload, which in turn resets the `window.onerror` property to its default value. With error dialog boxes turned off, the error handling function does not run.

opener

Value: Window object reference Read/Write

Compatibility: WinIE3+, MacIE3+, NN3+, Moz+, Safari+, Opera+, Chrome+

Many scripters make the mistake of thinking that a new browser window created with the `window.open()` method has a child-parent relationship similar to the one that frames have with their parents. That's not the case at all. New browser windows, when created, have a very slim link to the window from whence they came: via the `opener` property. The purpose of the `opener` property is to provide scripts in the new window with a valid reference back to the original window. For example, the original window may contain some variable values or general-purpose functions that a new window at this web site wants to use. The original window may also have form elements whose settings are of value to the new window, or that get set by user interaction in the new window.

Because the value of the `opener` property is a reference to a genuine `window` object, you can begin references with the property name. Or, you may use the more complete `window.opener` or `self.opener` reference. But then the reference must include some object or property of that original window, such as a window method or a reference to something contained by that window's document.

If a subwindow opens yet another subwindow, the chain is still valid, albeit one step longer. The third window can reach the main window with a reference that begins

```
opener.opener....
```

It's a good idea for the third window to store in a global variable the value of `opener.opener` while the page loads. Then, if the user closes the second window, the variable can be used to start a reference to the main window.

When a script that generates a new window is within a frame, the `opener` property of the subwindow points to that frame. Therefore, if the subwindow needs to communicate with the main window's parent or another frame in the main window, you have to very carefully build a reference to that distant object. For example, if the subwindow needs to get the `checked` property of a checkbox in a sister frame of the one that created the subwindow, the reference is

```
opener.parent.sisterFrameName.document.formName.checkboxName.checked
```

It is a long way to go, indeed, but building such a reference is always a case of mapping out the path from where the script is, to where the destination is, step by step.

Example

To demonstrate the importance of the `opener` property, take a look at how a new window can define itself from settings in the main window (see Listing 27-11). The `doNew()` function generates a small subwindow and loads the file in Listing 27-12 into the window. Notice the initial conditional statements in `doNew()` that make sure that if the new window already exists, it comes to the front, by invoking the new window's `focus()` method.

LISTING 27-11

Contents of a Main Window Document That Generates a Second Window

{
   if (!myWind || myWind.closed)
   {
      myWind = window.open("jsb27-12.html","subWindow","height=200, ↵
               width=350,resizable");
   }
   else
   {
      // bring existing subwindow to the front
      myWind.focus();
   }
}
```

LISTING 27-12

References to the opener Property

HTML: jsb27-12.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>New Window on the Block</title>
      <script type="text/javascript" src="jsb27-12.js"></script>
      <script type="text/javascript">
         document.write("<body bgcolor='" + getColor() + "'>")
      </script>
   </head>
   <body>
      <form>
         <input type="button" value="Who's in the Main window?"
                onclick="alert(self.opener.document.title)" />
         <p>Type text here for the main window:
            <input type="text" size="25"
                   onchange="self.opener.document.forms[0].entry.value ↩
                   = this.value" />
        </p>
      </form>
   </body>
</html>
```

JavaScript: jsb27-12.js

```
function getColor()
{
   // shorten the reference
   colorButtons = self.opener.document.forms[0].color;
   // see which radio button is checked
   for (var i = 0; i < colorButtons.length; i++)
   {
      if (colorButtons[i].checked)
      {
         return colorButtons[i].value;
      }
   }
   return "white";
}
```

In the `getColor()` function, the multiple references to the radio-button array can be very long. To simplify the references, the `getColor()` function starts by assigning the radio-button array to a variable we arbitrarily call `colorButtons.` That shorthand now stands in for lengthy references as we loop through the radio buttons to determine which button is checked, and retrieve its value property.

A button in the second window simply fetches the title of the opener window's document. Even if another document loads in the main window in the meantime, the `opener` reference still points to the main window: Its `document` object, however, will change.

Finally, the second window contains a text input object. Enter any text there that you like and then either tab or click out of the field. The `onchange` event handler updates the field in the opener's document (provided that the document is still loaded).

Related Items: `window.open()`, `window.focus()` methods

outerHeight
outerWidth

(See `innerHeight` and `innerWidth`, earlier in this chapter)

pageXOffset
pageYOffset

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari+, Opera+, Chrome+

The top-left corner of the content (inner) region of the browser window is an important geographical point for scrolling documents. When a document is scrolled all the way to the top and flush left in the window (or when a document is small enough to fill the browser window without displaying scroll bars), the document's location is said to be `0,0`, meaning zero pixels from the top and zero pixels from the left. If you were to scroll the document, some other coordinate point of the document would be under that top-left corner. That measure is called the *page offset,* and the `pageXOffset` and `pageYOffset` properties let you read the pixel value of the document at the inner window's top-left corner: `pageXOffset` is the horizontal offset, and `pageYOffset` is the vertical offset.

The value of these measures becomes clear if you design navigation buttons in your pages to carefully control paging of content being displayed in the window. For example, you might have a two-frame page in which one of the frames features navigation controls and the other displays the primary content. The navigation controls take the place of scroll bars, which, for aesthetic reasons, are turned off in the display frame. Scripts connected to the simulated scrolling buttons can determine the `pageYOffset` value of the document, and then use the `window.scrollTo()` method to position the document precisely to the next logical division in the document for viewing.

IE has corresponding values as `body` object properties: `body.scrollLeft` and `body.scrollTop` (see Chapter 29).

Related Items: `window.innerHeight`, `window.innerWidth`, `body.scrollLeft`, `body.scrollTop` properties; `window.scrollBy()`, `window.scrollTo()` methods

parent

Value: Window object reference Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+,Chrome+

The `parent` property (and the `top` property, discussed later in this section) comes into play primarily when a document is to be displayed as part of a multiframe window. The HTML documents that users see in the frames of a multiframe browser window are distinct from the document that specifies the frameset for the entire window. That document, though still in the browser's memory (and appearing as the URL in the location field of the browser), is not otherwise visible to the user (except in source view).

If scripts in your visible documents need to reference objects or properties of the frameset window, you can reference those frameset window items with the `parent` property. (Do not, however, expand the reference by preceding it with the `window` object, as in `window.parent.propertyName`, because this causes problems in early browsers.) In a way, the `parent` property seems to violate the object hierarchy because, from a single frame's document, the property points to a level seemingly higher in precedence. If you didn't specify the `parent` property, or instead specified the `self` property from one of these framed documents, the object reference is to the frame only, rather than to the outermost framesetting `window` object.

A nontraditional but perfectly legal way to use the `parent` object is as a means of storing temporary variables. Thus, you could set up a holding area for individual variable values, or even an array of data. Then these values can be shared among all documents loaded into the frames, even when documents change inside the frames. You have to be careful, however, when storing data in the parent on the fly (that is, in response to user action in the frames). In early browsers, variables can revert to their default values (the values set by the parent's own script) if the user resizes the window.

A child window can also call a function defined in the parent window. The reference for such a function is

```
parent.functionName([parameters])
```

At first glance, it may seem as though the `parent` and `top` properties point to the same framesetting `window` object. In an environment consisting of one frameset window and its immediate children, that's true. But if one of the child windows was itself another framesetting window, you wind up with three generations of windows. From the point of view of the youngest child (for example, a window defined by the second frameset), the `parent` property points to its immediate parent, whereas the `top` property points to the first framesetting window in this chain.

On the other hand, a new window created via the `window.open()` method has no parent–child relationship to the original window. The new window's `top` and `parent` point to that new window. You can read more about these relationships in the "Frames" section earlier in this chapter.

Example

To demonstrate how various `window` object properties refer to window levels in a multiframe environment, use your browser to load the Listing 27-13 document. It in turn sets each of two equal-size frames to the same document: Listing 27-14. This document extracts the values of several window properties, plus the `document.title` properties of two different window references.

LISTING 27-13

            msg += "window name: "
                + window.name + "<br />";
            msg += "self name: "
                + self.name + "<br />";
            msg += "self.document.title: "
                + self.document.title;
            return msg;
         }
      </script>
   </head>
```

continued

LISTING 27-14 *(continued)*

```
   <body>
      <script type="text/javascript">
         document.write(gatherWindowData());
      </script>
   </body>
</html>
```

In the two frames, the references to the `window` and `self` object names return the name assigned to the frame by the frameset definition (`JustAKid1` for the left frame, `JustAKid2` for the right frame). In other words, from each frame's point of view, the `window` object is its own frame. References to `self.document.title` refer only to the document loaded into that window frame. But references to the top and parent windows (which are one and the same in this example) show that those object properties are shared between both frames.

A couple of other fine points are worth highlighting. First, the name of the framesetting window is set as Listing 27-13 loads, rather than in response to an `onload` event handler in the `<frameset>` tag. The reason for this is that the name must be set in time for the documents loading in the frames to get that value. If we had waited until the frameset's `onload` event handler, the name wouldn't be set until after the frame documents had loaded. Second, we restore the parent window's name to an empty string when the framesetting document unloads. This is to prevent future pages from getting confused about the window name.

Related Items: `window.frames`, `window.self`, `window.top` properties

personalbar

(See `directories`)

returnValue

Value: Any data type — Read/Write

Compatibility: WinIE4+, MacIE5+, NN-, Moz+, Safari+, Opera-, Chrome-

Scripts use the `returnValue` property in a document that loads into the originally IE-specific modal dialog box. A modal dialog box is generated via the `showModalDialog()` method, which returns whatever data has been assigned to the `returnValue` property of the dialog-box window before it closes. This is possible because script processing in the main window freezes while the modal dialog box is visible. As the dialog box closes, a value can be returned to the main window's script right where the modal dialog box was invoked, and the main window's script resumes executing statements.

Example

See Listing 27-36 for the `showModalDialog()` method, for an example of how to get data back from a dialog box.

Related Item: `showModalDialog()` method

screen

Value: screen object Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Although the screen object appears as a property of the window object in modern browsers, the screen object is also available in NN4 (see Chapter 42), but as a stand-alone object. Because you can omit any reference to the window object for a window object's properties, the same windowless reference syntax can be used for compatibility with legacy browsers that support the screen object.

Example

See Chapter 42 for examples of using the screen object to determine the video-monitor characteristics of the computer running the browser.

Related Item: screen object

screenLeft
screenTop

Value: Integer Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari 1.2+, Opera+, Chrome+

WinIE5+ originally provided the screenLeft and screenTop properties of the window object to let you read the pixel position (relative to the top-left 0,0 coordinate of the video monitor) of what Microsoft calls the *client area* of the browser window. The client area excludes most window chrome, such as the title bar, address bar, and the window-sizing bar. Therefore, when the browser window is maximized (meaning that no sizing bars are exposed), the screenLeft property of the window is 0, whereas the screenTop property varies, depending on the combination of toolbars the user has elected to display. For nonmaximized windows, if the window has been positioned so that the top and/or left parts of the client area are out of view, their property values will be negative integers.

These two properties are read-only. You can position the browser window via the window.moveTo() and window.moveBy() methods, but these methods position the top-left corner of the entire browser window, not the client area. IE browsers through version 7 do not provide properties for the position of the entire browser window.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the screenLeft and screenTop properties. Start with the browser window maximized (if you are using Windows). Enter the following property name in the top text box:

```
window.screenLeft
```

Click the Evaluate button to see the current setting. Unmaximize the window, and drag it around the screen. Each time you finish dragging, click the Evaluate button again to see the current value. Do the same for window.screenTop.

Related Items: window.moveTo(), window.moveBy() methods

screenX
screenY

Value: Integer Read/Write

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari 1.2+, Opera+, Chrome+

NN6+/Moz/W3C provide the `screenX` and `screenY` properties to read the position of the outer boundary of the browser window relative to the top-left coordinates (`0,0`) of the video monitor. The browser window includes the 4-pixels-wide window-sizing bars that surround Win32 windows. Therefore, when the WinNN6+ browser window is maximized, the value for both `screenX` and `screenY` is `-4.` NN/Moz/W3C do not provide the equivalent measures of the browser window client area as found in the `screenLeft` and `screenTop` properties of IE5+. You can, however, find out whether various toolbars are visible in the browser window (see `window.directories`).

Although you can assign a value to either property, current versions of supporting browsers do not adjust the window position in response, if the user has set the preference that prevents window movement and resizing. Moving and resizing windows by script is considered by many web surfers to be unacceptable behavior.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `screenX` and `screenY` properties. Start with the browser window maximized (if you are using Windows). Enter the following property name in the top text box:

```
window.screenY
```

Click the Evaluate button to see the current setting. Unmaximize the window, and drag it around the screen. Each time you finish dragging, click the Evaluate button again to see the current value. Do the same for `window.screenY.`

Related Items: `window.moveTo()`, `window.moveBy()` methods

scrollbars

(See `directories`)

scrollMaxX
scrollMaxY

Value: Integer Read/Write

Compatibility: WinIE-, MacIE-, NN7.1+, Moz1.4+, Safari-, Opera-, Chrome-

The NN7.1+/Moz1.4+ `scrollMaxX` and `scrollMaxY` properties let you determine the maximum horizontal and vertical scrolling extents of a window. Scrolling is possible only if the window displays scroll bars along the desired axis. Values are pixel integers.

Related Items: `scrollX`, `scrollY` properties

scrollX
scrollY

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The NN6+/Mozilla/Safari `scrollX` and `scrollY` properties let you determine the horizontal and vertical scrolling of a window. Scrolling is possible only if the window displays scroll bars along the desired axis. Values are pixel integers.

Although the IE DOM does not provide similar properties for the window, the same information can be derived from the `body.scrollLeft` and `body.scrollTop` properties.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `scrollX` and `scrollY` properties. Enter the following property in the top text box:

```
window.scrollY
```

Now manually scroll the page down so that you can still see the Evaluate button. Click the button to see how far the window has scrolled along the *y*-axis.

Related Items: `body.scrollLeft`, `body.scrollTop` properties

self

Value: Window object reference Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Just as the `window` object reference is optional, so is the `self` property when the object reference points to the same window as the one containing the reference. In what may seem to be an unusual construction, the `self` property represents the same object as the `window.` For instance, to obtain the title of the document in a single-frame window, you can use any of the following three constructions:

```
window.document.title
self.document.title
document.title
```

Although `self` is a property of a window, you should not combine the references within a single-frame window script (for example, don't begin a reference with `window.self`, which has been known to cause numerous scripting problems). Specifying the `self` property, though optional for single-frame windows, can help make an object reference crystal clear to someone reading your code (and to you, for that matter). Multiple-frame windows are where you need to pay particular attention to this property.

JavaScript is pretty smart about references to a statement's own window. Therefore, you can generally omit the `self` part of a reference to a same-window document element. But when you intend to display a document in a multiframe window, complete references (including the `self` prefix) to an object make it much easier on anyone who reads or debugs your code to track who is doing what to whom. You are free to retrieve the `self` property of any window. The value that comes back is a `window` object reference.

Example

Listing 27-15 uses the same operations as Listing 27-5 but substitutes the `self` property for all `window` object references. The application of this reference is entirely optional, but it can be helpful for reading and debugging scripts if the HTML document is to appear in one frame of a multiframe window — especially if other JavaScript code in this document refers to documents

in other frames. The `self` reference helps anyone reading the code know precisely which frame was being addressed. When testing, remember that even though modern browsers support the `status` property, some of them do not display scripted status-bar text associated with links, in order to prevent link spoofing.

LISTING 27-15

Using the self Property

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>self Property</title>
      <script type="text/javascript">
         self.defaultStatus = "Welcome to my Website.";
      </script>
   </head>
   <body>
      <h1>self Property</h1>
      <hr />
      <p><a href="http://www.microsoft.com"
            onmouseover="self.status = 'Visit Microsoft\'s Home page.';return true;"
            onmouseout="self.status = '';return true;">Microsoft</a>
      </p>
      <p><a href="http://mozilla.org"
            onmouseover="self.status = 'Visit Mozilla\'s Home page.';return true;"
            onmouseout="self.status = self.defaultStatus;
            return true;">Mozilla</a></p>
   </body>
</html>
```

Related Items: `window.frames`, `window.parent`, `window.top` properties

sidebar

(See `appCore`)

status

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome-

At the bottom of the browser window is a status bar. Part of that bar includes an area that normally discloses the document loading progress or the URL of a link that the mouse is pointing to at any given instant. You can control the temporary content of that field by assigning a text string to the `window` object's `status` property. You should adjust the `status` property only in response to events that have a temporary effect, such as a link or image map area object's `onmouseover` event handler. When the `status` property is set in this situation, it overrides any other setting in the status bar. If the user then moves the mouse pointer away from the object that changes the status bar, the bar returns to its default setting (which may be empty on some pages). To prevent link spoofing, however, not all modern browsers display scripted status-bar text associated with links.

Use this window property as a friendlier alternative to displaying the URL of a link as a user rolls the mouse around the page. For example, if you'd rather use the status bar to explain the nature of the destination of a link, put that text into the status bar in response to the `onmouseover` event handler. But be aware that experienced web surfers like to see URLs down there. Therefore, consider creating a hybrid message for the status bar that includes a friendly description followed by the URL in parentheses. In multiframe environments, you can set the `window.status` property without having to worry about referencing the individual frame.

Example

In Listing 27-16, the `status` property is set in a handler embedded in the `onmouseover` attribute of two HTML link tags. Notice that the handler requires a `return true` statement (or any expression that evaluates to `return true`) as the last statement of the handler. This statement is required; otherwise, the status message will not display in all browsers. When testing, remember that even though modern browsers support the `status` property, some of them do not display scripted status-bar text associated with links, in order to prevent link spoofing.

LISTING 27-16

Links with Custom Status-Bar Messages

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>window.status Property</title>
   </head>
   <body>
      <h1>window.status Property</h1>
      <hr />
      <a href="http://www.dannyg.com"
         onmouseover="window.status = 'Go to my Home page. (www.dannyg.com)'; ↩
         return true">
         Home</a>
      <p>
         <a href = "http://mozilla.org"
            onmouseover="window.status = 'Visit Mozilla Home page. (mozilla.org)'; ↩
            return true">
         Mozilla</a>
      </p>
   </body>
</html>
```

As a safeguard against platform-specific anomalies that affect the behavior of `onmouseover` event handlers and the `window.status` property, you should also include an `onmouseout` event handler for links and client-side image map area objects. Such `onmouseout` event handlers should set the `status` property to an empty string. This setting ensures that the status-bar message returns to the `defaultStatus` setting when the pointer rolls away from these objects. If you want to write a generalizable function that handles all window status changes, you can do so, but word the `onmouseover` attribute carefully so that the event handler evaluates to `return true`. Listing 27-17 shows such

an alternative. Again, when testing, remember that some modern browsers do not display scripted status-bar text associated with links, in order to prevent link spoofing.

LISTING 27-17

Handling Status Message Changes

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Generalizable window.status Property</title>
      <script type="text/javascript">
         function showStatus(msg)
         {
            window.status = msg;
            return true;
         }
      </script>
   </head>
   <body>
      <h1>Generalizable window.status Property</h1>
      <hr />
      <a href="http://www.dannyg.com"
         onmouseover="return showStatus('Go to my Home page.')"
         onmouseout="return showStatus('')">Home</a>
      <p>
         <a href="http://mozilla.org"
            onmouseover="return showStatus('Visit Mozilla Home page.')"
            onmouseout="return showStatus('')">Mozilla</a></p>
   </body>
</html>
```

Notice how the event handlers return the results of the `showStatus()` method to the event handler, allowing the entire handler to evaluate to `return true`.

One final example of setting the status bar (shown in Listing 27-18) also demonstrates how to create a simple scrolling banner in the status bar.

LISTING 27-18

Creating a Scrolling Banner

HTML: jsb27-18.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
```

```
      <title>Message Scroller</title>
      <script type="text/javascript" src="jsb27-18.js"></script>
   </head>
   <body onload="scrollMsg()">
      <h1>Message Scroller</h1>
      <hr />
   </body>
</html>
```

JavaScript: jsb27-18.js

```
var msg = "Welcome to my world...";
var delay = 150;
var timerId;
var maxCount = 0;
var currCount = 1;

function scrollMsg()
{
   // set the number of times scrolling message is to run
   if (maxCount == 0)
   {
      maxCount = 3 * msg.length;
   }
   window.status = msg;

   // keep track of how many characters have scrolled
   currCount++;

   // shift first character of msg to end of msg
   msg = msg.substring (1, msg.length) + msg.substring (0, 1);

   // test whether we've reached maximum character count
   if (currCount >= maxCount)
   {
      timerID = 0;   // zero out the timer
      window.status = "";   // clear the status bar
      return;   // break out of function
   }
   else
   {
      // recursive call to this function
      timerId = setTimeout("scrollMsg()", delay);
   }
}
```

Because the status bar is being set by a stand-alone function (rather than by an `onmouseover` event handler), you do not have to append a `return true` statement to set the `status` property. The `scrollMsg()` function uses more advanced JavaScript concepts, such as the `window.setTimeout()` method (covered later in this chapter) and string methods (covered in

Chapter 15, "The String Object"). To speed the pace at which the words scroll across the status bar, reduce the value of `delay`.

Many web surfers (including us) don't care for these scrollers that run forever in the status bar. Rolling the mouse over links disturbs the banner display. Use scrolling bars sparingly or design them to run only a few times after the document loads.

Tip

Setting the `status` property with `onmouseover` event handlers has had checkered results along various implementations in Navigator. A script that sets the status bar is always in competition against the browser itself, which uses the status bar to report loading progress. When a hot spot on a page is at the edge of a frame, many times the `onmouseout` event fails to fire, preventing the status bar from clearing itself. Be sure to torture-test any such implementations before declaring your page ready for public access. ■

Related Items: `window.defaultStatus` property; `onmouseover`, `onmouseout` event handlers; `link` object

statusbar
toolbar

(See `locationbar`)

top

Value: Window object reference Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `window` object's `top` property refers to the topmost window in a frameset object hierarchy. For a single-frame window, the reference is to the same object as the window itself (including the `self` and `parent` properties), so do not include `window` as part of the reference. In a multiframe window, the top window is the one that defines the first frameset (in case of nested framesets). Users don't ever really see the top window in a multiframe environment, but the browser stores it as an object in its memory. The reason is that the top window has the road map to the other frames (in case one frame should need to reference an object in a different frame), and its child frames can call upon it. Such a reference looks like this:

```
top.functionName([parameters])
```

For more about the distinction between the `top` and `parent` properties, see the in-depth discussion about scripting frames at the beginning of this chapter. See also the example of the `parent` property for listings that demonstrate the values of the `top` property.

Related Items: `window.frames`, `window.self`, `window.parent` properties

window

Value: Window object Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Listing the `window` property as a separate property may be more confusing than helpful. The `window` property is the same object as the `window` object. You do not need to use a reference that begins with `window.window.` Although the `window` object is assumed for many references, you can use `window` as part of a reference to items in the same window or frame as the script statement that makes that reference. You should not, however, use `window` as a part of a reference involving items higher up in the hierarchy (`top` or `parent`).

Methods

alert("*message*")

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

An *alert dialog box* is a modal window that presents a message to the user with a single OK button to dismiss the dialog box. As long as the alert dialog box is showing, no other application or window can be made active. The user must dismiss the dialog box before proceeding with any more work in the browser.

The single parameter to the `alert()` method can be a value of any data type, including representations of some unusual data types whose values you don't normally work with in JavaScript (such as complete objects). This makes the alert dialog box a handy tool for debugging JavaScript scripts. Any time you want to monitor the value of an expression, use that expression as the parameter to a temporary `alert()` method in your code. The script proceeds to that point and then stops to show you the value. (See Chapter 48 for more tips on debugging scripts.)

What is often disturbing to application designers is that all JavaScript-created modal dialog boxes (via the `alert()`, `confirm()`, and `prompt()` methods) identify themselves as being generated by JavaScript or the browser. The purpose of this identification is to act as a security precaution against unscrupulous scripters who might try to spoof system or browser alert dialog boxes, inviting a user to reveal passwords or other private information. These identifying words cannot be overwritten or eliminated by your scripts. You can simulate a modal dialog-box window in a cross-browser fashion with regular browser windows, but it is not as robust as a genuine modal window, which you can create in IE4+, and some of the other modern browsers, via the `window.showModalDialog()` method.

Because the `alert()` method is of a global nature (that is, no particular frame in a multiframe environment derives any benefit from laying claim to the alert dialog box), a common practice is to omit all `window` object references from the statement that calls the method. Restrict the use of alert dialog boxes in your HTML documents and site designs. The modality of the windows is disruptive to the flow of a user's navigation around your pages. Communicate with users via forms or by writing to separate document window frames. Of course, alert boxes can still be very handy as a quick debugging aid.

Example

The parameter for the example in Listing 27-19 is a concatenated string. It joins two fixed strings and the value of the browser's `navigator.appName` property. Loading this document causes the alert dialog box to appear, as shown in several configurations in Figure 27-5. The JavaScript Alert line cannot be deleted from the dialog box in earlier browsers, while the title bar can't be changed in later browsers.

LISTING 27-19

Displaying an Alert Dialog Box

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>window.alert() Method</title>
   </head>
   <body>
      <h1>window.alert() Method</h1>
      <hr />
      <script type="text/javascript">
         alert("You are running the " + navigator.appName + " browser.");
      </script>
   </body>
</html>
```

FIGURE 27-5

Results of the alert() method in Listing 27-19 in Firefox and Internet Explorer.

Related Items: `window.confirm()`, `window.prompt()` methods

back()
forward()

Returns: Nothing

Compatibility: WinIE+, MacIE-, NN4+, Moz+, Safari+, Opera+, Chrome+

The purpose of the `window.back()` and `window.forward()` methods that began in NN4 is to offer a scripted version of the global back and forward navigation buttons while allowing the `history` object to control navigation strictly within a particular window or frame — as it should. Even though IE now supports these window methods, they did not catch on (and the `window` object is out of the scope of the W3C DOM Level 2), so you are better off staying with the `history` object's

methods for navigating browser history. For more information about version compatibility and about back and forward navigation, see the `history` object in Chapter 28.

Related Items: `history.back()`, `history.forward()`, `history.go()` methods

clearInterval(*intervalIDnumber*)

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Use the `window.clearInterval()` method to turn off an interval loop action started with the `window.setInterval()` method. The parameter is the ID number returned by the `setInterval()` method. A common application for the JavaScript interval mechanism is animation of an object on a page. If you have multiple intervals running, each has its own ID value in memory. You can turn off any interval by its ID value. As soon as an interval loop stops, your script cannot resume that interval: It must start a new one, which generates a new ID value.

Example

See Listing 27-33 and Listing 27-34 later in this chapter for an example of how `setInterval()` and `clearInterval()` are used together on a page.

Related Items: `window.setInterval()`, `window.setTimeout()`, `window.clearTimeout()` methods

clearTimeout(*timeoutIDnumber*)

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Use the `window.clearTimeout()` method in concert with the `window.setTimeout()` method, as described later in this chapter, when you want your script to cancel a timer that is waiting to run its expression. The parameter for this method is the ID number that the `window.setTimeout()` method returns when the timer starts ticking. The `clearTimeout()` method cancels the specified timeout. A good practice is to check your code for instances where user action may negate the need for a running timer — and to stop that timer before it goes off.

Example

The page in Listing 27-20 features one text box and two buttons. One button starts a countdown timer coded to last 1 minute (easily modifiable for other durations); the other button interrupts the timer at any time while it is running. When the minute is up, an alert dialog box lets you know.

LISTING 27-20

A Countdown Timer

HTML: jsb27-20.html

```
<!DOCTYPE html>
<html>
   <head>
```

continued

LISTING 27-20 *(continued)*

```
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Count Down Timer</title>
      <script type="text/javascript" src="jsb27-20.js"></script>
   </head>
   <body>
      <form>
         <input type="button" name="startTime" value="Start 1 min. Timer"
                onclick="startTimer()" />
         <input type="button" name="clearTime"
                value="Clear Timer" onclick="stopTimer()" />
         <p><input type="text" name="timerDisplay" value="" /></p>
      </form>
   </body>
</html>
```

JavaScript: jsb27-20.js

```
var running = false;
var endTime = null;
var timerID = null;

function startTimer()
{
   running = true;
   now = new Date();
   now = now.getTime();
   // change last multiple for the number of minutes
   endTime = now + (1000 * 60 * 1);
   showCountDown();
}

function showCountDown()
{
   var now = new Date();
   now = now.getTime();
      if (endTime - now <= 0)
      {
         stopTimer();
         alert("Time is up.  Put down your pencils.");
      }
      else
      {
         var delta = new Date(endTime - now);
         var theMin = delta.getMinutes();
         var theSec = delta.getSeconds();
         var theTime = theMin;
         theTime += ((theSec < 10) ? ":0" : ":") + theSec;
         document.forms[0].timerDisplay.value = theTime;
         if (running)
```

```
        {
           timerID = setTimeout("showCountDown()",1000);
        }
     }
}

function stopTimer()
{
   clearTimeout(timerID);
   running = false;
   document.forms[0].timerDisplay.value = "0:00";
}
```

Notice that the script establishes three variables with global scope in the window: `running`, `endTime`, and `timerID`. These values are needed inside multiple functions, so they are initialized outside the functions.

In the `startTimer()` function, you switch the running flag on, meaning that the timer should be going. Using some date functions (see Chapter 17, "The Date Object"), you extract the current time in milliseconds and add the number of milliseconds for the next minute (the extra multiplication by 1 is the place where you can change the amount to the desired number of minutes). With the end time stored in a global variable, the function now calls another function that compares the current and end times, and displays the difference in the text box.

Early in the `showCountDown()` function, check to see whether the timer has wound down. If so, you stop the timer and alert the user. Otherwise, the function continues to calculate the difference between the two times, and formats the time in mm:ss format. As long as the `running` flag is set to `true`, the function sets the 1-second timeout timer before repeating itself. To stop the timer before it has run out (in the `stopTimer()` function), the most important step is to cancel the timeout running inside the browser. The `clearTimeout()` method uses the global `timerID` value to do that. Then the function turns off the running switch and zeros out the display.

When you run the timer, you may occasionally notice that the time skips a second. It's not cheating. It just takes slightly more than 1 second to wait for the timeout and then finish the calculations for the next second's display. What you're seeing is the display catching up with the real time left.

Related Item: `window.setTimeout()` method

close()

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `window.close()` method closes the browser window referenced by the `window` object. Most likely, you will use this method to close subwindows created from a main document window. If the call to close the window comes from a window other than the new subwindow, the original `window` object must maintain a record of the subwindow object. You accomplish this by storing the value returned from the `window.open()` method in a global variable that will be available to other objects later (for example, a variable not initialized inside a function). If, on the other hand, an object inside the new subwindow calls the `window.close()` method, the `window` or `self` reference is sufficient.

Be sure to include a window as part of the reference to this method. Failure to do so may cause JavaScript to regard the statement as a `document.close()` method, which has a different behavior (see Chapter 29). Only the `window.close()` method can close the window via a script. Closing a window, of course, forces the window to trigger an `onunload` event handler before the window disappears from view, but after you've initiated the `window.close()` method, you cannot stop it from completing its task. Moreover, `onunload` event handlers that attempt to execute time-consuming processes (such as submitting a form in the closing window) may not complete because the window can easily close before the process completes — a behavior that has no workaround (with the exception of the `onbeforeunload` event handler in IE4+).

While we're on the subject of closing windows, a special case exists when a subwindow tries to close the main window (via a statement such as `self.opener.close()`) when the main window has more than one entry in its session history. As a safety precaution against scripts closing windows they did not create, modern browsers ask the user whether he or she wants the main window to close (via a browser-generated dialog box). This security precaution cannot be overridden except in NN4+/Moz via a signed script, when the user grants permission to control the browser (see Chapter 49).

Example

See Listing 27-4 (for the `window.closed` property), which provides a cross-platform example of applying the `window.close()` method across multiple windows.

Related Items: `window.open()`, `document.close()` methods

`confirm("message")`

Returns: Boolean

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

A confirm dialog box presents a message in a modal dialog box along with OK and Cancel buttons. Such a dialog box can be used to ask a question of the user, usually prior to a script's performing actions that will not be undoable. Querying a user about proceeding with typical web navigation in response to user interaction on a form element is generally a disruptive waste of the user's time and attention. But for operations that may reveal a user's identity or send form data to a server, a JavaScript confirm dialog box may make a great deal of sense. Users may also accidentally click buttons, so you should provide avenues for backing out of an operation before it executes.

Because this dialog box returns a Boolean value (OK = `true`; Cancel = `false`), you can use this method as a comparison expression or as an assignment expression. In a comparison expression, you nest the method within any other statement where a Boolean value is required. For example:

```
if (confirm("Are you sure?"))
{
   alert("OK");
}
else
{
   alert("Not OK");
}
```

Here, the returned value of the confirm dialog box provides the desired Boolean value type for the `if...else` construction (see Chapter 21).

This method can also appear on the right side of an assignment expression, as in:

```
var adult = confirm("Do you certify that you are over 18 years old?");
if (adult)
{
   //statements for adults
}
else
{
   //statements for children
}
```

You cannot specify other alert icons or labels for the two buttons in JavaScript confirm dialog-box windows.

The example in Listing 27-21 shows the user interface part of how you can use a confirm dialog box to query a user before clearing a table full of user-entered data. The text in the title bar, as shown in Figure 27-6, cannot be removed from the dialog box.

LISTING 27-21

The Confirm Dialog Box

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>window.confirm() Method</title>
      <script type="text/javascript">
         function clearTable()
         {
            if (confirm("Are you sure you want to empty the table?"))
            {
               alert("Emptying the table...");   // for demo purposes
               //statements that actually empty the fields
            }
         }
      </script>
   </head>
   <body>
      <h1>window.confirm() Method</h1>
      <hr />
      <form>
         <h3>A large table with data would be here.</h3>
         <input type="button" name="clear" value="Reset Table"
                onclick="clearTable()" />
      </form>
   </body>
</html>
```

FIGURE 27-6

A JavaScript confirm dialog box in Internet Explorer.

Related Items: `window.alert()`, `window.prompt()`, `form.submit()` methods

`createPopup()`

Returns: Pop-up object reference

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

An IE pop-up window is a chromeless rectangular space that overlaps the current window. Unlike the dialog boxes generated by the `showModalDialog()` and `showModelessDialog()` methods, the pop-up window's entire content must be explicitly controlled by script. That also goes for the size and location of the window. Generating the window via the `createPopup()` method simply creates the object in memory without displaying it. You can then use the reference to the pop-up window that is returned by the method to position the window, populate its content, and make it visible. See details in the description of the `popup` object later in this chapter.

Example

See Listing 27-46 later in this chapter for an example of the `createPopup()` method.

Related Item: `popup` object

`dump("`*`message`*`")`

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN7.1+, Moz1.4+, Safari-, Opera-, Chrome-

The `window.dump()` method is a debugging/diagnostic method that you can use to output a string of text to *standard output,* which is typically the operating system's console window. The `dump()` method provides a less intrusive alternative to displaying debugging messages via the `alert()` method.

`execScript("`*`exprList`*`"[, `*`language`*`])`

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The IE-specific `window.execScript()` method executes one or more script statements that are passed as string expressions. The first parameter is a string version of one or more script statements (multiple statements must be separated by semicolons). The second, optional, parameter is the language interpreter the browser should use to execute the script statement. Acceptable values for the

language are `JavaScript`, `JScript`, `VBS`, and `VBScript`. The default value is `JScript`, so you can omit the second parameter when supplying expressions in JavaScript.

Unlike the JavaScript core language `eval()` function (which also executes string versions of JavaScript statements), the `execScript()` method returns no values. Even so, the method operates within the global variable space of the window holding the current document. For example, if a document's script declares a global variable as follows

```
var myVar;
```

the `execScript()` method can read or write to that variable:

```
window.execScript("myVar = 10; myVar += 5");
```

After this statement runs, the global variable `myVar` has a value of `15`.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `execScript()` method. The Evaluator has predeclared global variables for the lowercase letters *a* through *z*. Enter each of the following statements in the top text box, and observe the results for each.

```
a
```

When first loaded, the variable is declared, but assigned no value, so it is undefined:

```
window.execScript("a = 5")
```

The method returns no value, so the mechanism inside The Evaluator says that the statement is undefined:

```
a
```

The variable is now 5.

```
window.execScript("b = a * 50")
b
```

The `b` global variable has a value of `250`. Continue exploring with additional script statements. Use semicolons to separate multiple statements within the string parameter.

Related Item: `eval()` function

find(["*searchString*" [, *matchCaseBoolean*, *searchUpBoolean*]])

Returns: Boolean value for non-dialog-box searches

Compatibility: WinIE-, MacIE-, NN4+, Moz1.0.1+, Safari+, Opera-, Chrome+

The `window.find()` method introduced in NN4 mimics the powers of the browser's Find dialog box, accessible from the Find button in the toolbar. This method was deactivated in NN6, but reactivated in NN7/Moz1.0.1.

If you specify no parameters, the browser's Find dialog box appears, just as though the user had clicked the Find button in the toolbar. With no parameters, this function does not return a value.

You can specify a search string as a parameter to the function. The search is based on simple string matching, and is not in any way connected with the regular-expression kind of search (see Chapter 45, "The Regular Expression and RegExp Objects"). If the search finds a match, the browser scrolls to that matching word and highlights the word, just as though it were using the browser's own Find dialog box. The function also returns a Boolean `true` after a match is found. If no match is found in the document, or no more matches occur in the current search direction (the default direction is from top to bottom), the function returns `false`.

Table 27-3 lists the optional parameters you can use; in all cases, the default value is `false`. These choices are identical to the ones that appear in NN4+'s Find dialog box.

TABLE 27-3

window.find() Method Attributes Controllable via Script

Attribute	Description
`caseSensitive`	Boolean; `true` specifies that the search is case sensitive
`backwards`	Boolean; `true` specifies that the search is backwards
`wraparound`	Boolean; `true` specifies that the search will wrap to the top of the document when the bottom is reached.
`wholeWord`	Boolean; `true` specifies that the search is a whole word search.
`searchInFrames`	Boolean; `true` specifies to search in frames.
`showDialog`	Boolean; `true` specifies to display the browser's find dialog.

Some modern browsers such as Firefox have evolved to forego the Find dialog box in favor of an integrated find feature that appears at the bottom of the browser window. This approach to find can be applied to the entire page at the same time, in which case all the text matches are highlighted.

IE4+ also has a scripted text search facility, but it is implemented in an entirely different way (using the `TextRange` object described in Chapter 33, "Body Text Objects"). The visual behavior also differs in that it does not highlight and scroll to a matching string in the text.

Example

A simple call to the `window.find()` method looks as follows:

```
var success = window.find("contract");
```

And if you want the search to be case sensitive, add at least one of the optional parameters:

```
success = window.find(matchString,caseSensitive);
```

In many ways, the `window.find()` method is a remnant of NN4. Refer to discussions of the `TextRange` and `Range` objects in Chapter 33 for more modern implementations of body-text searching.

Related Items: `TextRange`, `Range` objects (Chapter 33)

`forward()`

(See `window.back()`)

`geckoActiveXObject("`*progID*`")`

Returns: WMP control object

Compatibility: WinIE-, MacIE-, NN7.1+, Moz1.4+, Safari-, Opera-, Chrome-

One interesting result of the NN/IE browser wars is Microsoft's victory in establishing Windows Media Player as the PC media player of choice in the Windows operating system. Because WMP is implemented as an ActiveX control, NN/Moz browsers were somewhat left out in the cold in terms of scriptability. The `window.geckoActiveXObject()` method was added to Moz1.4 browsers to give them the capability of accessing WMP as an ActiveX control. Although the name of the method suggests generic support for ActiveX controls, it currently enables you to open only the WMP control.

The only parameter to `geckoActiveXObject()` is a programmatic ID, which for WMP is currently `MediaPlayer.MediaPlayer.1`. So, to grab a WMP control reference for media playback using the `geckoActiveXObject()` method, use code such as this:

```
var player = new GeckoActiveXObject("MediaPlayer.MediaPlayer.1");
```

`getComputedStyle(elementNodeRef, "pseudoElementName")`

Returns: CSS style object

Compatibility: WinIE-, MacIE-, NN-, Moz+, Safari+, Opera+, Chrome+

The `window.getComputedStyle()` method enables you to access the cascading style sheet (CSS) style object associated with a given element. You specify an element node reference as the first parameter to the method, along with the optional name of a specific pseudoelement to which the style applies. We say *optional* because you can pass an empty string as the second parameter to obtain a style object with no pseudoelement implications.

Note

Although various browsers support the `getComputedStyle()` method, the values returned could be in different formats, depending on the style specified for the element. For example, if you requested the style of an element that had a background color, Opera would return the color in hex format, and Firefox, Safari, and Chrome would return it in `rgb()` format. ■

Although the `getComputedStyle()` method is defined (and works) for the `window` object, the W3C DOM prefers `document.defaultView.getComputedStyle()` as the standard means of accessing a style object for an element. It's the same method that's ultimately being called; the way it's accessed is what differs.

`getSelection()`

Returns: Selection object

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

This method takes the place of the deprecated method of the same name that appeared in the `document` object. The method offers a scripted way of capturing the text selected by a user in a page, which is a common task involving the selection and copying of body text in a document for pasting into other application documents. The `window.getSelection()` method returns the string of text

selected by the user. If nothing is selected, an empty string is the result. Returned values consist only of the visible text on the page and not the underlying HTML or style of the text.

The WinIE4+ equivalent involves the `document.selection` property, which returns an IE `selection` object. To derive the text from this object, you must create a `TextRange` object from it and then inspect the `text` property:

```
var selectedText = document.selection.createRange().text;
```

Example

The document in Listing 27-22 provides a cross-browser (but not MacIE5) solution to capturing text that a user selects in the page. Selected text is displayed in the text area. The script uses browser detection and branching to account for the differences in event handling between Mozilla and Internet Explorer.

LISTING 27-22

Retrieving Selected Text

HTML: jsb27-22.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Getting Selected Text</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb27-22.js"></script>
   </head>
   <body>
      <h1>Getting Selected Text</h1>
      <hr />
      <p>Select some text and see how JavaScript can capture the selection:</p>
      <h2>ARTICLE I</h2>
      <p>Congress shall make no law respecting an establishment of religion, or
         prohibiting the free exercise thereof; or abridging the freedom of
         speech, or of the press; or the right of the people peaceably to
         assemble, and to petition the government for a redress of grievances.
      </p>
      <form>
         <textarea name="selectedText" rows="3" cols="40" wrap="virtual">
         </textarea>
      </form>
   </body>
</html>
```

JavaScript: jsb27-22.js

```
addEvent(document, "mouseup", showSelection);
```

```
function showSelection()
{
   if (window.getSelection)
   {
      document.forms[0].selectedText.value = window.getSelection();
   }
   else if (document.selection)
   {
      document.forms[0].selectedText.value = document.selection.createRange().text;
      event.cancelBubble = true;
   }
}
```

Related Item: `document.selection` property

home()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari-, Opera+, Chrome-

Like many of the window methods originally introduced in Navigator 4, the `window.home()` method provides a scripted way of replicating the action of a toolbar button: the Home button. The action navigates the browser to whatever URL is set in the browser preferences for home-page location. You cannot control the default home page of a visitor's browser.

Related Items: `window.back()`, `window.forward()` methods; `window.toolbar` property

moveBy(*deltaX*,*deltaY*)
moveTo(*x*,*y*)

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome-

Version 4 browsers introduced the capability of allowing JavaScript to adjust the location of a browser window onscreen. This applies to the main window or any subwindow generated by script. NN/Moz regard the possibility of a window moved out of screen view as a potential security hole, so signed scripts are needed in NN4+/Moz to move a window offscreen. While these methods are compatible with Chrome, Chrome ignores them.

You can move a window to an absolute position onscreen or adjust it along the horizontal and/or vertical axis by any number of pixels, irrespective of the absolute pixel position. The coordinate space for the *x* (horizontal) and *y* (vertical) position is the entire screen, with the top-left corner representing `0,0`. The point of the window you set with the `moveBy()` and `moveTo()` methods is the top-left corner of the outer edge of the browser window. Therefore, when you move the window to point `0,0`, the window is set flush with the top-left corner of the screen. This may not be the equivalent of a truly maximized window for all browsers and operating systems, however, because a maximized window's coordinates may be negative by a handful of pixels.

The difference between the `moveTo()` and `moveBy()` methods is that one is an absolute move, whereas the other is relative with respect to the current window position. Parameters you specify for `moveTo()` are the precise horizontal and vertical pixel counts onscreen where you want the top-left

corner of the window to appear. By contrast, the parameters for `moveBy()` indicate how far to adjust the window location in either direction. If you want to move the window 25 pixels to the right, you must still include both parameters, but the *y* value will be zero:

```
window.moveBy(25,0);
```

To move to the left, the first parameter must be a negative number.

Example

Several examples of using the `window.moveTo()` and `window.moveBy()` methods are shown in Listing 27-23. The page presents four buttons, each of which performs a different kind of browser-window movement.

JavaScript: jsb27-23.js

```
// wait in onload for page to load and settle in IE
function init()
{
   // fill missing IE properties
   if (!window.outerWidth)
   {
      window.outerWidth = document.body.clientWidth;
      window.outerHeight = document.body.clientHeight + 30;
   }
}

// function to run when window captures a click event
function moveOffScreen()
{
   // branch for NN security
   if (window.netscape)
   {
      // will also get here if in Opera, but Opera will throw error, so...
      try
      {
        netscape.security.PrivilegeManager.enablePrivilege("UniversalBrowserWrite");
      }
      catch (e)
      {
         null;
      }
   }
   var maxX = screen.width;
   var maxY = screen.height;
   window.moveTo(maxX+1, maxY+1);
   setTimeout("window.moveTo(0,0)",500);
   if (window.netscape)
   {
      // will also get here if in Opera, but Opera will throw error, so...
      try
      {
       netscape.security.PrivilegeManager.disablePrivilege("UniversalBrowserWrite");
      }
      catch (e)
      {
         null;
      }
   }
}

// moves window in a circular motion
function revolve()
```

continued

LISTING 27-23 *(continued)*

```
{
   var winX = (screen.availWidth - window.outerWidth) / 2;
   var winY = 50;
   window.resizeTo(400,300);
   window.moveTo(winX, winY);
   for (var i = 1; i < 36; i++)
   {
      winX += Math.cos(i * (Math.PI/18)) * 5;
      winY += Math.sin(i * (Math.PI/18)) * 5;
      window.moveTo(winX, winY);
   }
}

// moves window in a horizontal zig-zag pattern
function zigzag()
{
   window.resizeTo(400,300);
   window.moveTo(0,80);
   var incrementX = 2;
   var incrementY = 2;
   var floor = screen.availHeight - window.outerHeight;
   var rightEdge = screen.availWidth - window.outerWidth;
   for (var i = 0; i < rightEdge; i += 2)
   {
      window.moveBy(incrementX, incrementY);
      if (i%60 == 0)
      {
         incrementY = -incrementY;
      }
   }
}

// resizes window to occupy all available screen real estate
function maximize()
{
   window.moveTo(0,0);
   window.resizeTo(screen.availWidth, screen.availHeight);
}
```

To run successfully in NN/Moz, the first button requires that you have codebase principals turned on (see Chapter 49 to take advantage of what would normally be a signed script). The `moveOff-Screen()` function momentarily moves the window entirely out of view. Interestingly, Opera recognizes `window.netscape` but throws an error if an attempt is made to turn on the codebase principals. A `try catch` gets around that problem. Notice how the script determines the size of the screen before deciding where to move the window. After the journey offscreen, the window comes back into view at the top-left corner of the screen.

If using the web sometimes seems like going around in circles, the second function, `revolve()`, should feel just right. After reducing the size of the window and positioning it near the top center of the screen, the script uses a bit of math to position the window along 36 spots around a perfect circle (at 10-degree increments). This is an example of how to control a window's position dynamically based on math calculations. IE complicates the job a bit by not providing properties that reveal the outside dimensions of the browser window.

To demonstrate the `moveBy()` method, the third function, `zigzag()`, uses a `for` loop to increment the coordinate points to make the window travel in a sawtooth pattern across the screen. The *x* coordinate continues to increment linearly until the window is at the edge of the screen (also calculated on the fly to accommodate monitors of any size). The *y* coordinate must increase and decrease as that parameter changes direction as it moves around the screen.

In the fourth function, you see some practical code (finally) that demonstrates how best to simulate maximizing the browser window to fill the entire available screen space on the visitor's monitor.

Related Items: `window.outerHeight`, `window.outerWidth` properties; `window.resizeBy()`, `window.resizeTo()` methods

navigate(*"URL"*)

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera+, Chrome-

The `window.navigate()` method is an IE-original method that lets you load a new document into a window or frame. This method's action is the same as assigning a URL to the `location.href` property — a property that is available on all scriptable browsers. If your audience is entirely IE or Opera based, this method is safe. Otherwise, we recommend the `location.href` property as the best navigation approach.

Example

Supply any valid URL as the parameter to the method, as in:

```
window.navigate("http://www.dannyg.com");
```

Related Item: `location` object

open(*"URL"*, *"windowName"* [, *"windowFeatures"*] [,*replaceFlag*])

Returns: A window object representing the newly created window; `null` if method fails

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

With the `window.open()` method, a script provides a web-site designer an immense range of options for the way a second or third web browser window looks on the user's computer screen. Moreover, most of this control can work with all JavaScript-enabled browsers without the need for signed scripts. Because the interface elements of a new window are easier to envision, we cover those aspects of the `window.open()` method parameters first.

Setting new window features

The optional `windowFeatures` parameter is one string consisting of a comma-separated list of assignment expressions (behaving something like HTML tag attributes). *Important:* For the best browser compatibility, do not put spaces after the commas. If you omit the third parameter, JavaScript creates the same type of new window you get from the New Web Browser menu choice in the File menu. But you can control which window elements appear in the new window with the third parameter. Remember this important rule: If you specify even one of the method's original set of third parameter values, all other features are turned off unless the parameters specify the features to be switched on. Table 27-4 lists the attributes that you can control for a newly created window in all browsers. Except where noted, all Boolean values default to `yes` if you do not specify the third parameter.

TABLE 27-4

window.open() Method Attributes Controllable via Script

Attribute	Browsers	Description
`alwaysLowered`[3]	NN4+/Moz+	(Boolean) Always behind other browser windows
`alwaysRaised`[3]	NN4+/Moz+	(Boolean) Always in front of other browser windows
`channelMode`	IE4+	(Boolean) Theater mode with channel band (default is `no`)
`chrome`[3]	NN7.2+/Moz1.7+	(Boolean) Browser user interface features
`close`	NN4+/Moz+	(Boolean) System close command icon and menu item at top of dialog window
`dependent`[6]	NN4+/Moz+	(Boolean) Subwindow closes if the opener window closes
`directories`[7]	NN2+/Moz+, IE3–6	(Boolean) Displays personal/bookmarks/links toolbar
`fullscreen`[5]	IE4+	(Boolean) No title bar or menus (default is `no`)
`height`	NN2+/Moz+, IE3+, Safari+, Opera+, Chrome+	(Integer) Content region height in pixels
`innerHeight`[4]	NN4+/Moz+, Safari+, Chrome+	(Integer) Content region height; same as old height property
`innerWidth`[4]	NN4+/Moz+, Safari+, Chrome+	(Integer) Content region width; same as old width property
`left`	NN6+/Moz+, IE4+, Safari+, Opera+, Chrome+	(Integer) Horizontal position of top-left corner onscreen
`location`[8]	NN2+/Moz+, IE3+, Safari	(Boolean) Field displaying the current URL
`menubar`[1]	NN2+/Moz+, IE3+, Safari	(Boolean) Menu bar at top of window

Attribute	Browsers	Description
`minimizable`	NN7.1+/Moz1.2+	(Boolean) Minimize command icon at top of dialog windows only
`modal`[3]	NN7.1+/Moz1.2+	(Boolean) Modality of window, as in preventing access to the main window until the opened window is closed
`outerHeight`[4]	NN4+/Moz+	(Integer) Visible window height
`outerWidth`[4]	NN4+/Moz+	(Integer) Visible window width
`personalBar`[7]	NN4+/Moz+	(Boolean) Mozilla-specific version of the `directories` attribute
`resizable`[2,9]	NN2+/Moz0−1.4, IE3+	(Boolean) Interface elements that allow resizing by dragging
`screenX`[4]	NN4+/Moz+	(Integer) Horizontal position of top-left corner onscreen
`screenY`[4]	NN4+/Moz+	(Integer) Vertical position of top-left corner onscreen
`scrollbars`	NN2+/Moz+, IE3+, Opera+	(Boolean) Displays scroll bars if document is larger than window
`status`	NN2+/Moz+, IE3+, Safari	(Boolean) Status bar at bottom of window
`titlebar`[3]	NN4+/Moz+	(Boolean) Title bar and all other border elements
`toolbar`	NN2+/Moz+, IE3+, Safari	(Boolean) Back, Forward, and other buttons in the row
`top`	NN6+/Moz+, IE4+, Safari+, Opera+, Chrome+	(Integer) Vertical position of top-left corner onscreen
`width`	NN2+/Moz+, IE3+, Safari+, Opera+, Chrome+	(Integer) Content region width in pixels
`z-lock`[3]	NN4+/Moz+	(Boolean) Window layer is fixed below browser windows

[1]Not on Macintosh because the menu bar is not in the browser window; when off in MacNN4, displays an abbreviated Mac menu bar.
[2]Macintosh windows are always resizable.
[3]Requires a signed script.
[4]Requires a signed script to size or position a window beyond safe threshold. `Left` and `Top` have precedence over these two features, respectively.
[5]Behavior changed in IE6+. Its use is not recommended and, except in a kiosk type situation, we strongly concur as its use has always upset users.
[6]Behavior changed in Moz5. It was never implemented on Mac OS. It is currently under revision to be removed.
[7]In Mozilla based browsers, this feature only works if `toolbar` is also set to `yes`.
[8]In Safari, if `toolbar` is checked, then `location` always behaves as checked.
[9]In IE7+ this feature disables tabs in the new window. In FF3+ new windows are always resizable.

***windowObject*.open()**

Boolean values are handled a bit differently than you might expect. The value for `true` can be `yes`, `1`, or just the feature name by itself; for `false`, use a value of `no` or `0`. If you omit any Boolean attributes, they are rendered as `false`. Therefore, if you want to create a new window that shows only the toolbar and status bar and is resizable, the method looks like this:

```
window.open("newURL","NewWindow", "toolbar,status,resizable");
```

A new window whose height and width has not been specified is set to the default size of the browser window that the browser creates from a File menu's New Web Browser command. In other words, a new window does not automatically inherit the size of the window making the `window.open()` method call. A new window created via a script is positioned somewhat arbitrarily unless you use the window positioning attributes available in modern browsers. Notice that the position attributes are different for each browser (`screenX` and `screenY` for NN/Moz/W3C; `left` and `top` for IE). You can include both sets of attributes in a single parameter string because the browser ignores attributes that it doesn't recognize.

Note

The ability to invoke `window.open()` via a window's `onload` and `onunload` event handlers has led to severe abuse in the form of unwanted pop-up advertising windows. Browsers that include pop-up blockers (such as IE6+, and Mozilla/WebKit/Presto-based browsers) prevent the method from being invoked by these event handlers. With more browsers and users employing pop-up blockers every day, you should not even think about blasting pop-up ads to web surfers. ■

Netscape/Mozilla-only signed scripts

Many NN/Moz-specific attributes are deemed to be security risks, and thus require signed scripts and the user's permission before they are recognized. If the user fails to grant permission, the secure parameter is ignored.

To apply signed scripts to opening a new window with the secure window features, you must enable `UniversalBrowserWrite` privileges as you do for other signed scripts (see Chapter 49). A code fragment that generates an `alwaysRaised` style window follows:

```
<script type="text/javaScript" archive="myJar.jar" id="1">
function newRaisedWindow()
{
  netscape.security.PrivilegeManager.enablePrivilege("UniversalBrowserWrite");
  var newWindow = window.open("","","height=100,width=300,alwaysRaised=yes");
  netscape.security.PrivilegeManager.disablePrivilege("UniversalBrowserWrite");
  var newContent = "<html><body><b> "On top of spaghetti!"</b>";
  newContent += "<form><center><input type='button' value='OK'";
  newContent += "onclick='self.close()'></center></form></body></html>";
  newWindow.document.write(newContent);
  newWindow.document.close();
}
</script>
```

You can experiment with the look and behavior of new windows with any combination of attributes with the help of the script in Listing 27-24. This page presents a table of new window Boolean attributes and creates a new 300×300 pixel window based on your choices. This page assumes that if you are using NN/Moz, you have codebase principals turned on for signed scripts (see Chapter 49).

Be careful with turning off the title bar. With the title bar off, the content appears to float in space because absolutely no borders are displayed. However, hotkeys are always turned on, so you can use Ctrl+W to close this borderless window (except on the Mac, for which the hotkeys are always disabled with the title bar off). In browsers that support the `titlebar` feature, you can turn a computer into a kiosk by sizing a window to the screen's dimensions and setting the window options to `"titlebar=no"`. In IE you can also add `fullscreen=yes` to the feature list.

               null;
            }
         }
      }
```

Specifying a window name

Getting back to the other parameters of `window.open()`, the second parameter is the name for the new window. Don't confuse this parameter with the document's title, which normally would be set by whatever HTML text determines the content of the window. A window name must be the same style of the one-word identifier that you use for other object names and variables. This name is also an entirely different entity from the `window` object that the `open()` method returns. You don't use the name in your scripts. At most, the name can be used for `target` attributes of links and forms.

Loading content into a new window

A script generally populates a window with one of two kinds of information:

- An existing HTML document whose URL is known beforehand
- An HTML page created on the fly

To create a new window that displays an existing HTML document, supply the URL as the first parameter of the `window.open()` method. If your page is having difficulty loading a URL into a new page, try specifying the complete URL of the target document (instead of just the filename).

Leaving the first parameter as an empty string forces the window to open with a blank document, ready to have HTML written to it by your script (or loaded separately by another statement that sets that window's location to a specific URL). If you plan to write the content of the window on the fly, assemble your HTML content as one long string value and then use the `document.write()` method to post that content to the new window. If you plan to append

no further writing to the page, also include a `document.close()` method at the end to tell the browser that you're finished with the layout (so that the `Layout:Complete` or `Done` message appears in the status bar, if your new window has one).

A call to the `window.open()` method returns a reference to the new window's object if the window opens successfully. This value is vitally important if your script needs to address elements of that new window (such as when writing to its document).

To allow other functions in your script to reference the subwindow, you should assign the result of a `window.open()` method to a global variable. Before writing to the new window the first time, test the variable to make sure that it is not a `null` value; the window may have failed to open because of low memory, for instance. If everything is okay, you can use that variable as the beginning of a reference to any property or object within the new window. For example:

```
var newWindow
//...
function createNewWindow()
{
   newWindow = window.open("","");
   if (newWindow != null)
   {
      newWindow.document.write("<html><head><title>Hi!</title></head>");
   }
}
```

That global variable reference continues to be available for another function — perhaps one that closes the subwindow (via the `close()` method).

When scripts in the subwindow need to communicate with objects and scripts in the originating window, you must make sure that the subwindow has an `opener` property if the level of JavaScript in the visitor's browser doesn't automatically supply one. See the discussion about the `window.opener` property earlier in this chapter.

Invoking multiple `window.open()` methods with the same window name parameter (the second parameter) does not create additional copies of that window in Netscape browsers (although it does in Internet Explorer). JavaScript prevents you from creating two windows with the same name. Also be aware that a `window.open()` method does not bring an existing window of that name to the front of the window layers: Use `window.focus()` for that.

Internet Explorer idiosyncrasies

Creating subwindows in IE can sometimes be complicated by undesirable behavior by the browser. One of the most common problems occurs when you attempt to use `document.write()` to put content into a newly created window. IE, including some of the latest versions, fails to complete the window opening job before the script statement that uses `document.write()` executes. This causes a script error because the reference to the subwindow is not yet valid. To work around this, you should put the HTML assembly and `document.write()` statements in a separate function that gets invoked via a `setTimeout()` method after the window is created. You can see an example of this in Listing 27-25.

Another problem that affects IE is the occasional security violation ("access denied") warning when a script attempts to access a subwindow. This problem goes away when the page that includes the script for opening and accessing the subwindow is served from an HTTP server rather than accessed from a local hard disk.

Example

The page rendered by Listing 27-25 displays a single button that generates a new window of a specific size that has only the status bar turned on. The script here shows all the elements necessary to create a new window that has all the right stuff on most platforms. The new window object reference is assigned to a global variable, `newWindow`. Before a new window is generated, the script looks to see whether the window has never been generated before (in which case `newWindow` would be `null`) or, for newer browsers, the window is closed. If either condition is `true`, the window is created with the `open()` method; otherwise, the existing window is brought forward with the `focus()` method.

Due to the timing problem that afflicts all IE generations, the HTML assembly and writing to the new window are separated into their own function, which is invoked after a 50-millisecond delay (other browsers go along for the ride even if they could accommodate the assembly and writing without the delay). To build the string that is eventually written to the document, we use the += (add-by-value) operator, which appends the string on the right side of the operator to the string stored in the variable on the left side. In this example, the new window is handed an `<h1>`-level line of text to display.

LISTING 27-25

Creating a New Window

HTML: jsb27-25.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>New Window</title>
      <script type="text/javascript" src="jsb27-25.js"></script>
   </head>
   <body>
      <h1>Creating a New Window</h1>
      <hr />
      <form>
         <input type="button" name="newOne" value="Create New Window"
                onclick="makeNewWindow()" />
      </form>
   </body>
</html>
```

JavaScript: jsb27-25.js

```
var newWindow;

function makeNewWindow()
{
   if (!newWindow || newWindow.closed)
   {
      newWindow = window.open("","","status,height=200,width=300");
      // force small delay for IE to catch up
      setTimeout("writeToWindow()", 50);
```

continued

LISTING 27-25 *(continued)*

```
      }
      else
      {
         // window's already open; bring to front
         newWindow.focus();
      }
   }

   function writeToWindow()
   {
      // assemble content for new window
      var newContent = "<html><head><title>One Sub Window<\/title><\/head>";
      newContent += "<body><h1>This window is brand new.<\/h1>";
      newContent += "<\/body><\/html>";
      // write HTML to new window document
      newWindow.document.write(newContent);
      newWindow.document.close();   // close layout stream
   }
```

The `window.open()` method can potentially create problems in browsers such as IE7+ and FF2+ that support tabbed browsing where multiple pages are opened as different tabs within the same browser instance. The default response to `window.open()` is to open a new tab for the new window, as opposed to a new browser window, which can be a problem if the script is truly expecting a completely new browser window.

Related Items: `window.close()`, `window.blur()`, `window.focus()`, `window.openDialog()` methods; `window.closed` property

openDialog("*URL*", "*windowName*" [, "*windowFeatures*"] [, *arg1*][, *arg2*] ...)

Returns: A window object representing the newly created dialog box (window); `null` if method fails

Compatibility: WinIE-, MacIE-, NN7+, Moz1.0.1+, Safari-, Opera-, Chrome-

The `window.openDialog()` method is a Mozilla-specific method that serves as a XUL counterpart to the `window.open()` method. XUL is Mozilla's XML-based user interface description language that is used throughout the Mozilla application suite. The `openDialog()` method offers a few extra window features, along with the ability to pass a varying number of arguments, which can be handy when creating custom windows.

The parameters to the `openDialog()` method are similar to those found in the `open()` method, except for the optional `arg1`, `arg2`, and so on. One notable difference is the addition of the `all` window feature, which is used to show (`all=yes`) or hide (`all=no`) all window features except `chrome`, `dialog`, and `modal`; these excluded features can still be shown or hidden individually.

Related Item: `window.open()` method

print()

Returns: Nothing

Compatibility: WinIE5+, MacIE5+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `print()` method provides a scripted way of sending the window or a frame from a frameset to the printer. In all cases, the Print dialog box appears for the user to make the printer choices typical of printing manually. This prevents a rogue `print()` command from tying up a printer without the user's permission. Rather disconcertingly, the user has to reload the page to see the page content after sending the page to the printer.

WinIE5 introduced some print-specific event handlers that are triggered by scripted printing as well as manual printing. The events begin to fire after the user has accepted the Print dialog box. An `onbeforeprint` event handler can be used to show content that might be hidden from view but should appear in the printout. After the content has been sent to the print spooler, the `onafterprint` event can restore the page.

Example

Listing 27-26 is a frameset that loads Listing 27-27 into the top frame, and a copy of the Bill of Rights into the bottom frame.

LISTING 27-26

Print Example Frameset

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>window.print() method</title>
   </head>
   <frameset rows="25%,75%">
      <frame name="controls" src="jsb27-27.html" />
      <frame name="display" src="bofright.html" />
   </frameset>
</html>
```

Two buttons in the top control panel (see Listing 27-27) let you print the whole frameset (in those browsers and OS's that support it) or just the bottom frame. To print the entire frameset, the reference includes the parent window; to print the bottom frame, the reference is directed at the `parent.display` frame.

LISTING 27-27

Printing Control

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
```

continued

LISTING 27-27 *(continued)*

```
      <title>Print()</title>
   </head>
   <body>
      <h1>Print()</h1>
      <hr />
      <form>
         <input type="button" name="printWhole"
                value="Print Entire Frameset"
                onclick="parent.print()" />
         <p><input type="button" name="printFrame"
                   value="Print Bottom Frame Only"
                   onclick="parent.display.print()" />
         </p>
      </form>
   </body>
</html>
```

If you don't like some facet of the printed output, blame the browser's print engine, not JavaScript. The `print()` method merely invokes the browser's regular printing routines.

Related Items: `window.back()`, `window.forward()`, `window.home()`, `window.find()` methods

prompt(*"message"*, *"defaultReply"*)

Returns: String of text entered by user, or `null`

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The third kind of dialog box that JavaScript can display includes a message from the script author, a field for user entry, and two buttons (OK and Cancel). The script writer can supply a prewritten answer so that a user confronted with a prompt dialog box can click OK (or press Enter) to accept that answer without further typing. Supplying both parameters to the `window.prompt()` method is important. Even if you don't want to supply a default answer, enter an empty string as the second parameter:

```
prompt("What is your postal code?","");
```

If you omit the second parameter, JavaScript inserts the string `undefined` into the dialog box's field. This message is disconcerting to most web-page visitors.

The value returned by this method is a string in the dialog box's field when the user clicks the OK button. If you're asking the user to enter a number, remember that the value returned by this method is a string. You may need to perform data-type conversion with the `parseInt()` or `parseFloat()` function (see Chapter 24, "Global Functions and Statements") to use the returned values in math calculations.

When the user clicks the prompt dialog box's OK button without entering any text in a blank field, the returned value is an empty string (`""`). Clicking the Cancel button, however, makes the method

return a `null` value. Therefore, the scripter must test for the type of returned value to make sure that the user entered some data that can be processed later in the script, as in:

```
var entry = prompt("Enter a number between 1 and 10:","");
if (entry != null)
{
   //statements to execute with the value
}
```

This script excerpt assigns the results of the prompt dialog box to a variable and executes the nested statements if the returned value of the dialog box is not `null` (if the user clicked the OK button). The rest of the statements then include data validation to make sure that the entry is a number within the desired range (see Chapter 46, "Data-Entry Validation," on the CD-ROM).

It may be tempting to use the prompt dialog box as a handy user input device. But as with the other JavaScript dialog boxes, the modality of the prompt dialog box is disruptive to the user's flow through a document and can also trap automated macros that some users activate to capture web sites. In forms, HTML fields are better user interface elements for attracting user text entry. Perhaps the safest way to use a prompt dialog box is to have it appear when a user clicks a button element on a page — and then only if the information you require of the user can be provided in a single prompt dialog box. Presenting a sequence of prompt dialog boxes is downright annoying to users.

Example

The function that receives values from the prompt dialog box in Listing 27-28 (see the dialog box in Figure 27-7) does some data-entry validation (but certainly not enough for a commercial site). The function first checks to make sure that the returned value is neither `null` (Cancel) nor an empty string (the user clicked OK without entering any values). See Chapter 46 for more about data-entry validation.

LISTING 27-28

The Prompt Dialog Box

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>window.prompt() Method</title>
      <script type="text/javascript">
         function populateTable()
         {
            var howMany = prompt("Fill in table for how many factors?","");
            if (howMany != null && howMany != "")
            {
               alert("Filling the table for " + howMany);   // for demo
               //statements that validate the entry and
               //actually populate the fields of the table
            }
         }
      </script>
```

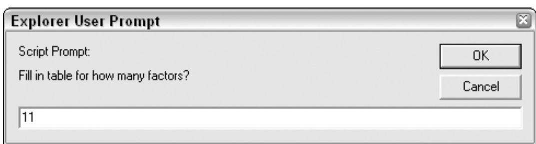
continued

LISTING 27-28 *(continued)*

```
   </head>
   <body>
      <h1>window.prompt() Method</h1>
      <hr />
      <form>
         <h3>Other statements that display and populate a large table
             would be here.</h3>
         <input type="button" name="fill" value="Fill Table..."
                onclick="populateTable()" />
      </form>
   </body>
</html>
```

FIGURE 27-7

The prompt dialog box from Listing 27-28 displayed in Internet Explorer.



Notice one important user interface element in Listing 27-28. Because clicking the button leads to a dialog box that requires more information from the user, the button's label ends in an ellipsis (or, rather, three periods acting as an ellipsis character). The ellipsis is a common courtesy to let users know that a user interface element leads to a dialog box of some sort. Consistent with stand-alone applications, the user should be able to cancel out of that dialog box and return to the same screen state that existed before the button was clicked.

Related Items: `window.alert()`, `window.confirm()` methods

resizeBy(*deltaX*,*deltaY*)
resizeTo(*outerwidth*,*outerheight*)

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN4, Moz+, Safari 1+, Opera-, Chrome-

Starting with version 4 browsers, scripts can control the size of the current browser window on the fly (no longer available in Mozilla-based browsers). Although you can set the individual inner and (in NN4) outer width and height properties of a window, the `resizeBy()` and `resizeTo()` methods let you adjust both axis measurements in one statement. In both instances, all adjustments affect the bottom-right corner of the window. To move the top-left corner, use the `window.moveBy()` or `window.moveTo()` methods.

Each resize method requires a different kind of parameter. The `resizeBy()` method adjusts the window by a certain number of pixels along one or both axes. Therefore, it is not concerned with the specific size of the window beforehand — only by how much each axis is to change. For example, to increase the current window size by 100 pixels horizontally and 50 pixels vertically, the statement is

```
window.resizeBy(100, 50);
```

Both parameters are required, but if you want to adjust the size in only one direction, set the other to zero. You may also shrink the window by using negative values for either or both parameters.

You may find a greater need for the `resizeTo()` method, especially when you know that on a particular platform, the window needs adjustment to a specific width and height to best accommodate that platform's display of form elements. Parameters for the `resizeTo()` method are the actual pixel width and height of the outer dimension of the window — the same as NN4's `window.outerWidth` and `window.outerHeight` properties.

To resize the window so that it occupies all screen real estate (except for the Windows taskbar and Macintosh menu bar), use the `screen` object properties that calculate the available screen space:

```
window.resizeBy(screen.availWidth, screen.availHeight);
```

This action, however, is not precisely the same in Windows as maximizing the window. To achieve that same effect, you must move the window to coordinates -4, -4 and add 8 to the two parameters of `resizeBy()`:

```
window.moveTo(-4,-4);
window.resizeTo(screen.availWidth + 8, screen.availHeight + 8);
```

This hides the window's own 4-pixels-wide border, as occurs during OS-induced window maximizing. See also the `screen` object discussion (see Chapter 41, "Table and List Objects") for more OS-specific details.

On some platforms, the dimensions are applied to the inner width and height rather than outer. If a specific outer size is necessary, use the NN-specific `window.outerHeight` and `window.outerWidth` properties instead.

Navigator 4 imposes some security restrictions for maximum and minimum size for a window. For both methods, you are limited to the viewable area of the screen and visible minimums unless the page uses signed scripts (see Chapter 49). With signed scripts and the user's permission, for example, you can adjust windows beyond the available screen borders.

Example

You can experiment with the resize methods with the page in Listing 27-29. Two parts of a form let you enter values for each method. The one for `window.resize()` also lets you enter several repetitions to better see the impact of the values. Enter zero and negative values to see how those affect the method. Also test the limits of different browsers.

LISTING 27-29

Window Resize Methods

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Window Resize Methods</title>
      <style type="text/css">
         .instructions
         {
            font-weight:bold;
         }
      </style>
      <script type="text/javascript">
         function doResizeBy(form)
         {
            var x = parseInt(form.resizeByX.value);
            var y = parseInt(form.resizeByY.value);
            var count = parseInt(form.count.value);
            for (var i = 0; i < count; i++)
            {
               window.resizeBy(x, y);
            }
         }
         function doResizeTo(form)
         {
            var x = parseInt(form.resizeToX.value);
            var y = parseInt(form.resizeToY.value);
            window.resizeTo(x, y);
         }
      </script>
   </head>
   <body>
      <h1>Window Resize Methods</h1>
      <hr />
      <form>
         <div class="instructions">Enter the x and y increment,
            plus how many times the window should
            be resized by these increments:
         </div>
         Horiz:<input type="text" name="resizeByX" size="4" />
         Vert:<input type="text" name="resizeByY" size="4" />
         How Many:<input type="text" name="count" size="4" />
         <input type="button" name="ResizeBy" value="Show resizeBy()"
                onclick="doResizeBy(this.form)" />
         <hr />
         <div class="instructions">Enter the desired width
            and height of the current window:</div>
         Width:<input type="text" name="resizeToX" size="4" />
```

```
        Height:<input type="text" name="resizeToY" size="4" />
        <input type="button" name="ResizeTo" value="Show resizeTo()"
               onclick="doResizeTo(this.form)" />
      </form>
   </body>
</html>
```

Related Items: `window.outerHeight`, `window.outerWidth` properties; `window.moveTo()`, `window.sizeToContent()` methods

`scroll (`*`horizontalCoord, verticalCoord`*`)`

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The `window.scroll()` method was introduced in NN3 and has been implemented in all scriptable browsers since then. But in the meantime, the method has been replaced by the `window.scrollTo()` method, which is in more syntactic alliance with many other window methods.

The `window.scroll()` method takes two parameters: the horizontal (x) and vertical (y) coordinates of the document that is to be positioned at the top-left corner of the window or frame. You must realize that the window and document have two similar, but independent, coordinate schemes. From the window's point of view, the top-left pixel (of the content area) is point `0,0`. All documents also have a `0,0` point: the very top left of the document. The window's `0,0` point doesn't move, but the document's `0,0` point can move — via manual or scripted scrolling. Although `scroll()` is a window method, it seems to behave more like a document method, as the document appears to reposition itself within the window. Conversely, you can also think of the window moving to bring its `0,0` point to the designated coordinate of the document.

Although you can set values beyond the maximum size of the document or to negative values, the results vary from platform to platform. For the moment, the best usage of the `window.scroll()` method is as a means of adjusting the scroll to the very top of a document (`window.scroll(0,0)`) when you want the user to be at a base location in the document. For vertical scrolling within a text-heavy document, an HTML anchor may be a better alternative for now (though it doesn't readjust horizontal scrolling).

Related Items: `window.scrollBy()`, `window.scrollTo()` methods

Unwanted User Scrolling

Wheeled mice have become increasingly popular. These mice include a scroll wheel that is activated by pressing down on the wheel and spinning the wheel. Be aware that even if your page design loads into frames or new windows that intentionally lack scroll bars, the page will be scrollable via this wheel if the document or its background image is larger than the window or frame. Users may not even be aware that they have scrolled the page (because there are no scroll-bar visual clues). If this affects your design, you may need to build in a routine (via `setTimeout()`) that periodically sets the scroll of the window to `0,0`.

```
scrollBy(deltaX,deltaY)
scrollTo(x,y)
```

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Modern browsers provide a related pair of window scrolling methods. The `window.scrollTo()` method is the newer version of the `window.scroll()` method. The two work identically to position a specific coordinate point of a document at the top-left corner of the inner window region.

By contrast, the `window.scrollBy()` method allows for relative positioning of the document. Parameter values indicate by how many pixels the document should scroll in the window (horizontally and vertically). Negative numbers are allowed if you want to scroll to the left and/or up. The `scrollBy()` method comes in handy if you elect to hide the scroll bars of a window or frame and offer other types of scrolling controls for your users. For example, to scroll down one entire screen of a long document, you can use the `window.innerHeight` (in NN/Moz) or `document.body.clientHeight` (in IE) properties to determine what the offset from the current position would be:

```
// assign IE body clientHeight to window.innerHeight
if (document.body && document.body.clientHeight)
{
   window.innerHeight = document.body.clientHeight;
}
window.scrollBy(0, window.innerHeight);
```

To scroll up, use a negative value for the second parameter:

```
window.scrollBy(0, -window.innerHeight);
```

The window scroll methods are not the ones to use to produce the scrolling effect of a positioned element. That kind of animation is accomplished by adjusting `style` position properties (see Chapter 43, “Positioned Objects”).

Example

To work with the `scrollTo()` method, you can use Listing 27-30, Listing 27-31, and Listing 27-32. The code in Listing 27-34 includes a control panel frame (similar to Listing 27-32) that provides input to experiment with the `scrollBy()` method.

LISTING 27-30

Frameset for ScrollBy Controller

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>window.scrollBy() Method</title>
   </head>
```

```
   <frameset rows="50%,50%">
      <frame src="jsb27-31.html" name="display" />
      <frame src="jsb27-32.html" name="control" />
   </frameset>
</html>
```

LISTING 27-31

The Image to Be Scrolled

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Arch</title>
   </head>
   <body>
      <h1>
         A Picture is Worth...
      </h1>
      <hr />
      <center>
         <table border="3">
            <caption align="bottom">
               A Splendid Arch
            </caption>
            <tr>
               <td>
                  <img alt="image" src="arch.gif" />
               </td>
            </tr>
         </table>
      </center>
   </body>
</html>
```

Notice in Listing 27-32 that all references to window properties and methods are directed to the `display` frame. String values retrieved from text fields are converted to numbers with the `parseInt()` global function.

LISTING 27-32

ScrollBy Controller

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>ScrollBy Controller</title>
      <script type="text/javascript">
```

continued

LISTING 27-32 *(continued)*

```
         function page(direction)
         {
            var pixFrame = parent.display;
            var deltaY = (pixFrame.innerHeight) ? pixFrame.innerHeight :
               pixFrame.document.body.scrollHeight;
            if (direction == "up")
            {
               deltaY = -deltaY;
            }
            parent.display.scrollBy(0, deltaY);
         }
         function customScroll(form)
         {
            parent.display.scrollBy(parseInt(form.x.value), parseInt(form.y.value));
         }
      </script>
   </head>
   <body>
      <h1>ScrollBy Controller</h1>
      <hr />
      <form name="custom">
         Enter an Horizontal increment
         <input type="text" name="x" value="0" size="4" />
         and Vertical
         <input type="text" name="y" value="0" size="4" /> value.
         <br />
         Then
         <input type="button" value="click to scrollBy()"
                onclick="customScroll(this.form)" />
         <hr />
         <input type="button" value="PageDown" onclick="page('down')" />
         <input type="button" value="PageUp" onclick="page('up')" />
      </form>
   </body>
</html>
```

Related Items: `window.pageXOffset`, `window.pageYOffset` properties; `window.scroll()` method

`scrollByLines(`*`intervalCount`*`)`
`scrollByPages(`*`intervalCount`*`)`

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera-, Chrome-

The `window.scrollByLines()` and `window.scrollByPages()` methods scroll the document by a specified number of lines or pages, respectively. You can think of these methods as the script equivalents to clicking the arrow (`scrollByLines()`) and page (`scrollByPages()`) regions of

the browser's vertical scroll bar. The argument to each method determines how many lines or pages to scroll, with positive values resulting in downward scrolling, and negative values resulting in upward scrolling.

setInterval("*expr*", *msecDelay* [, *language*])
setInterval(funcRef, msecDelay [, funcarg1, ... , funcargn])

Returns: Interval ID integer

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

It is important to understand the distinction between the `setInterval()` and `setTimeout()` methods. Before the `setInterval()` method was part of JavaScript, authors replicated the behavior with `setTimeout()`, but the task often required reworking scripts a bit.

Use `setInterval()` when your script needs to call a function or execute some expression repeatedly with a fixed time delay between calls to that function or expression. The delay is not at all like a wait state in some languages: Other processing does not halt while the delay is in effect. Typical applications include animation by moving an object around the page under controlled speed (instead of letting the JavaScript interpreter whiz the object through its path at CPU-dependent speeds). In a kiosk application, you can use `setInterval()` to advance slides that appear in other frames or as layers, perhaps changing the view every 10 seconds. Clock displays and countdown timers would also be suitable uses of this method (even though you see examples in this book that use the old-fashioned `setTimeout()` way to perform timer and clock functions).

By contrast, `setTimeout()` is best suited for those times when you need to carry out a function or expression once in the future — even if that future is only a second or two away. In other words, `setTimeout()` gives you a one-shot timer, whereas `setInterval()` gives you a recurring timer. See the discussion of the `setTimeout()` method later in this chapter for details on this application.

Although the primary functionality of the `setInterval()` method is the same in all browsers, NN/Moz and IE offer some extra possibilities depending on the way you use parameters to the method. For simple invocations of this method, the same parameters work in all browsers that support the method. First, we address the parameters that all browsers have in common.

The first parameter of the `setInterval()` method is the name of the function or expression to run after the interval elapses. This item must be a quoted string. If the parameter is a function, no function arguments are allowed inside the function's parentheses unless the arguments are literal strings (but see the next section, "Passing function parameters").

The second parameter of this method is the number of milliseconds (1,000 per second) that JavaScript should use as the interval between invocations of the function or expression. Even though the measure is in extremely small units, don't rely on 100 percent accuracy of the intervals. Various other internal processing delays may throw off the timing just a bit.

Just like `setTimeout()`, `setInterval()` returns an integer value that is the ID for the interval process. That ID value lets you turn off the process with the `clearInterval()` method, which takes the ID value as its sole parameter. This mechanism allows for the setting of multiple running interval processes and gives your scripts the power to stop individual processes at any time without interrupting the others.

IE4+ uses the optional third parameter to specify the scripting language of the statement or function being invoked in the first parameter. As long as you are scripting exclusively in JavaScript (the same as JScript), there is no need to include this parameter.

Passing function parameters

NN4+/Moz provides a mechanism for easily passing evaluated parameters to a function invoked by `setInterval()`. To use this mechanism, the first parameter of `setInterval()` must not be a string, but a reference to the function (no trailing parentheses). The second parameter remains the amount of delay. But beginning with the third parameter, you can include evaluated function arguments as a comma-delimited list:

```
intervalID = setInterval(cycleAnimation, 500, "figure1");
```

The function definition receives those parameters in the same form as any function:

```
function cycleAnimation(elemID) {...}
```

For use with a wider range of browsers, you can also cobble together the ability to pass parameters to a function invoked by `setInterval()`. Because the call to the other function is a string expression, you can use computed values as part of the strings, via string concatenation. For example, if a function uses event handling to find the element that a user clicked (to initiate some animation sequence), that element's ID, referenced by a variable, can be passed to the function invoked by `setInterval()`:

```
function findAndCycle()
{
   var elemID;
   // statements here that examine the event info
   // and extract the ID of the clicked element,
   // assigning that ID to the elemID variable
   intervalID = setInterval("cycleAnimation(" + elemID + ")", 500);
}
```

If you need to pass ever-changing parameters with each invocation of the function from `setInterval()`, look instead to using `setTimeout()` at the end of a function to invoke that same function again.

Example

The demonstration of the `setInterval()` method entails a two-framed environment. The frameset-ting document is shown in Listing 27-33.

LISTING 27-33

SetInterval() Demonstration Frameset

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
<title>setInterval() Method</title>
   </head>
   <frameset rows="50%,50%">
      <frame src="jsb27-34.html" name="control" />
      <frame src="bofright.html" name="display" />
   </frameset>
</html>
```

In the top frame is a control panel with several buttons that control the automatic scrolling of the Bill of Rights text document in the bottom frame. Listing 27-34 shows the control-panel document. Many functions here control the interval, scrolling jump size, and direction, and they demonstrate several aspects of applying `setInterval()`.

Notice that in the beginning the script establishes several global variables. Three of them are parameters that control the scrolling; the last one is for the ID value returned by the `setInterval()` method. The script needs that value to be a global value so that a separate function can halt the scrolling with the `clearInterval()` method.

All scrolling is performed by the `autoScroll()` function. For the sake of simplicity, all controlling parameters are global variables. In this application, placement of those values in global variables helps the page restart autoscrolling with the same parameters as it had when it last ran.

LISTING 27-34

SetInterval() Control Panel

HTML: jsb27-34.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>ScrollBy Controller</title>
      <script type="text/javascript" src="jsb27-34.js"></script>
   </head>
   <body onload="startScroll()">
      <h1>AutoScroll by setInterval() Controller</h1>
      <hr />
      <form name="custom">
         <input type="button" value="Start Scrolling"
                onclick="startScroll()" />
         <input type="button" value="Stop Scrolling"
                onclick="stopScroll()" />
         <p>
            <input type="button" value="Shorter Time Interval"
                   onclick="reduceInterval()" />
            <input type="button" value="Longer Time Interval"
                   onclick="increaseInterval()" />
         </p>
         <p><input type="button" value="Bigger Scroll Jumps"
                   onclick="increaseJump()" />
            <input type="button" value="Smaller Scroll Jumps"
                   onclick="reduceJump()" />
         </p>
         <p><input type="button" value="Change Direction"
                   onclick="swapDirection()" />
         </p>
      </form>
   </body>
</html>
```

continued

LISTING 27-34 *(continued)*

```
JavaScript: jsb27-34.js

var scrollSpeed = 500;
var scrollJump = 1;
var scrollDirection = "down";
var intervalID;

function autoScroll()
{
   if (scrollDirection == "down")
   {
      scrollJump = Math.abs(scrollJump);
   }
   else if (scrollDirection == "up" && scrollJump > 0)
   {
      scrollJump = -scrollJump;
   }
   parent.display.scrollBy(0, scrollJump);
   if (parent.display.pageYOffset <= 0)
   {
      clearInterval(intervalID);
   }
}

function reduceInterval()
{
   stopScroll();
   scrollSpeed -= 200;
   startScroll();
}
function increaseInterval()
{
   stopScroll();
   scrollSpeed += 200;
   startScroll();
}
function reduceJump()
{
   scrollJump -= 2;
}
function increaseJump()
{
   scrollJump += 2;
}
function swapDirection()
{
   scrollDirection = (scrollDirection == "down") ? "up" : "down";
}
function startScroll()
```

```
{
   parent.display.scrollBy(0, scrollJump);
   if (intervalID)
   {
      clearInterval(intervalID);
   }
   intervalID = setInterval("autoScroll()",scrollSpeed);
}
function stopScroll()
{
   clearInterval(intervalID);
}
```

The `setInterval()` method is invoked inside the `startScroll()` function. This function initially burps the page by one `scrollJump` interval so that the test in `autoScroll()` for the page being scrolled all the way to the top doesn't halt a page from scrolling before it gets started. Notice, too, that the function checks for the existence of an interval ID. If one is there, it is cleared before the new one is set. This is crucial within the design of the example page, because repeated clicking of the Start Scrolling button triggers multiple interval timers inside the browser. Only the most recent one's ID would be stored in `intervalID`, allowing no way to clear the older ones. But this little side trip makes sure that only one interval timer is running. One of the global variables, `scrollSpeed`, is used to fill the delay parameter for `setInterval()`. To change this value on the fly, the script must stop the current interval process, change the `scrollSpeed` value, and start a new process.

The intensely repetitive nature of this application is nicely handled by the `setInterval()` method.

Related Items: `window.clearInterval()`, `window.setTimeout()` methods

setTimeout("*expr*", *msecDelay* [, *language*])
setTimeout(*functionRef*, *msecDelay* [, *funcarg1*, ... , *funcargn*])

Returns: ID value for use with `window.clearTimeout()` method

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The name of this method may be misleading, especially if you have done other kinds of programming involving timeouts. In JavaScript, a *timeout* is an amount of time (in milliseconds) before a stated expression evaluates. A timeout is not a wait or script delay, but a way to tell JavaScript to hold off executing a statement or function for a desired amount of time. Other statements following the one containing `setTimeout()` execute immediately.

Suppose that you have a web page designed to enable users to interact with a variety of buttons or fields within a time limit (this is a web page running at a freestanding kiosk). You can turn on the timeout of the window so that if no interaction occurs with specific buttons or fields lower in the document after, say, 2 minutes (120,000 milliseconds), the window reverts to the top of the document or to a help screen. To tell the window to switch off the timeout after a user does navigate within the allotted time, you need to have any button that the user interacts with call the other side of a `setTimeout()` method — the `clearTimeout()` method — to cancel the current timer. (The `clearTimeout()` method is explained earlier in this chapter.) Multiple timers can run concurrently and are completely independent of one another.

Although the primary functionality of the `setTimeout()` method is the same in all browsers, NN/Moz and IE offer some extra possibilities depending on the way you use parameters to the method. For simple invocations of this method, the same parameters work in all browsers that support the method. We first address the parameters that all browsers have in common.

The expression that comprises the first parameter of the method `window.setTimeout()` is a quoted string that can contain either a call to any function or method, or a stand-alone JavaScript statement. The expression evaluates after the time limit expires.

Understanding that this timeout does not halt script execution is very important. In fact, if you use a `setTimeout()` method in the middle of a script, the succeeding statements in the script execute immediately; after the delay time, the expression in the `setTimeout()` method executes. Therefore, we've found that the best way to design a timeout in a script is to plug it in as the last statement of a function: Let all other statements execute and then let the `setTimeout()` method appear to halt further execution until the timer goes off. In truth, however, although the timeout is holding, the user is not prevented from performing other tasks. And after a timeout timer is ticking, you cannot adjust its time. Instead, clear the timeout and start a new one.

If you need to use `setTimeout()` as a delay inside a function, break the function into two parts, using the `setTimeout()` method as a bridge between the two functions. You can see an example of this in Listing 27-25, where IE needs a little delay to finish opening a new window before content can be written for it. If it weren't for the required delay, the HTML assembly and writing would have been accomplished in the same function that opens the new window.

It is not uncommon for a `setTimeout()` method to invoke the very function in which it lives. For example, if you have written a Java applet to perform some extra work for your page, and you need to connect to it via the NPAPI, your scripts must wait for the applet to load and carry out its initializations. Although an `onload` event handler in the document ensures that the applet object is visible to scripts, it doesn't know whether the applet has finished its initializations. A JavaScript function that inspects the applet for a clue might need to poll the applet every 500 milliseconds until the applet sets some internal value indicating that all is ready, as shown here:

```
var t;
function autoReport()
{
   if (!document.myApplet.done)
   {
      t = setTimeout("autoReport()",500);
   }
   else
   {
      clearTimeout(t);
      // more statements using applet data //
   }
}
```

JavaScript provides no built-in equivalent for a `wait` command. The worst alternative is to devise a looping function of your own to trap script execution for a fixed amount of time. Unfortunately, this approach prevents other processes from being carried out, so you should consider reworking your code to rely on a `setTimeout()` method instead.

NN4+/Moz provides a mechanism for passing parameters to functions invoked by `setTimeout()`. See the section "Passing function parameters" in the discussion of `window.setInterval()` for details on this topic, and on passing parameters in other browser versions.

As a note to experienced programmers, neither `setInterval()` nor `setTimeout()` spawns new threads in which to run its invoked scripts. When the timer expires and invokes a function, the process gets at the end of the pending script processing queue in the JavaScript execution thread.

Example

When you load the HTML page in Listing 27-35, it triggers the `updateTime()` function, which displays the time (in hh:mm am/pm format) in the status bar. Instead of showing the seconds incrementing one by one (which may be distracting to someone trying to read the page), this function alternates the last character of the display between an asterisk and nothing, like a visual heartbeat.

LISTING 27-35

Display the Current Time

```
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Status Bar Clock</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript">
         // initialize when the page has loaded
         addEvent(window, "load", updateTime);

         var flasher = false;
         // calculate current time, determine flasher state,
         // and insert time into status bar every second
         function updateTime()
         {
            var now = new Date();
            var theHour = now.getHours();
            var theMin = now.getMinutes();
            var theTime = "" + ((theHour > 12) ? theHour - 12 : theHour);
            theTime += ((theMin < 10) ? ":0" : ":") + theMin;
            theTime  += (theHour >= 12) ? " pm" : " am";
            theTime += ((flasher) ? " " : "*");
            flasher = !flasher;
            window.status = theTime;
            // recursively call this function every second to keep timer going
            timerID = setTimeout("updateTime()",1000);
         }
      </script>
   </head>
   <body>
      <h1>Status Bar Clock</h1>
      <hr />
   </body>
</html>
```

In this function, the `setTimeout()` method works in the following way: When the current time (including the flasher status) appears in the status bar, the function waits approximately 1 second

(1,000 milliseconds) before calling the same function again. You don't have to clear the `timerID` value in this application because JavaScript does it for you every time the 1,000 milliseconds elapse.

A logical question to ask is whether this application should be using `setInterval()` instead of `setTimeout()`. This is a case in which either one does the job. Using `setInterval()` here would require that the interval process start outside the `updateTime()` function, because you need only one process running that repeatedly calls `updateTime()`. It would be a cleaner implementation instead of the numerous timeout processes spawned by Listing 27-35. On the other hand, the application would not run in legacy browsers, as Listing 27-35 does. That's likely not a problem at this point in time, but this application remains a decent example of the `setTimeout()` function.

To demonstrate passing parameters, you can modify the `updateTime()` function to add the number of times it gets invoked to the display in the status bar. For that to work, the function must have a parameter variable so that it can catch a new value each time it is invoked by `setTimeout()`'s expression. For all browsers, the function would be modified as follows (unchanged lines are represented by the ellipsis):

```
function updateTime(i)
{
   //...
   window.status = theTime + "  (" + i + ")";
   // pass updated counter value with next call to this function
   timerID = setTimeout("updateTime(" + i+1 + ")",1000);
}
```

If you were running this exclusively in NN4+/Moz, you could use its more convenient way of passing parameters to the function:

```
timerID = setTimeout(updateTime, 1000, i+1);
```

In either case, the `onload` event handler would also have to be modified to get the ball rolling with an initial parameter:

```
onload = "updateTime(0)";
```

Related Items: `window.clearTimeout()`, `window.setInterval()`, `window.clearInterval()` methods

showHelp("*URL*",["*contextID*"])

Returns: Nothing

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The IE-specific `showHelp()` method lets a script open a Winhelp window with a particular `.hlp` file. This method is specific to Win32 operating systems.

If your Winhelp file has context identifiers specified in various places, you can pass the ID as an optional second parameter. This lets the call to `showHelp()` navigate to the particular area of the `.hlp` file that applies to a specific element on the page.

See the Microsoft Visual Studio authoring environment for details on building Winhelp files.

showModalDialog("*URL*"[, *arguments*][, *features*])
showModelessDialog("*URL*"[, *arguments*][, *features*])

Returns: `returnValue` (modal) or `window` object (modeless)

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari 2.01+, Opera-, Chrome+

IE, Safari, Chrome, and Mozilla-based browsers such as Firefox, provide methods for opening a modal dialog-box window, which always stays in front of the main browser window, while making the main window inaccessible to the user. In WinIE5, Microsoft added the modeless type of dialog box, which is not supported by Safari, Chrome and Mozilla-based browsers such as Firefox. The modeless type of dialog box also stays in front but allows user access to whatever can be seen in the main window. You can load any HTML page or image that you like into the dialog-box window by providing a URL as the first parameter. Optional parameters let you pass data to a dialog box and give you considerable control over the look of the window. A similar type of dialog-box window is available in NN/Moz via the `window.openDialog()` method.

The windows generated by both methods are (almost) full-fledged `window` objects, with some extra properties that are useful for what these windows are intended to do. Perhaps the most important property is the `window.dialogArgument` property. This property lets a script read the data that is passed to the window via the second parameter of both `showModalDialog()` and `showModelessDialog()`. Passed data can be in any valid JavaScript data type, including objects and arrays.

Displaying a modal dialog box has some ramifications for scripts. In particular, script execution in the main window halts at the statement that invokes the `showModalDialog()` method as long as the modal dialog box remains visible. Scripts are free to run in the dialog-box window during this time. The instant the user closes the dialog box, execution resumes in the main window. A call to show a modeless dialog box, on the other hand, does not halt processing because scripts in the main page or dialog-box window are allowed to communicate live with the other window.

Retrieving dialog-box data

To send data back to the main window's script from a modal dialog-box window, a script in the dialog-box window can set the `window.returnValue` property to any JavaScript value. It is this value that gets assigned to the variable receiving the returned value from the `setModelDialog()` method, as shown in the following example:

```
var specifications = window.showModalDialog("preferences.html");
```

The makeup and content of the returned data are in the hands of your scripts. No data is automatically returned for you.

Because a modeless dialog box coexists with your live main page window, returning data is not as straightforward as for a modal dialog box. The second parameter of the `showModelessDialog()` method takes on a special task that isn't exactly the same as passing parameters to the dialog box. Instead, if you define a global variable or a function in the main window's script, pass a reference to that variable or function as the second parameter to display the modeless dialog box. A script in the modeless dialog box can then point to that reference as the way to send data back to the main window before the dialog box closes (or when a user clicks something, such as an Apply button). This

mechanism even allows for passing data back to a function in the main window. For example, say that the main window has a function defined as the following:

```
function receivePrefsDialogData(a, b, c)
{
   // statements to process incoming values //
}
```

Then pass a reference to this function when opening the window:

```
dlog = showModelessDialog("prefs.html", receivePrefsDialogData);
```

A script statement in the dialog-box window's document can pick up that reference so that other statements, such as a function for an Apply button's `onclick` event handler, can use it:

```
var returnFunc = window.dialogArguments;
//...
function apply(form)
{
   returnFunc(form.color.value, form.style.value, form.size.value);
}
```

Although this approach seems to block ways of getting parameters to the dialog box when it opens, you can always reference the dialog box in the main window's script and set form or variable values directly:

```
dlog = showModelessDialog("prefs.html", receivePrefsDialogData);
dlog.document.forms[0].userName.value = GetCookie("userName");
```

Be aware that a dialog-box window opened with either of these methods does not maintain a connection to the originating window via the `opener` property. The `opener` property for both dialog-box types is undefined.

Dialog-box window features

Both methods provide an optional third property that lets you specify visible features of the dialog-box window. Omitting the property sets all features to their default values. All parameters are to be contained by a single string, and each parameter's name–value pair is in the form of CSS `attribute:value` syntax. Table 27-5 lists all the window features available for the two window styles. If you are designing for backward compatibility with IE4, you are restricted to the modal dialog box and a subset of features, as noted in the table. All values listed as Boolean take only the following four values: `yes`, `no`, `1`, and `0`.

The CSS-type of syntax for these features lets you thread multiple features together by separating each pair with a semicolon within the string. For example:

```
var dlogData = showModalDialog("prefs.html", defaultData,
   "dialogHeight:300px; dialogWidth:460px; help:no");
```

Although they are not explicitly listed among the window features, scroll bars are normally displayed in the window if the content exceeds the size assigned or available to the dialog box. If you don't want scroll bars to appear, have your dialog-box document's script set the `document.body.scroll` property to `false` as the page opens.

TABLE 27-5

IE Dialog-Box Window Features

Feature	Type	Default	Description
`center`	Boolean	`yes`	Whether to center dialog box (overridden by `dialogLeft` and/or `dialogTop`).
`dialogHeight`	Length	Varies	Outer height of the dialog-box window. IE4 default length unit is `em`; IE5+/Moz/Safari/Chrome is pixel (`px`).
`dialogLeft`	Integer	Varies	Pixel offset of dialog box from left edge of screen.
`dialogTop`	Integer	Varies	Pixel offset of dialog box from top edge of screen.
`dialogWidth`	Length	Varies	Outer width of the dialog-box window. IE4 default length unit is `em`; IE5+/Moz/Safari/Chrome is pixel (`px`).
`edge`	String	`raised` | `sunken`	Border style (IE only).
`resizable`	Boolean	`no`	Dialog box is resizable.
`scroll`	Boolean	`yes`	Display scrollbars
`status`	Boolean	Varies	Display status bar at window bottom (IE5+/Safari/Chrome only). Default is `yes` for untrusted dialog box, `no` for trusted dialog box.

Dialog-box cautions

A potential user problem to watch for is that typically, a dialog-box window does not open until the HTML file for the dialog box has loaded. Therefore, if there is substantial delay before a complex document loads, the user does not see any action indicating that something is happening. You may want to experiment with setting the `cursor` style sheet property and restoring it when the dialog box's document loads.

Example

To demonstrate the two styles of dialog boxes, we have implemented the same functionality (setting some session visual preferences) for both modal and modeless dialog boxes. This tactic shows you how to pass data back and forth between the main page and both styles of dialog-box windows.

The first example demonstrates how to use a modal dialog box. In the process, data is passed into the dialog-box window, and values are returned. Listing 27-36 is the HTML and scripting for the main page. A button's `onclick` event handler invokes a function that opens the modal dialog box. The dialog box's document (see Listing 27-37) contains several form elements for entering a user name and selecting a few color styles for the main page. Data from the dialog box is fashioned into an array to be sent back to the main window. That array is initially assigned to a local variable, `prefs`, as the dialog box closes. If the user cancels the dialog box, the returned value is an empty string, so nothing more in `getPrefsData()` executes. But when

the user clicks OK, the array comes back. Each of the array items is read and assigned to its respective form value or style property. These values are also preserved in the global `currPrefs` array. This allows the settings to be sent to the modal dialog box (as the second parameter to `showModalDialog()`) the next time the dialog box is opened.

LISTING 27-36

Main Page for showModalDialog()

```
<html>
   <head>
      <title>window.setModalDialog() Method</title>
      <script type="text/javascript" src="jsb27-36.js"></script>
   </head>
   <body bgcolor="#EEEEEE" style="margin:20px" onload="init()">
      <h1>window.setModalDialog() Method</h1>
      <hr />
      <h2 id="welcomeHeader">Welcome, <span id="firstName">.</span>!</h2>
      <hr />
      <p>Use this button to set style preferences for this page:
         <button id="prefsButton" onclick="getPrefsData()">Preferences</button>
      </p>
   </body>
</html>
```

JavaScript: jsb27-36.js

```
var currPrefs = new Array();
var nameHolder;

function getPrefsData()
{
   var prefs = showModalDialog("jsb27-37.html", currPrefs,
               "dialogWidth:400px; dialogHeight:300px;");
   if (prefs)
   {
      if (prefs["name"])
      {
         if (nameHolder.textContent == "friend")
         {
            nameHolder.textContent = prefs["name"];
         }
         else
         {
            //IE
            nameHolder.innerText = prefs["name"];
         }
         currPrefs["name"] = prefs["name"];
      }
```

```
      if (prefs["bgColor"])
      {
         document.body.style.backgroundColor = prefs["bgColor"];
         currPrefs["bgColor"] = prefs["bgColor"];
      }
      if (prefs["textColor"])
      {
         document.body.style.color = prefs["textColor"];
         currPrefs["textColor"] = prefs["textColor"];
      }
      if (prefs["h1Size"])
      {
         if (document.all)
         {
            document.all.welcomeHeader.style.fontSize = prefs["h1Size"];
         }
         else
         {
            document.getElementById("welcomeHeader").style.fontSize
            = prefs["h1Size"];
         }
         currPrefs["h1Size"] = prefs["h1Size"];
      }
   }
}
function init()
{
   nameHolder = document.getElementById("firstName");
   if (nameHolder.textContent == ".")
   {
      nameHolder.textContent = "friend";
   }
   else
   {
      //IE
      nameHolder.innerText = "friend";
   }
}
```

The dialog box's document, shown in Listing 27-37, is responsible for reading the incoming data (and setting the form elements accordingly) and assembling form data for return to the main window's script. Notice when you load the example that the `title` element of the dialog box's document appears in the dialog-box window's title bar.

When the page loads into the dialog-box window, the `init()` function examines the `window.dialogArguments` property. If it has any data, the data is used to preset the form elements to mirror the current settings of the main page. A utility function, `setSelected()`, preselects the option of a `select` element to match the current settings.

Buttons at the bottom of the page are explicitly positioned to be at the bottom-right corner of the window. Each button invokes a function to do what is needed to close the dialog box. In the case of the OK button, the `handleOK()` function sets the `window.returnValue` property to the data

that comes back from the `getFormData()` function. This latter function reads the form element values and packages them in an array using the form elements' names as array indices. This helps keep everything straight back in the main window's script, which uses the index names, and therefore is not dependent upon the precise sequence of the form elements in the dialog-box window.

{
   for (var i = 0; i < select.options.length; i++)
   {
      if (select.options[i].value == value)
      {
         select.selectedIndex = i;
         break;
      }
   }
   return;
}

// Utility function to accept a press of the
// Enter key in the text field as a click of OK
function checkEnter()
{
   if (window.event.keyCode == 13)
   {
      handleOK();
   }
}
```

One last convenience feature of the dialog-box window is the `onkeypress` event handler in the text box. The function it invokes looks for the Enter key. If that key is pressed while the box has focus, the same `handleOK()` function is invoked, as though the user had clicked the OK button. This feature makes the dialog box behave as though the OK button is an automatic default, just as in real dialog boxes.

You should observe several important structural changes that were made to turn the modal approach into a modeless one. Listing 27-38 shows a version of the main window modified for use with a modeless dialog box. Another global variable, `prefsDlog`, is initialized to eventually store the reference to the modeless window returned by the `showModelessWindow()` method. The variable gets used to invoke the `init()` function inside the modeless dialog box, but also as a condition in an `if` construction surrounding the generation of the dialog box. The reason this is needed is to prevent multiple instances of the dialog box from being created (the button is still alive while the modeless window is showing). The dialog box won't be created again as long as there is a value in `prefsDlog` and the dialog-box window has not been closed (picking up the `window.closed` property of the dialog-box window).

The `showModelessDialog()` method's second parameter is a reference to the function in the main window that updates the main document. As you see in a moment, that function is invoked from the dialog box when the user clicks the OK or Apply button.

Main Page for showModelessDialog()

HTML: jsb27-38.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>window.setModelessDialog() Method</title>
      <script type="text/javascript" src="jsb27-38.js"></script>
   </head>
   <body bgcolor="#EEEEEE" style="margin:20px" onload="init()">
      <h1>window.setModelessDialog() Method</h1>
      <hr />
      <h2 id="welcomeHeader">Welcome, <span id="firstName"> </span>!</h2>
      <hr />
      <p>Use this button to set style preferences for this page:
      <button id="prefsButton"
              onclick="getPrefsData()">Preferences</button>
      </p>
   </body>
</html>
```

JavaScript: jsb27-38.js

```
var currPrefs = new Array();
var prefsDlog;
function getPrefsData()
{
   if (!prefsDlog || prefsDlog.closed)
   {
      prefsDlog = showModelessDialog("jsb27-39.html", setPrefs,
                  "dialogWidth:400px; dialogHeight:300px");
      prefsDlog.init(currPrefs);
   }
}

function setPrefs(prefs)
{
   if (prefs["bgColor"])
   {
      document.body.style.backgroundColor = prefs["bgColor"];
      currPrefs["bgColor"] = prefs["bgColor"];
   }
   if (prefs["textColor"])
   {
      document.body.style.color = prefs["textColor"];
      currPrefs["textColor"] = prefs["textColor"];
   }
   if (prefs["h1Size"])
```

```
   {
      document.all.welcomeHeader.style.fontSize = prefs["h1Size"];
      currPrefs["h1Size"] = prefs["h1Size"];
   }
   if (prefs["name"])
   {
      document.all.firstName.innerText = prefs["name"];
      currPrefs["name"] = prefs["name"];
   }
}

function init()
{
   document.all.firstName.innerText = "friend";
}
```

Changes to the dialog-box window document for a modeless version (see Listing 27-39) are rather limited. A new button is added to the bottom of the screen for an Apply button. As in many dialog-box windows you see in Microsoft products, the Apply button lets current settings in dialog boxes be applied to the current document, but without closing the dialog box. This approach makes experimenting with settings easier.

The Apply button invokes a `handleApply()` function, which works the same as `handleOK()`, except that the dialog box is not closed. But these two functions communicate back to the main window differently from a modal dialog box. The main window's processing function is passed as the second parameter of `showModelessDialog()` and is available as the `window.dialogArguments` property in the dialog-box window's script. That function reference is assigned to a local variable in both functions, and the remote function is invoked, passing the results of the `getFormData()` function as parameter values back to the main window.

```

The biggest design challenge you probably face with respect to these windows is deciding between a modal and modeless dialog-box style. Some designers insist that modality has no place in a graphical user interface; others say that there are times when you need to focus the user on a very specific task before any further processing can take place. That's where a modal dialog box makes perfect sense.

Related Item: `window.open()` method

sizeToContent()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera-, Chrome-

The NN6+/Moz `window.sizeToContent()` method can be a valuable aid in making sure that a window (especially a subwindow) is sized for the optimum display of the window's content. But you must be cautious with this method, or it will do more harm than good.

Invoking the `sizeToContent()` method resizes the window so that all content is visible. Concerns about variations in OS-specific rendering become a thing of the past. Naturally, you should perform this action only on a window whose content occupies, at the most, a space smaller than the smallest video monitor running your code (typically 640×480 pixels, but conceivably much smaller for future versions of the browser used on handheld computers).

You can get the user in trouble, however, if you invoke the method twice on the same window that contains the resizing script. This action can cause the window to expand to a size that may exceed the pixel size of the user's video monitor. Successive invocations fail to cinch up the window's size to fit its content again. Multiple invocations are safe, however, on subwindows when the resizing script statement is in the main window.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") in NN6+/Moz to try the `sizeToContent()` method. Assuming that you are running The Evaluator from the `Chap13` directory on the CD-ROM (or the directory copied as is to your hard disk), you can open a subwindow with one of the other files in the directory and then size the subwindow. Enter the following statement in the top text box:

```
a = window.open("jsb13-02.html","")
```

You might, depending on where you installed the CD-ROM, have to alter the path in the above statement to something like this:

```
a = window.open("../../Chap13/lst13-02.htm","")
```

The file will open, depending on the browser version and your browser configuration settings, in either a new tab or a new subwindow. Enter the following statement in the top text box:

```
a.sizeToContent()
```

The resized window (if a new tab was opened) or subwindow is at the minimum recommended width for a browser window and at a height tall enough to display the little bit of content in the document.

As with any method that changes the size of the browser window, problems arise in browsers such as Firefox 2 that support tabbed browsing where multiple pages are opened as different tabs within the same browser instance. In a tabbed browser, it is impossible to resize the window of one page without altering all others. It's certainly still possible to open multiple browser instances to resolve this problem, but the default response to `window.open()` is to open a new tab, not a new browser window.

Related Item: `window.resizeTo()` method

stop()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari+, Opera+, Chrome-

The NN/Moz original `stop()` method offers a scripted equivalent of clicking the Stop button in the toolbar. The availability of this method allows you to create your own toolbar on your page and hide the toolbar (in the main window with signed scripts, or in a subwindow). For example, if you have an image representing the Stop button in your page, you can surround it with a link whose action stops loading, as in the following:

```
<a href="javascript: void stop()"><img src="myStop.gif" border="0"></a>
```

A script cannot stop its own document from loading, but it can stop the loading of another frame or window. Similarly, if the current document dynamically loads a new image or a multimedia MIME type file as a separate action, the `stop()` method can halt that process. Even though the `stop()` method is a window method, it is not tied to any specific window or frame: Stop means stop.

Related Items: `window.back()`, `window.find()`, `window.forward()`, `window.home()`, `window.print()` methods

Event handlers

onafterprint
onbeforeprint

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Each of these event handlers fires after the user has clicked the OK button in IE's Print dialog box. This goes for printing that is invoked manually (via menus and browser shortcut buttons) and the `window.print()` method.

Although printing is usually WYSIWYG, it is conceivable that you may want the printed version of a document to display more, or less, of the document than is showing at that instant. For example, you may have a special copyright notice that you want appended to the end of a page whenever it goes to the printer. In that case, the element with that content can have its `display` style sheet property set to `none` when the page loads. Before the document is sent to the printer, a script needs to adjust that style property to display the element as a block item; after printing, have your script revert the setting to `none`.

Immediately after the user clicks the OK button in the Print dialog box, the `onbeforeprint` event handler fires. As soon as the page is sent to the printer or spooler, the `onafterprint` event handler fires.

Example

The following script fragment assumes that the page includes a `div` element whose style sheet includes a setting of `display:none` as the page loads. Somewhere in the `head`, the print-related event handlers are set as properties:

```
function showPrintCopyright()
{
   document.all.printCopyright.style.display = "block";
}
function hidePrintCopyright()
{
   document.all.printCopyright.style.display = "none";
}
window.onbeforeprint = showPrintCopyright;
window.onafterprint = hidePrintCopyright;
```

onbeforeunload

Compatibility: WinIE4+, MacIE5+, NN-, Moz+, Safari+, Opera-, Chrome+

Any user or scripted action that normally forces the current page to be unloaded or replaced causes the `onbeforeunload` event handler to fire. Unlike the `onunload` event handler, however, `onbeforeunload` is a bit better behaved when it comes to allowing complex scripts to finish before the actual unloading takes place. Moreover, you can assign a string value to the `event.returnValue` property in the event handler function. That string becomes part of a message in an alert window that gives the user a chance to stay on the page. If the user agrees to stay, the page does not unload, and any action that caused the potential replacement is canceled.

Example

The simple page in Listing 27-40 shows you how to give the user a chance to stay on the page.

LISTING 27-40

Using the onbeforeunload Event Handler

```
<html>
   <head>
      <title>onbeforeunload Event Handler</title>
```

continued

LISTING 27-40 *(continued)*

```
      <script type="text/javascript">
         function verifyClose()
         {
            return "We really like you and hope you will stay longer.";
         }
      </script>
   </head>
   <body onbeforeunload="return verifyClose()">
      <h1>onbeforeunload Event Handler</h1>
      <hr />
      <p>Use this button to navigate to the previous page:
         <button id="go"
                 onclick="history.back()">Go Back</button>
      </p>
   </body>
</html>
```

Related Item: `onunload` event handler

onerror

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari-, Opera-, Chrome-

(See the discussion of the `window.onerror` property earlier in this chapter.)

onhelp

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The generic `onhelp` event handler, discussed in Chapter 26, also fires when the user activates the context-sensitive help within a modal or modeless dialog box. In the latter case, a user can click the Help icon in the dialog box's title bar, at which time the cursor changes to a question mark. The user can then click any element in the window. At that second click, the `onhelp` event handler fires, and the `event` object contains information about the element clicked (the `event.srcElement` is a reference to the specific element), allowing a script to supply help about that element.

To prevent the browser's built-in help window from appearing, the event handler must evaluate to `return false` (IE4+) or set the `event.returnValue` property to `false` (IE5+).

Example

The following script fragment can be used to provide context-sensitive help within a dialog box. Help messages for only two form elements are shown here, but in a real application, you could easily add more messages.

```
function showHelp()
{
   switch (event.srcElement.name)
```

```
      {
         case "bgColor" :
            alert("Choose a color for the main window\'s background.");
            break;
         case "name" :
            alert("Enter your first name for a friendly greeting.");
            break;
         default :
            alert("Make preference settings for the main page styles.");
      }
      event.returnValue = false;
   }
   window.onhelp = showHelp;
```

Because this page's help focuses on form elements, the `switch` construction cases are based on the `name` properties of the form elements. For other kinds of pages, the `id` properties may be more appropriate.

Related Items: `event` object (Chapter 32, "Event Objects"); `switch` construction (Chapter 21, "Control Structures and Exception Handling")

onload

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `onload` event handler fires in the current window at the end of the document loading process (after all text and image elements have been transferred from the source file server to the browser, and after all plug-ins and Java applets have loaded and started running). At that point, the browser's memory contains all the objects and script components in the document that the browser can possibly know about.

The `onload` handler is an attribute of a `<body>` tag for a single-frame document, or of the `<frameset>` tag for the top window of a multiple-frame document. When the handler is an attribute of a `<frameset>` tag, the event triggers only after all frames defined by that frameset have completely loaded.

Use either of the following scenarios to insert an `onload` handler into a document the old way:

```
<html>
   <head>
   </head>
   <body [other attributes] onload="statementOrFunction">
      [body content]
   </body>
</html>

<html>
   <head>
   </head>
   <frameset [other attributes] onload="statementOrFunction">
      <frame [frame specification attributes] />
   </frameset>
</html>
```

Alternatively, you can bind an event listener to the `window` object using the W3C `addEventListener()` method. Chapter 32 explains the modern cross-browser event-handling technique.

This handler has a special capability when it's part of a frameset definition: The handler won't fire until the `onload` event handlers of all child frames in the frameset have fired. Therefore, if some initialization scripts depend on components existing in other frames, trigger them from the frameset's `onload` event handler. This brings up a good general rule of thumb for writing JavaScript: Scripts that execute during a document's loading should contribute to the process of generating the document and its objects. To act immediately on those objects, design additional functions that are called by the `onload` event handler for that window.

The type of operations suited for an `onload` event handler are those that can run quickly and without user intervention. Users shouldn't be penalized by having to wait for considerable postloading activity to finish, before they can interact with your pages. At no time should you present a modal dialog box as part of an `onload` handler. Users who design macros on their machines to visit sites unattended may get hung up on a page that automatically displays an alert, confirm, or prompt dialog box. On the other hand, an operation such as setting the `window.defaultStatus` property is a perfect candidate for an `onload` event handler, as is initializing event handlers as properties of element objects in the page.

Note

Browsers equipped with pop-up window blockers ignore all `window.open()` method calls in `onload` event handler functions. ■

Related Items: `onunload` event handler; `window.defaultStatus` property

`onresize`

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

If a user resizes a window, the action causes the `onresize` event handler to fire for the `window` object. When you assign a function to the event (for example, `window.onresize = handleResizes`), the NN/Moz event object conveys `width` and `height` properties that reveal the outer width and height of the entire window. A window resize should not reload the document such that an `onload` event handler fires (although some early Navigator versions did fire the extra event).

Related Item: `event` object (Chapter 32, "Event Objects")

`onscroll`

Compatibility: WinIE4+, MacIE4+, NN7+, Moz+, Safari 1.3+, Opera+, Chrome+

The `onscroll` event handler fires for the `body` element object as the result of manual scrolling of the document (via scroll bars or navigation keyboard keys) and scripted scrolling via the `doScroll()` method, via the `scrollIntoView()` method, or by adjusting the `scrollTop` and/or `scrollLeft` properties of the `body` element object. For manual scrolling and scrolling by `doScroll()`, the event seems to fire twice in succession. Moreover, the `event.srcElement` property is `null` even when the `body` element is handling the `onscroll` event handler.

Example

Listing 27-41 is a highly artificial demonstration of what can be a useful tool for some page designs. Consider a document that occupies a window or frame but that you don't want scrolled, even by accident with a mouse wheel. (Be aware that the `onscroll` event is not fired if the user scrolls the page

with a mouse wheel in Safari and Chrome in some versions of Windows, but is fired on the Mac.) If scrolling of the content would destroy the appearance or value of the content, you want to make sure that the page always zips back to the top. The `onscroll` event handler in Listing 27-41 does just that. Notice that the event handler is set as a property of the `window` object.

LISTING 27-41

Preventing a Page from Scrolling

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>onscroll Event Handler</title>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript">
         addEvent(window, "scroll", zipBack);
         //window.onscroll = zipBack;

         function zipBack()
         {
            window.scroll(0,0);
         }
      </script>
   </head>
   <body>
      <h1>onscroll Event Handler</h1>
      <hr />
      <div>This page always zips back to the top if you try to scroll it.</div>
      <p>
         <iframe frameborder="0" scrolling="no" height="1000"
                 src="bofright.html"></iframe>
      </p>
   </body>
</html>
```

Related Items: `scrollBy()`, `scrollByLines()`, `scrollByPages()` methods

onunload

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera-, Chrome+

An `unload` event reaches the current window just before a document is cleared from view. The most common ways windows are cleared are when new HTML documents are loaded into them, when the user clicks the `back` button or the `reload` button, or when the user does the reload keyboard shortcut, when a script begins writing new HTML on the fly for the window or frame. Be aware that in Safari the unload event is not fired when closing the tab/browser in some versions of Windows.

Limit your use of the `onunload` event handler to quick operations that do not inhibit the transition from one document to another. Do not invoke any methods that display dialog boxes. You specify `onunload` event handlers in the same places in an HTML document as the `onload` handlers:

as a `<body>` tag attribute for a single-frame window or as a `<frameset>` tag attribute for a multiframe window. Both `onload` and `onunload` event handlers can appear in the same `<body>` or `<frameset>` tag without causing problems. The `onunload` event handler merely stays safely tucked away in the browser's memory, waiting for the `unload` event to arrive for processing as the document gets ready to clear the window.

One caution about the `onunload` event handler: Even though the event fires before the document goes away, don't burden the event handler with time-consuming tasks, such as generating new objects or submitting a form. The document will probably go away before the function completes, leaving the function looking for objects and values that no longer exist. The best defense is to keep your `onunload` event handler processing to a minimum.

Note

Browsers equipped with pop-up window blockers ignore all `window.open()` method calls in `onunload` event handler functions. ■

Syntax

Accessing properties or methods of a `frame` element object from a `frameset`:

```
(IE4+)     document.all.frameID. property | method([parameters])
(IE5+/W3C) document.getElementById("frameID"). property |
           method([parameters])
```

Accessing properties or methods of a `frame` element from a frame document:

```
(IE4+)     parent.document.all.frameID. property | method([parameters])
(IE5+/W3C) parent.document.getElementById("frameID"). property |
           method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

As noted in the opening section of this chapter, a `frame` element object is distinct from the frame object that acts as a `window` object in a document hierarchy. The `frame` element object is available to scripts only when all HTML elements are exposed in the object model.

Because the `frame` element object is an HTML element, it shares the properties, methods, and event handlers of all HTML elements, as described in Chapter 26. By and large, you access the `frame` element object to set or modify an attribute value in the `<frame>` tag. If so, you simplify matters if you assign an identifier to the `id` attribute of the tag. Your tag still needs a `name` attribute if your scripts refer to frames through the original object model (a `parent.frameName` reference). Although there is no law against using the same identifier for both `name` and `id` attributes, using different names to prevent potential conflict with references in browsers that recognize both attributes is best.

To modify the dimensions of a frame, you must go to the `frameset` element object that defines the `cols` and `rows` attributes for the frameset. These properties can be modified on the fly in modern browsers.

Properties

allowTransparency

Value: Boolean Read/Write

Compatibility: WinIE6+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `allowTransparency` property indicates whether the frame's background is transparent. This property applies primarily to the `iframe` object, because framesets don't have background colors or images to show through a transparent frame.

borderColor

Value: Hexadecimal triplet or color name string Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

If a frame displays a border (as determined by the `frameborder` attribute of the `frame` element, or `border` attribute of the `frameset` element), it can have a color set separately from the rest of the frames. The initial color (if different from the rest of the frameset) is usually set by the `bordercolor` attribute of the `<frame>` tag. After that, scripts can modify settings as needed.

Modifying a single frame's border can be risky at times, depending on your color combinations. In practice, different browsers appear to follow different rules when it comes to negotiating conflicts or defining just how far a single frame's border extends into the border space. Color changes to individual frame borders do not always render. Verify your designs on as many browsers and operating system variations as you can to test your combinations.

Example

Although you may experience problems changing the color of a single frame border, the W3C DOM syntax would look like the following if the script were inside the framesetting document:

```
document.getElementById("contentsFrame").borderColor = "red";
```

The IE-only version would be

```
document.all["contentsFrame"].borderColor = "red";
```

These examples assume that the frame name arrives to a script function as a string. If the script is executing in one of the frames of the frameset, add a reference to `parent` in the preceding statements.

Related Items: `frame.frameBorder`, `frameset.frameBorder` properties

contentDocument

Value: `document` object reference — Read-Only

Compatibility: WinIE8+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `contentDocument` property of a `frame` element object is nothing more than a reference to the document contained by that frame. This property bridges the gap between the `frame` element object and the `frame` object. Both of these objects contain the same `document` object, but from a scripting point of view, references most typically use the frame object to reach the document inside a frame, whereas the `frame` element is used to access properties equated with the `frame` tag's attributes. But if your script finds that it has a reference to the `frame` element object, you can use the `contentDocument` property to get a valid reference to the document and, therefore, any other content of the frame.

Example

A framesetting document script might be using the ID of a `frame` element to read or adjust one of the element properties, and then need to perform some action on the content of the page through its `document` object. You can get the reference to the `document` object via a statement such as the following:

```
var doc = document.getElementById("Frame3").contentDocument;
```

Then your script can, for example, dive into a form in the document:

```
var val = doc.mainForm.entry.value;
```

Related Items: contentWindow property; document object

contentWindow

Value: document object reference Read-Only

Compatibility: WinIE5.5+, MacIE-, NN7+, Moz1.0.1+, Safari+, Opera+, Chrome+

The contentWindow property of a frame element object is simply a reference to the window generated by that frame. This property provides access to the frame's window, which can then be used to reach the document inside the frame.

Example

You can get the reference to the window object associated with a frame via a statement such as the following:

```
var win = document.getElementById("Frame3").contentWindow;
```

Related Item: window object

frameBorder

Value: yes | no | 1 | 0 as strings Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The frameBorder property offers scripted access to a frame element object's frameborder attribute setting. Except for IE, none of the browsers we tested responded well to modifying this property after the page has loaded.

Values for the frameBorder property are strings that substitute for Boolean values. Value yes or 1 means that the border is (supposed to be) turned on; no or 0 (supposedly) turns off the border. There is no consistent default behavior among the browsers.

Example

The default value for the frameBorder property is yes. You can use this setting to create a toggle script (which, unfortunately, does not change the border's appearance in IE). The W3C-compatible version looks like the following:

```
function toggleFrameScroll(frameID)
{
   var theFrame = document.getElementById(frameID);
   if (theFrame.frameBorder == "yes")
   {
      theFrame.frameBorder = "no";
   }
   else
   {
      theFrame.frameBorder = "yes";
   }
}
```

Related Items: frameset.frameBorder properties

height
width

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera-, Chrome+

These two properties enable you to retrieve the height and width of a `frame` element object. These values are not necessarily the same as `document.body.clientHeight` and `document.body.clientWidth`, because the frame dimensions include chrome associated with the frame, such as scroll bars. These values are read-only. If you need to modify the dimensions of a frame, do so via the `frameset` element object's `rows` and/or `cols` properties. Reading integer values for a frame's height and width properties is much easier than trying to parse the `rows` and `cols` string properties.

Example

The following fragment assumes a frameset defined with two frames set up as two columns within the frameset. The statements here live in the framesetting document. They retrieve the current width of the left frame and increase the width of that frame by 10 percent. Syntax shown here is for the W3C DOM, but can easily be adapted to IE-only terminology.

```
var frameWidth = document.getElementById("leftFrame").width;
document.getElementById("mainFrameset").cols =
   (Math.round(frameWidth * 1.1)) + ",*";
```

Notice that the numeric value of the existing frame width is first increased by 10 percent and then concatenated to the rest of the string property assigned to the frameset's `cols` property. The asterisk after the comma means that the browser should figure out the remaining width and assign it to the right frame.

Related Item: `frameset` object

longDesc

Value: URL string Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `longDesc` property is the scripted equivalent of the `longdesc` attribute of the `<frame>` tag. This HTML 4 attribute is intended to provide browsers a URL to a document that contains a long description of the element. Future browsers can use this feature to provide information about the frame for visually impaired site visitors.

marginHeight
marginWidth

Value: Integer Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

Browsers tend to insert content within a frame automatically by adding a margin between the content and the edge of the frame. These values are represented by the `marginHeight` (top and bottom edges) and `marginWidth` (left and right edges) properties. Although the properties are not read-only, changing the values after the frameset has loaded does not alter the appearance of the

document in the frame. If you need to alter the margin(s) of a document inside a frame, adjust the `document.body.style` margin properties.

Also be aware that although the default values of these properties are empty (meaning when no `marginheight` or `marginwidth` attributes are set for the `<frame>` tag), margins are built into the page. The precise pixel count of those margins varies with operating system.

Related Item: `style` object (Chapter 38, "Style Sheet and Style Objects")

name

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `name` property is the identifier associated with the frame for use as a reference. Scripts can reference the frame through the `name` property (for example, `top.frames["myFrame"]`), which is typically assigned via the `name` attribute.

noResize

Value: Boolean Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

Web designers commonly fix their framesets so that users cannot resize the frames (by dragging any divider border between frames). The `noResize` property lets you read and adjust that behavior of a frame after the page has loaded. For example, during some part of the interaction with a user on a page, you may allow the user to modify the frame size manually while in a certain mode. Or you may grant the user one chance to resize the frame. When the `onresize` event handler fires, a script sets the `noResize` property of the `frame` element to `false.` If you turn off resizing for a frame, all edges of the frame become nonresizable, regardless of the `noResize` value setting of adjacent frames. Turning off resizability has no effect on the ability of scripts to alter the sizes of frames via the `frameset` element object's `cols` or `rows` properties.

Example

The following statement turns off the ability for a frame to be resized:

```
parent.document.getElementById("myFrame1").noResize = true;
```

Because of the negative nature of the property name, it may be difficult to keep the logic straight (setting `noResize` to `true` means that resizability is turned off). Keep a watchful eye on your Boolean values.

Related Items: `frameset.cols`, `frameset.rows` properties

scrolling

Value: `yes | no | 1 | 0` as strings Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `scrolling` property lets scripts turn scroll bars on and off inside a single frame of a frameset. By default, scrolling is turned on unless overridden by the `scroll` attribute of the `<frame>` tag.

Values for the `scrolling` property are strings that substitute for Boolean values. Value `yes` or `1` means that scroll bars are visible (provided that there is more content than can be viewed without

scrolling); `no` or `0` hides scroll bars in the frame. IE also recognizes (and sets as default) the `auto` value.

Note

Although this property is read/write, changing its value by script does not alter a frame's appearance in WinIE, Mozilla browsers, or Safari. ■

Example

Listing 27-42 produces a frameset consisting of eight frames. The content for the frames is generated by a script within the frameset (via the `fillFrame()` function). Event handlers (`onclick`) in the `body` of each frame invoke the `toggleFrameScroll()` function. Both ways of referencing the `frame` element object are shown, with the IE-only version commented out.

In the `toggleFrameScroll()` function, the `if` condition checks whether the property is set to something other than `no`. This allows the condition to evaluate to `true` if the property is set to either `auto` (the first time) or `yes` (as set by the function). Note that the scroll bars don't disappear from the frames in IE, NN6+, Safari, Opera, or Chrome.

LISTING 27-42

Controlling the frame.scrolling Property

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>frame.scrolling Property</title>
      <script type="text/javascript">
         function toggleFrameScroll(frameID)
         {
            // IE5+/W3C version
            var theFrame = document.getElementById(frameID);

            if (theFrame.scrolling != "no")
            {
               theFrame.scrolling = "no";
            }
            else
            {
               theFrame.scrolling = "yes";
            }
         }

         // generate content for each frame
         function fillFrame(frameID)
         {
            var page = "<html><body onclick='parent.toggleFrameScroll(\""
                     +  frameID
```

```
                 + "\")'><span style='font-size:24pt'>";
         page += "<p>This frame has the ID of:<\/p><p>"
              + frameID
              + ".<\/p>";
         page += "<\/span><\/body><\/html>";
         return page;
      }
   </script>
</head>
<frameset id="outerFrameset" cols="50%,50%">
   <frameset id="innerFrameset1" rows="25%,25%,25%,25%">
      <frame id="myFrame1" src="javascript:parent.fillFrame('myFrame1')" />
      <frame id="myFrame2" src="javascript:parent.fillFrame('myFrame2')" />
      <frame id="myFrame3" src="javascript:parent.fillFrame('myFrame3')" />
      <frame id="myFrame4" src="javascript:parent.fillFrame('myFrame4')" />
   </frameset>
   <frameset id="innerFrameset2" rows="25%,25%,25%,25%">
      <frame id="myFrame5" src="javascript:parent.fillFrame('myFrame5')" />
      <frame id="myFrame6" src="javascript:parent.fillFrame('myFrame6')" />
      <frame id="myFrame7" src="javascript:parent.fillFrame('myFrame7')" />
      <frame id="myFrame8" src="javascript:parent.fillFrame('myFrame8')" />
   </frameset>
</frameset>
</html>
```

src

Value: URL string Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `src` property of a `frame` element object offers an additional way of navigating to a different page within a frame (meaning other than assigning a new URL to the `location.href` property of the frame object). For backward compatibility with older browsers, however, continue using `location.href` for scripted navigation. Remember that the `src` property belongs to the `frame` element object, not the `window` object it represents. Therefore, references to the `src` property must be via the element's ID and/or node hierarchy.

Example

For best results, use fully formed URLs as values for the `src` property, as shown here:

```
parent.document.getElementById("mainFrame").src = "http://www.dannyg.com";
```

Relative URLs and `javascript:` pseudo-URLs will also work most of the time.

Syntax

Accessing properties or methods of a `frameset` element object from a `frameset`:

```
(IE4+)     document.all.framesetID. property | method([parameters])
(IE5+/W3C) document.getElementById("framesetID"). property |
           method([parameters])
```

Accessing properties or methods of a `frameset` element from a frame document:

```
(IE4+)     parent.document.all.framesetID. property | method([parameters])
(IE5+/W3C) parent.document.getElementById("framesetID"). property |
           method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

The `frameset` element object is the script-accessible equivalent of the element generated via the `<frameset>` tag. This element is different from the parent (window-type) object of the original object model. A `frameset` element object has properties and methods that impact the HTML element; by contrast, the `window` object referenced from documents inside frames via the `parent` or `top` window references, contains a document and all the content that goes along with it.

When framesets are nested in side one another, a node parent–child relationship exists between containing and contained framesets. For example, consider the following skeletal nested frameset structure:

```
<frameset id="outerFrameset" cols="30%, 70%">
   <frame id="frame1">
   <frameset id="innerFrameset" rows="50%,50%">
```

```
        <frame id="frame2">
        <frame id="frame3">
    </frameset>
</frameset>
```

When writing scripts for documents that go inside any of the frames of this structure, references to the framesetting window and frames are a flatter hierarchy than the HTML signifies. A script in any frame references the framesetting window via the `parent` reference; a script in any frame references another frame via the `parent.frameName` reference. In other words, the `window` objects of the frameset defined in a document are all siblings, and have the same parent.

Such is not the case when viewing the preceding structure from the perspective of W3C node terminology. Parent–child relationships are governed by the nesting of HTML elements, irrespective of whatever windows get generated by the browser. Therefore, `frame2` has only one sibling: `frame3`. Both of those share one parent: `innerFrameset`. Both `innerFrameset` and `frame1` are children of `outerFrameset`. If your script were sitting on a reference to `frame2`, and you wanted to change the `cols` property of `outerFrameset`, you would have to traverse two generations of nodes:

```
frame2Ref.parentNode.parentNode.cols = "40%,60%";
```

What might confuse matters ever more in practice is that a script belonging to one of the frames must use window object terminology to jump out of the current `window` object to the frameset that generated the frame window for the document. In other words, there is no immediate way to jump directly from a document to the `frame` element object that defines the frame in which the document resides. The document's script accesses the node hierarchy of its frameset via the `parent.document` reference. But this reference is to the `document` object that contains the entire frameset structure. Fortunately, the W3C DOM provides the `getElementById()` method to extract a reference to any node nested within the document. Thus, a document inside one of the frames can access the `frame` element object just as though it were any element in a typical document (which it is):

```
parent.document.getElementById("frame2")
```

No reference to the containing `frameset` element object is necessary. To make that column width change from a script inside one of the frame windows, the statement would be

```
parent.document.getElementById("outerFrame").cols = "40%,60%";
```

The inner frameset is equally accessible by the same syntax.

Properties

`border`

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `border` property of a `frameset` element object lets you read the thickness (in pixels) of the borders between frames of a frameset. If you do not specify a `border` attribute in the frameset's tag, the property is empty, rather than reflecting the actual border thickness applied by default.

Example

Even though the property is read/write, changing the value does not change the thickness of the border you see in the browser. If you need to find the thickness of the border, a script reference from one of the frame's documents would look like the following:

```
var thickness = parent.document.all.outerFrameset.border;
```

Related Item: `frameset.frameBorder` property

borderColor

Value: Hexadecimal triplet or color name string   Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `borderColor` property lets you read the value of the color assigned to the `bordercolor` attribute of the frameset's tag. Although the property is read/write, changing the color by script does not alter the border colors rendered in the browser window. Attribute values set as color names are returned as hexadecimal triplets when you read the property value.

Example

To retrieve the current color setting in a frameset, a script reference from one of the frame's documents would look like the following:

```
var borderColor = parent.document.all.outerFrameset.borderColor;
```

Related Items: `frame.borderColor`, `frameset.frameBorder` properties

cols
rows

Value: String   Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cols` and `rows` properties of a `frameset` element object let you read and modify the sizes of frames after the frameset has loaded. These two properties are defined in the W3C DOM. Values for both properties are strings, which may include percent symbols or asterisks. Therefore, if you are trying to increase or decrease the size of a frame column or row gradually, you must parse the string for the necessary original values before performing any math on them (or, in IE4+, use the `frame` element object's `height` and `width` properties to gauge the current frame size in pixels).

Adjusting these two properties lets you modify the frameset completely, including adding or removing columns or rows in the frameset grid. Because a change in the frameset structure could impact scripts by changing the size of the frames array associated with the parent window or unloading documents that contain needed data, be sure to test your scripts with both states of your frameset. If you want to remove a frame from a frameset view, you might be safer to specify the size of zero for that particular row or column in the frameset. Of course, a size of zero still leaves a 1-pixel frame, but it is essentially invisible if borders are not turned on and the 1-pixel frame has the same background color as the other frames. Another positive byproduct of this technique is that you can restore the other frame with its document state identical from when it was hidden.

When you have nested framesets defined in a single document, be sure to reference the desired `frameset` element object. One object may be specifying the columns, and another (nested) one

specifies the rows for the grid. Assign a unique ID to each `frameset` element so that references can be reliably directed to the proper object.

Example

Listings 27-43, 27-44, and 27-45 show the HTML for a frameset and two of the three documents that go into the frameset. The final document is an HTML version of the U.S. Bill of Rights, which is serving here as a content frame for the demonstration.

The frameset listing (see Listing 27-43) shows a three-frame setup. Down the left column is a table of contents (see Listing 27-44). The right column is divided into two rows. In the top row is a simple control (see Listing 27-45) that hides and shows the table-of-contents frame. As the user clicks the hot spot of the control (located inside a `span` element), the `onclick` event handler invokes the `toggleTOC()` function in the frameset.

LISTING 27-43

Frameset and Script for Hiding/Showing a Frame

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Hide/Show Frame Example</title>
      <script type="text/javascript">
         var origCols;
         function toggleTOC()
         {
            if (origCols)
            {
               showTOC();
            }
            else
            {
               hideTOC();
            }
         }
         function hideTOC()
         {
            var frameset = document.getElementById("outerFrameset");
            origCols = frameset.cols;
            frameset.cols = "0,*";
         }
         function showTOC()
         {
            if (origCols)
            {
               document.getElementById("outerFrameset").cols = origCols;
               origCols = null;
            }
         }
      </script>
```

continued

LISTING 27-43 *(continued)*

```
  </head>
  <frameset id="outerFrameset" frameborder="no" cols="150,*">
     <frame id="TOC" name="TOCFrame" src="jsb27-44.html" />
     <frameset id="innerFrameset1" rows="80,*">
        <frame id="controls" name="controlsFrame" src="jsb27-45.html" />
        <frame id="content" name="contentFrame" src="bofright.html" />
     </frameset>
  </frameset>
</html>
```

When a user clicks the hot spot to hide the frame, the script copies the original `cols` property settings to a global variable. The variable is used in `showTOC()` to restore the frameset to its original proportions. This allows a designer to modify the HTML for the frameset without also having to dig into scripts to hard-wire the restored size.

LISTING 27-44

Table of Contents Frame Content

```

               target="contentFrame">Article V</a></li>
        <li><a href="bofright.htm#article6"
```

```
                target="contentFrame">Article VI</a></li>
         <li><a href="bofright.htm#article7"
                target="contentFrame">Article VII</a></li>
         <li><a href="bofright.htm#article8"
                target="contentFrame">Article VIII</a></li>
         <li><a href="bofright.htm#article9"
                target="contentFrame">Article IX</a></li>
         <li><a href="bofright.htm#article10"
                target="contentFrame">Article X</a></li>
      </ul>
   </body>
</html>
```

LISTING 27-45

Control Panel Frame

```
<html>
   <head>
      <title>Control Panel</title>
      <style type="text/css">
         span
         {
            text-decoration:underline; cursor:pointer;
         }
      </style>
   </head>
   <body>
      <p><span id="tocToggle"
               onclick="parent.toggleTOC()">
            &lt;&lt;Hide/Show&gt;&gt;</span> Table of Contents
      </p>
   </body>
</html>
```

Related Item: `frame` object

frameBorder

Value: `yes` | `no` | `1` | `0` as strings — Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `frameBorder` property offers scripted access to a `frameset` element object's `frameborder` attribute setting. IE4+ does not respond well to modifying this property after the page has loaded.

Values for the `frameBorder` property are strings that substitute for Boolean values. Value `yes` or `1` means that the border is (supposed to be) turned on; `no` or `0` turns off the border.

Example

The default value for the `frameBorder` property is `yes`. You can use this setting to create a toggle script (which, unfortunately, does not change the appearance in IE). The IE5+ version looks like the following:

```
function toggleFrameScroll(framesetID)
{
   var theFrameset = document.getElementById(framesetID);
   if (theFrameset.frameBorder == "yes")
   {
      theFrameset.frameBorder = "no";
   }
   else
   {
      theFrameset.frameBorder = "yes";
   }
}
```

Related Item: `frame.frameBorder` property

frameSpacing

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `frameSpacing` property of a `frameset` element object lets you read the spacing (in pixels) between frames of a frameset. If you do not specify a `framespacing` attribute in the frameset's tag, the property is empty, rather than reflecting the actual border thickness applied by default (usually 2).

Example

If you need to change the spacing, a script reference would look like the following:

```
document.getElementById("outerFrameset").frameSpacing = "10";
```

Related Item: `frameset.border` property

Syntax

Accessing properties or methods of an `iframe` element object from a containing document:

```
(IE4+)     document.all.iframeID. property | method([parameters])
(IE4+/NN6) window.frames["iframeName"]. property | method([parameters])
(IE5+/W3C) document.getElementById("iframeID"). property |
           method([parameters])
```

Accessing properties of methods of an `iframe` element from a document inside the `iframe` element:

```
(IE4+)     parent.document.all.iframeID. property | method([parameters])
(IE5+/W3C) parent.document.getElementById("iframeID"). property |
           method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

An `iframe` element allows HTML content from a separate source to be loaded within the body of another document. In some respects, the NN4 `layer` element was a precursor to the `iframe` concept, but unlike the `layer`, an `iframe` element is not inherently positionable. It is positionable the same way as any other HTML element: by assigning positioning attributes to a style sheet associated with the `iframe`. Without explicit positioning, an `iframe` element appears in the body of a

document in the normal source-code order of elements. Unlike a frame of a frameset, an `iframe` can be placed arbitrarily in the middle of any document. If the `iframe` changes size under script control, the surrounding content moves out of the way or cinches up.

What truly sets the `iframe` apart from other HTML elements is its ability to load and display external HTML files and, with the help of scripts, have different pages loaded into the `iframe` without disturbing the rest of the content of the main document. Pages loaded into the `iframe` can also have scripts and any other features that you may like to put into an HTML document (including XML, in IE for Windows).

The `iframe` element has a rich set of attributes that lets the HTML author control the look, size (`height` and `width`), and, to some degree, behavior of the frame. Most of these attributes are accessible to scripts as properties of an `iframe` element object.

It is important to bear in mind that an `iframe` element is in many respects like a `frame` element, especially when it comes to window kinds of relationships. If you plant an `iframe` element in a document of the main window, that element shows up in the main window's object model as a frame, accessible via common frames terminology:

```
window.frames[i]
window.frames[frameName]
```

Within that `iframe` frame object is a document and all its contents. All references to the document objects inside the `iframe` must flow through the portal of the `iframe` frame.

Conversely, scripts in the document living inside an `iframe` can communicate with the main document via the `parent` reference. Of course, you cannot replace the content of the main window with another HTML document (using `location.href`, for instance) without destroying the `iframe` that was in the original document.

Properties

`align`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `align` property governs how an `iframe` element aligns itself with respect to surrounding content on the page. Two of the possible values (`left` and `right`) position the `iframe` along the left and right edge (respectively) of the `iframe`'s containing element (usually the `body`). Just as with an image, when an `iframe` is floated along the left and right edges of a container, other content wraps around the element. Table 27-6 shows all possible values and their meanings.

As your script changes the value of the `align` property, the page automatically reflows the content to suit the new alignment.

Example

The default setting for an `iframe` alignment is `baseline.` A script can shift the `iframe` to be flush with the right edge of the containing element as follows:

```
document.getElementById("iframe1").align = "right";
```

TABLE 27-6

Values of the align Property

Value	Description
`absbottom`	Aligns the bottom of the `iframe` with the imaginary line that extends along character descenders of surrounding text
`absmiddle`	Aligns the middle of the `iframe` with the center point between the surrounding text's `top` and `absbottom`
`baseline`	Aligns the bottom of the `iframe` with the baseline of surrounding text
`bottom`	Aligns the bottom of the `iframe` with the bottom of the surrounding text
`left`	Aligns the `iframe` flush with left edge of the containing element
`middle`	Aligns the imaginary vertical center line of surrounding text with the same for the `iframe` element
`right`	Aligns the `iframe` flush with the right edge of the containing element
`texttop`	Aligns the top of the `iframe` element with the imaginary line that extends along the tallest ascender of surrounding text
`top`	Aligns the top of the `iframe` element with the surrounding element's `top`

Related Items: `iframe.hspace`, `iframe.vspace` properties

allowTransparency

Value: Boolean Read/Write

Compatibility: WinIE6+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `allowTransparency` property indicates whether the frame's background is transparent. By setting this property to `true`, you allow a background color or image to show through the transparent frame.

contentDocument

Value: `document` object reference Read-Only

Compatibility: WinIE8+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `contentDocument` property of an `iframe` element object is nothing more than a reference to the document contained by that frame. If your script finds that it has a reference to an `iframe` element object, you can use the `contentDocument` property to get a valid reference to the document and, therefore, any other content of the frame.

Example

A document script might be using the ID of an `iframe` element to read or adjust one of the element properties; then it needs to perform some action on the content of the page through its

document object. You can get the reference to the document object via a statement such as the following:

```
var doc = document.getElementById("Frame3").contentDocument;
```

Then your script can, for example, dive into a form in the document:

```
var val = doc.mainForm.entry.value;
```

Related Items: contentWindow property; document object

contentWindow

Value: document object reference Read-Only

Compatibility: WinIE5.5+, MacIE-, NN7+, Moz1.0.1+, Safari+, Opera+, Chrome+

The contentWindow property of an iframe element object serves as a reference to the window object generated by the frame. You can then use this window object as a means of accessing the document object and any document elements.

Related Items: contentDocument property; window object

frameBorder

(See frame.frameBorder() and frameset.frameBorder())

frameSpacing

(See frameset.frameSpacing())

height
width

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The height and width properties provide access to the height and width of the iframe object, and allow you to alter the size of the frame. Both properties are specified in pixels.

hspace
vspace

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

These IE-specific properties allow for margins to be set around an iframe element. In general, hspace and vspace properties (and their HTML attributes) have been replaced by CSS margins and padding. These properties and their attributes are not recognized by any W3C standard (including HTML 4).

Values for these properties are integers representing the number of pixels of padding between the element and surrounding content. The hspace value assigns the same number of pixels to the left and

right sides of the element; the `vspace` value is applied to both the top and bottom edges. Scripted changes to these values have no effect in WinIE5+.

Related Item: `style.padding` property

longDesc

Value: URL string Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `longDesc` property is the scripted equivalent of the `longdesc` attribute of the `<iframe>` tag. This HTML 4 attribute is intended to provide browsers a URL to a document that contains a long description of the element. Future browsers can use this feature to provide information about the frame for visually impaired site visitors.

marginHeight
marginWidth

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Browsers tend to insert content within a frame automatically by adding a margin between the content and the edge of the frame. These values are represented by the `marginHeight` (top and bottom edges) and `marginWidth` (left and right edges) properties. Although the properties are not read-only, changing the values after the frameset has loaded does not alter the appearance of the document in the frame. If you need to alter the margin(s) of a document inside a frame, adjust the `document.body.style` margin properties.

Also be aware that although the default values of these properties are empty (that is, when no `marginheight` or `marginwidth` attributes are set for the `<iframe>` tag), margins are built into the page. The precise pixel count of those margins varies with different operating systems.

Related Item: `style` object (Chapter 38, "Style Sheet and Style Objects")

name

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `name` property is the identifier associated with the frame for use as a reference. Scripts can reference the frame through the `name` property (for example, `window.frames["myIframe"]`), which is typically assigned via the `name` attribute.

noResize

(See `frame.noResize()`)

scrolling

Value: `yes | no | 1 | 0` as strings Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `scrolling` property lets scripts turn scroll bars on and off inside an `iframe` element. By default, scrolling is turned on unless overridden by the `scroll` attribute of the `<iframe>` tag.

Values for the `scrolling` property are strings that substitute for Boolean values. Value `yes` or `1` means that scroll bars are visible (provided that there is more content than can be viewed without scrolling); `no` or `0` hides scroll bars in the frame. IE4+ also recognizes (and sets as default) the `auto` value.

Example

The following `toggleIFrameScroll()` function accepts a string of the `iframe` element's ID as a parameter, and switches between on and off scroll bars in the `iframe`. The `if` condition checks whether the property is set to something other than `no`. This test allows the condition to evaluate to `true` if the property is set to either `auto` (the first time) or `yes` (as set by the function).

```
function toggleFrameScroll(frameID)
{
   // IE5 & NN6 version
   var theFrame = document.getElementById(frameID);

   if (theFrame.scrolling != "no")
   {
      theFrame.scrolling = "no";
   }
   else
   {
      theFrame.scrolling = "yes";
   }
}
```

Related Item: `frame.scrolling` property

src

Value: URL string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `src` property of an `iframe` element object offers an additional way of navigating to a different page within an inline frame (that is, other than assigning a new URL to the `location.href` property of the frame object). Remember that the `src` property belongs to the `iframe` element object, not the `window` object it represents. Therefore, references to the `src` property must be via the element's ID and/or node hierarchy.

Example

For best results, use fully formed URLs as values for the `src` property, as shown here:

```
document.getElementById("myIframe").src = "http://www.dannyg.com";
```

Relative URLs and `javascript:` pseudo-URLs also work most of the time.

Related Item: `location.href` property

popup Object

Properties	Methods	Event Handlers
document	hide()	
isOpen	show()	

Syntax

Creating a popup object:

```
var popupObj = window.createPopup()
```

Accessing properties or methods of a popup object from a document in the window that created the pop-up:

```
popupObj.property | method([parameters])
```

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

About this object

A popup object is a chromeless window space that overlaps the window whose document generates the pop-up. A pop-up also appears in front of any dialog boxes. Unlike the dialog-box windows generated via showModalDialog() and showModelessDialog() methods, your scripts must not only create the window, but also put content in it, and then define where on the screen, and how big, it will be. Because the pop-up window IE creates is a window and not a dialog box, there is no exact W3C equivalent. However, with the ability to add and delete elements to the node tree using the W3C DOM, you can achieve the same type of functionality. See Chapter 25, "Document Object Model Essentials," for more information.

Because the pop-up window has no chrome (title bar, resize handles, and so on), you should populate its content with a border and/or background color so that it stands out from the main window's content. The following statements reflect a typical sequence of creating, populating, and showing a popup object:

```
var popup = window.createPopup();
var popupBody = popup.document.body;
popupBody.style.border = "solid 2px black";
popupBody.style.padding = "5px";
popupBody.innerHTML = "<p>Here is some text in a popup window</p>";
popup.show(200,100, 200, 50, document.body);
```

Note

As handy as it may be, in a strict W3C approach to JavaScript, you wouldn't use the innerHTML property, because it isn't officially part of the W3C standard. However, it is often too powerful a convenience property to ignore, as much of the code throughout this book is a testament. The book does show the W3C node manipulation alternative to innerHTML in some examples. Refer to Chapter 29 for a thorough explanation and examples of the W3C alternative to innerHTML. ■

The pop-up window that IE creates is, in fact, a window, but only from the point of view of the document that it contains. In other words, although the number of properties and methods for the `popup` object is small, the `parentWindow` property of the document inside the pop-up points to a genuine `window` property. Even so, be aware that this pop-up does not appear as a distinct window among those listed in the Windows Taskbar. If a user clicks outside the pop-up or switches to another application, the pop-up disappears, and you must reinvoke the `show()` method by script (complete with dimension and position parameters) to force the pop-up to reappear.

When you assign content to a pop-up, you are also responsible for making sure that the content fits the size of the pop-up you specify. If the content runs past the rectangular space (body text word wraps within the pop-up's rectangle), no scroll bars appear.

Properties

document

Value: `document` object reference Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Use the `document` property as a gateway to the content of a pop-up window. This property is the only access point available from the script that creates the pop-up, to the pop-up itself. The most common application of this property is to set document properties governing the content of the pop-up window. For example, to give the pop-up a border (because the pop-up itself has no window chrome), the script that creates the window can assign values to the `style` property of the document in the pop-up window, as follows:

```
myPopup.document.body.style.border = "solid 3px gray";
```

Be aware that the `document` object of a pop-up window may not implement the full flexibility you're used to with primary window `document` objects. For example, you are not allowed to assign a URL to the `document.URL` property in a pop-up window.

Example

Use The Evaluator (Chapter 4, "JavaScript") to experiment with the `popup` object and its properties. Enter the following statements in the top text box. The first statement creates a pop-up window whose reference is assigned to the `a` global variable. Next, a reference to the body of the pop-up's document is preserved in the `b` variable for the sake of convenience. Further statements work with these two variables.

```
a = window.createPopup()
b = a.document.body
b.style.border = "solid 2px black"
b.style.padding = "5px"
b.innerHTML = "<p>Here is some text in a popup window</p>"
a.show(200,100, 200, 50, document.body)
```

See the description of the `show()` method for details on the parameters.

Related Item: `document` object

isOpen

Value: Boolean Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

While a pop-up window is visible, its `isOpen` property returns `true`; otherwise, the property returns `false`. Because any user action in the browser causes the pop-up to hide itself, the property is useful only for script statements that are running on their own after the pop-up is made visible.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `isOpen` property. Enter the following statements in the top text box. The sequence begins with a creation of a simple pop-up window, whose reference is assigned to the `a` global variable. Note that the final statement is actually two statements, designed so that the second statement executes while the pop-up window is still open.

```
a = window.createPopup();
a.document.body.innerHTML = "<p>Here is a popup window</p>";
a.show(200,100, 200, 50, document.body); alert("Popup is open:" + a.isOpen);
```

If you then click in the main window to hide the pop-up, you will see a different result if you enter the following statement in the top text box by itself:

```
alert("Popup is open:" + a.isOpen);
```

Related Item: `popup.show()` method

Methods

hide()
show(left, top, width, height[, positioningElementRef])

Returns: Nothing

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

After you have created a `popup` object with the `window.createPopup()` method and populated it with content, you must explicitly show the window via the `show()` method. If the window is hidden because a user clicked the main browser window somewhere, the `show()` method (and all its parameters) must be invoked again. To have a script hide the window, invoke the `hide()` method for the `popup` object.

The first four parameters of the `show()` method are required; they define the pixel location and size of the pop-up window. By default, the coordinate space for the `left` and `top` parameters is the video display. Thus, a `left` and `top` setting of zero places the pop-up in the top-left corner of the video screen. But you can define a different coordinate space by adding an optional fifth parameter. This parameter must be a reference to an element on the page. To confine the coordinate space to the content region of the browser window, specify the `document.body` object as the positioning element reference.

***popupObject*.show()**

Example

Listing 27-46 demonstrates the `show()` and `hide()` methods for a `popup` object. A click of the button on the page invokes the `selfTimer()` function, which acts as the main routine for this page. The goal is to produce a pop-up window that self-destructs 5 seconds after it appears. Along the way, a message in the pop-up counts down the seconds.

A reference to the pop-up window is preserved as a global variable called `popup`. After the `popup` object is created, the `initContent()` function stuffs the content into the pop-up by way of assigning `style` properties, and some `innerHTML`, for the body of the document that is automatically created when the pop-up is generated. A `span` element is defined so that another function later on can modify the content of just that segment of text in the pop-up. Notice that the assignment of content to the pop-up is predicated on the pop-up window's having been initialized (by virtue of the `popup` variable's having a value assigned to it) and that the pop-up window is not showing. Although invoking `initContent()` under any other circumstances is probably impossible, the validation of the desired conditions is good programming practice.

Back in `selfTimer()`, the `popup` object is displayed. Defining the desired size requires some trial and error to make sure that the pop-up window comfortably accommodates the text that is put into the pop-up in the `initContent()` function.

With the pop-up window showing, now is the time to invoke the `countDown()` function. Before the function performs any action, it validates that the pop-up has been initialized and is still visible. If a user clicks the main window while the counter is counting down, this changes the value of the `isOpen` property to `false`, and nothing inside the `if` condition executes.

This `countDown()` function grabs the inner text of the `span` and uses `paresInt()` to extract just the integer number (using base 10 numbering, because we're dealing with zero-leading numbers that can potentially be regarded as octal values). The condition of the `if` construction decreases the retrieved integer by one. If the decremented value is zero, the time is up, and the pop-up window is hidden with the `popup` global variable returned to its original, `null` value. But if the value is other than zero, the inner text of the `span` is set to the decremented value (with a leading zero), and the `setTimeout()` method is called upon to reinvoke the `countDown()` function in 1 second (1,000 milliseconds).

LISTING 27-46

Hiding and Showing a Pop-Up

HTML: jsb27-46.html

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>popup Object</title>
      <script type="text/javascript" src="jsb27-46.js"></script>
   </head>
   <body>
      <form>
```

```
        <input type="button" value="Impossible Mission"
               onclick="selfTimer()" />
      </form>
   </body>
</html>
```

JavaScript: jsb27-46.js

```
var popup;
function initContent()
{
   if (popup && !popup.isOpen)
   {
      var popBody = popup.document.body;
      popBody.style.border = "solid 3px red";
      popBody.style.padding = "10px";
      popBody.style.fontSize = "24pt";
      popBody.style.textAlign = "center";
      var bodyText = "<P>This popup will self-destruct in ";
      bodyText += "<span id='counter'>05<\/span>";
      bodyText += " seconds...<\/P>";
      popBody.innerHTML = bodyText;
   }
}
function countDown()
{
   if (popup && popup.isOpen)
   {
      var currCount = parseInt(popup.document.all.counter.innerText, 10);
      if (--currCount == 0)
      {
         popup.hide();
         popup = null;
      }
      else
      {
         popup.document.all.counter.innerText = "0" + currCount;
         setTimeout("countDown()", 1000);
      }
   }
}
function selfTimer()
{
   popup = window.createPopup();
   initContent();
   popup.show(200,200,400,100,document.body);
   setTimeout("countDown()", 1000);
}
```

***popupObject*.show()**

The `hide()` method here is invoked by a script that is running while the pop-up window is showing. Because a pop-up window automatically goes away if a user clicks the main window, it is highly unlikely that the `hide()` method would ever be invoked by itself in response to user action in the main window. If you want a script in the pop-up window to close the pop-up, use `parentWindow.close()`.

CHAPTER 28

Location and History Objects

Not all objects in the document object model (DOM) are things you can see in the content area of the browser window. Each browser window or frame maintains a bunch of other information about the page you are currently visiting and where you have been. The URL of the page you see in the window is called the *location,* and browsers store this information in the `location` object. As you surf the Web, the browser stores the URLs of your past pages in the `history` object. You can manually view what that object contains by looking in the browser menu for the item that enables you to jump back to a previously visited page. This chapter is all about these two nearly invisible, but important, objects.

These objects are not only valuable to your browser, but also valuable to snoopers who might want to write scripts to see what URLs you're viewing in another frame, or the URLs of other sites you've visited in the past dozen mouse clicks. As a result, security restrictions built into browsers limit access to some of these objects' properties (unless you use signed scripts in NN4+/Moz). For older browsers, these properties simply are not available from a script.

IN THIS CHAPTER

Loading new pages and other media types via the location object

Security restrictions across frames

Navigating through the browser history under script control

location Object

Properties	Methods	Event Handlers
`hash`	`assign()`	None
`host`	`reload()`	
`hostname`	`replace()`	
`href`		
`pathname`		

Properties	Methods	Event Handlers
port		
protocol		
search		

Syntax

Loading a new document into the current window:

```
[window.]location.href = "URL";
```

Accessing location object properties or methods:

```
[window.]location.property | method([parameters])
```

About this object

In its place one level below window-style objects in the original document object hierarchy, the location object represents information about the URL of any currently open window, or of a specific frame. To display the URL of the current web page, you can reference the location object like this:

```
document.write(location.href);
```

In this example, the href property evaluates to the URL, which is written to the current page in its entirety. The location object also allows you to access individual parts of the URL, as you will see in a moment.

When you reference the location object in the framesetting document of a multiple-frame window, the location is given as the parent window's URL, which appears in the Location (or Address) field of the browser. Each frame also has a location associated with it, although you may not see any overt reference to the frame's URL in the browser. To get URL information about a document located in another frame, the reference to the location object must include the window frame reference. For example, if you have a window consisting of two frames, Table 28-1 shows the possible references to the location objects for all frames comprising the web presentation.

Note

Scripts cannot alter the URL displayed in the browser's Location/Address box. For security and privacy reasons, that text box cannot display anything other than the URL of a current page or URL in transit. ■

Most properties of a location object deal with network-oriented information. This information involves various data about the physical location of the document on the network, including the host server, the protocol being used, and other components of the URL. Given a complete URL for a typical World Wide Web page, the window.location object assigns property names to various segments of the URL, as shown here:

```
http://www.example.com:80/promos/newproducts.html#giantGizmo
```

Property	Value
`protocol`	`"http:"`
`hostname`	`"www.example.com"`
`port`	`"80"`
`host`	`"www.example.com:80"`
`pathname`	`"/promos/newproducts.html"`
`hash`	`"#giantGizmo"`
`href`	`"http://www.example.com:80/promos newproducts.html#giantGizmo"`

TABLE 28-1

Location Object References in a Two-Frame Browser Window

Reference	Description
`location` (or `window.location`)	URL of frame displaying the document that runs the script statement containing this reference
`parent.location`	URL information for parent window that defines the `<frameset>`
`parent.frames[0].location`	URL information for first visible frame
`parent.frames[1].location`	URL information for second visible frame
`parent.otherFrameName.location`	URL information for another named frame in the same frameset

The `window.location` object is handy when a script needs to extract information about the URL, perhaps to obtain a base reference on which to build URLs for other documents to be fetched as the result of user action. This object can eliminate a nuisance for web authors who develop sites on one machine and then upload them to a server (perhaps at an Internet service provider) with an entirely different directory structure. By building scripts to construct base references from the directory location of the current document, you can construct the complete URLs for loading documents. You don't have to change the base reference data manually in your documents as you shift the files from computer to computer or from directory to directory. To extract the segment of the URL and place it in the enclosing directory, use the following:

```
var baseRef = location.href.substring(0,location.href.lastIndexOf("/") + 1);
```

Caution

Security alert: To allay fears of Internet security breaches and privacy invasions, scriptable browsers prevent your script in one frame from retrieving `location` object properties from other frames whose domain and server are not your own (unless you use signed scripts in NN4+/Moz or the user has set the IE browser to trust your site). This restriction puts a damper on many scripters' well-meaning designs and aids for web watchers and visitors. If you attempt such property accesses, however, you receive an "access denied" (or similar) security warning dialog box. ■

Setting the value of some `location` properties is the preferred way to control which document gets loaded into a window or frame. Though you may expect to find a method somewhere in JavaScript that contains a plain-language *Go* or *Open* word (to simulate what you see in the browser menu bar), you point your browser to another URL by setting the `window.location.href` property to that URL, as in:

```
window.location.href = "http://www.dannyg.com/";
```

The equals assignment operator (=) in this kind of statement is a powerful weapon. In fact, setting the `location.href` object to a URL of a different MIME type, such as one of the variety of sound and video formats, causes the browser to load those files into the plug-in or helper application designated in your browser's settings. The `location.assign()` method was originally intended for internal use by the browser, but it is available for scripters (although I don't recommend using it for navigation). Internet Explorer's object model includes a `window.navigate()` method that also loads a document into a window, but you can't use it for cross-browser applications.

Two other methods complement the `location` object's capability to control navigation. One method is the script equivalent of clicking Reload; the other method enables you to replace the current document's entry in the history with that of the next URL of your script's choice.

Properties

hash

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The *hash mark* (#) is a URL convention that directs the browser to an anchor located in the document. Any name you assign to an anchor (with the `<a name="..."> ...</a>` tag pair) becomes part of the URL after the hash mark. A `location` object's `hash` property is the name of the anchor part of the current URL (which consists of the hash mark and the name).

If you have written HTML documents with anchors and directed links to navigate to those anchors, you have probably noticed that although the destination location shows the anchor as part of the URL (for example, in the Location field), the window's anchor value does not change as the user manually scrolls to positions in the document where other anchors are defined. An anchor appears in the URL only when the window has navigated there as part of a link or in response to a script that adjusts the URL.

Just as you can navigate to any URL by setting the `window.location.href` property, you can navigate to another hash in the same document by adjusting only the `hash` property of the location without the hash mark (as shown in the following example).

Listing 28-1 demonstrates how to use the `hash` property to access the anchor part of a URL. When you load the script in Listing 28-1, adjust the height of the browser window so that only one section is visible at a time. When you click a button, the script navigates to the next logical section in the progression and eventually takes you back to the top. The page won't scroll any farther than the bottom

of the document. Therefore, an anchor near the bottom of the page may not appear at the top of the browser window.

LISTING 28-1

A Document with Anchors

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>location.hash Property</title>
      <script type="text/javascript">
      function goNextAnchor(where)
      {
         window.location.hash = where;
      }
      </script>
   </head>
   <body>
      <h1><a id="start" name="start">Top</a></h1>
      <form>
         <input type="button" name="next" value="NEXT"
         onclick="goNextAnchor('sec1')" />
      </form>
      <hr /><br /><br /><br /><br /><br />
      <h1><a id="sec1" name="sec1">Section 1</a></h1>
      <form>
         <input type="button" name="next" value="NEXT"
         onclick="goNextAnchor('sec2')" />
      </form>
      <hr /><br /><br /><br /><br /><br />
      <h1><a id="sec2" name="sec2">Section 2</a></h1>
      <form>
         <input type="button" name="next" value="NEXT"
         onclick="goNextAnchor('sec3')" />
      </form>
      <hr /><br /><br /><br /><br /><br />
      <h1><a id="sec3" name="sec3">Section 3</a></h1>
      <form>
         <input type="button" name="next" value="BACK TO TOP"
         onclick="goNextAnchor('start')" />
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique used in the previous example and throughout the chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." Several other chapters use the modern technique extensively. ■

Anchor names are passed as parameters with each button's `onclick` event handler. Instead of going through the work of assembling a `window.location` value in the function by appending a literal hash mark and the value for the anchor, here we simply modify the `hash` property of the current window's location. This is the preferred, cleaner method.

If you attempt to read back the `window.location.hash` property in an added line of script, however, the window's actual URL probably will not have been updated yet, and the browser will appear to be giving your script false information. To prevent this problem in subsequent statements of the same function, construct the URLs of those statements from the same variable values you use to set the `window.location.hash` property; don't rely on the browser to give you the values you expect.

Related Item: `location.href` property

host

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `location.host` property describes both the hostname and port of a URL. The port is included in the value only when the port is an explicit part of the URL. If you navigate to a URL that does not display the port number in the Location field of the browser, the `location.host` property returns the same value as the `location.hostname` property. As with the `location.hostname` property, the `location.host` property will likely come up blank for pages that you open from your local hard drive (localhost) in some browsers — for example, IE and WebKit browsers such as Chrome.

Use the `location.host` property to extract the `hostname:port` part of the URL of any document loaded in the browser. This capability may be helpful for building a URL to a specific document that you want your script to access on-the-fly.

Use the documents in Listing 28-2, Listing 28-3, and Listing 28-4 as tools to help you learn the values that the various `window.location` properties return. In the browser, open the file for Listing 28-2. This file creates a two-frame window. The left frame contains a temporary placeholder (see Listing 28-4) that displays some instructions. The right frame has a document (see Listing 28-3) that enables you to load URLs into the left frame and get readings on three different windows available: the parent window (which creates the multiframe window), the left frame, and the right frame.

               <td><textarea name="windHref" rows="3" cols="30" wrap="soft">
                  </textarea></td>
            </tr>
            <tr>
               <td align="right">pathname:</td>
               <td><textarea name="windPath" rows="3" cols="30" wrap="soft">
                  </textarea></td>
            </tr>
            <tr>
               <td align="right">port:</td>
               <td><input type="text" name="windPort" size="30" /></td>
            </tr>
            <tr>
               <td align="right">protocol:</td>
               <td><input type="text" name="windProtocol" size="30" /></td>
            </tr>
            <tr>
               <td align="right">search:</td>
               <td><textarea name="windSearch" rows="3" cols="30"
                  wrap="soft"></textarea></td>
            </tr>
         </table>
      </center>
   </form>
</body>
</html>
```

LISTING 28-4

Placeholder Document for Listing 28-2

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
   <title>Opening Placeholder</title>
   </head>
   <body>
      Initial placeholder. Experiment with other URLs for this frame (see
      right).
   </body>
</html>
```

For the best results, open a URL to a web document on the network from the same domain and server from which you load the listings (perhaps your local hard disk). If you open a URL to a web document that is not from the same domain and server, be sure to specify the fully qualified URL. If possible, load a document that includes anchor points to navigate through a long document. Click

the Left frame radio button and then click the button that shows all properties. This action fills the table in the right frame with all the available `location` properties for the selected window.

Related Items: `location.port`, `location.hostname` properties

hostname

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The hostname of a typical URL is the name of the server on the network that stores the document you view in the browser. For most web sites, the server name includes not only the domain name, but also the `www.` prefix. The hostname does not, however, include the port number if the URL specifies such a number. Keep in mind that the `hostname` property will likely come up blank for pages that you open from your local hard drive (localhost) in some browsers — for example, IE and WebKit browsers such as Chrome.

See Listing 28-2, Listing 28-3, and Listing 28-4 for a set of related pages to help you view the hostname data for a variety of other pages.

Related Items: `location.host`, `location.port` properties

href

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Of all the `location` object properties, `href` (hypertext reference) is probably the one most often called upon in scripting. The `location.href` property supplies a string of the entire URL of the specified `window` object.

Using this property on the left side of an assignment statement is the JavaScript way of opening a URL for display in a window. Any of the following statements can load my web site's index page into a single-frame browser window:

```
window.location = "http://www.dannyg.com";
window.location.href = "http://www.dannyg.com";
```

At times, you may encounter difficulty by omitting a reference to a window. JavaScript may get confused and reference the `document.location` property. To prevent this confusion, the `document.location` property was deprecated (put on the no-no list) and replaced by the `document.URL` property. In the meantime, you can't go wrong by always specifying a window in the reference.

Note

You should be able to omit the `href` property name when assigning a new URL to the `location` object (for example, `location = "http://www.dannyg.com"`). Although this works in most browsers most of the time, some early browsers behave more reliably if you assign a URL explicitly to the `location.href` property. If you want to play it safe, use `location.href` at all times. ■

Sometimes, you must extract the name of the current directory in a script so that another statement can append a known document to the URL before loading it into the window. Although the other `location` object properties yield an assortment of a URL's segments, none of them provides the

full URL to the current URL's directory. But you can use JavaScript string manipulation techniques to accomplish this task. Listing 28-5 shows such a possibility.

Depending on your browser, the values for the `location.href` property may be encoded with ASCII equivalents of nonalphanumeric characters. Such an ASCII value includes the `%` symbol and the ASCII numeric value. The most common encoded character in a URL is the space: `%20`. If you need to extract a URL and display that value as a string in your documents, you can safely pass all such potentially encoded strings through the JavaScript `unescape()` function. For example, if a URL is `http://www.example.com/product%20list`, you can convert it by passing it through the `unescape()` function, as in the following example.

```
var plainURL = unescape(window.location.href);
// result = "http://www.example.com/product list";
```

The inverse function, `escape()`, is available for sending encoded strings to server applications, such as CGI scripts. See Chapter 24, "Global Functions and Statements," for more details on these functions.

Listing 28-5 shows how the `href` property can be used to view the directory URL of the current page. This example includes the `unescape()` function in front of the part of the script that captures the URL. This function serves cosmetic purposes by displaying the pathname in alert dialog boxes for browsers that normally display the ASCII-encoded version.

Note

Although Listing 28-5 uses the `unescape()` global function for backward compatibility, that function (and its partner, `escape()`) have been removed from the ECMAScript standard as of version 3. These functions have been replaced by more modern versions, `decodeURI()` and `encodeURI()`. See Chapter 24 for details. ■

LISTING 28-5

Extracting the Directory of the Current Document

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Extract pathname</title>
      <script type="text/javascript">
      // general purpose function to extract URL of current directory
      function getDirPath(URL)
      {
         var result = unescape(URL.substring(0,(URL.lastIndexOf("/")) + 1));
         return result;
      }

      // handle button event, passing work onto general purpose function
      function showDirPath(URL)
      {
         alert(getDirPath(URL));
      }
      </script>
   </head>
```

continued

LISTING 28-5 *(continued)*

```
   <body>
      <form>
         <input type="button" value="View directory URL"
         onclick="showDirPath(window.location.href)" />
      </form>
   </body>
</html>
```

Related Items: `location.pathname`, `document.location` properties; `String` object (Chapter 15, "The String Object")

pathname

Value: String   Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The pathname component of a URL consists of the directory structure relative to the server's root volume. In other words, the root (the server name in an `http:` connection) is not part of the pathname. If the URL's path is to a file in the root directory, the `location.pathname` property is a single slash (`/`) character. Any other pathname starts with a slash character, indicating a directory nested within the root. The value of the `location.pathname` property also includes the document name.

See Listing 28-2, Listing 28-3, and Listing 28-4 earlier in this chapter for a multiple-frame example you can use to view the `location.pathname` property for a variety of URLs of your choice.

Related Item: `location.href` property

port

Value: String   Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

These days, few consumer-friendly web sites need to include the port number as part of their URLs. You see port numbers mostly in the less-popular protocols, in URLs to sites used for private development purposes, or in URLs to sites that have no assigned domain names. You can retrieve the value with the `location.port` property. If you extract the value from one URL and intend to build another URL with that component, be sure to include the colon delimiter between the server's IP address and port number.

If you have access to URLs containing port numbers, use the documents in Listing 28-2, Listing 28-3, and Listing 28-4 to experiment with the output of the `location.port` property.

Related Item: `location.host` property

protocol

Value: String   Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The first component of any URL is the protocol used for the particular type of communication. For World Wide Web pages, the Hypertext Transfer Protocol (`http`) is the standard. Other common protocols you may see in your browser include HTTP-Secure (`https`), File Transfer Protocol (`ftp`), File (`file`), and Mail (`mailto`); web pages opened from your local hard drive use the `file` protocol. Values for the `location.protocol` property include not only the name of the protocol, but also the trailing colon delimiter. Thus, for a typical web-page URL, the `location.protocol` property is

```
http:
```

Notice that the usual slashes after the protocol in the URL are not part of the `location.protocol` value. Of all the `location` object properties, only the full URL (`location.href`) reveals the slash delimiters between the protocol and other components.

See Listing 28-2, Listing 28-3, and Listing 28-4 for a multiple-frame example you can use to view the `location.protocol` property for a variety of URLs. Notice that the protocol shows up initially as `file:` to indicate that the first page in the left frame is stored locally and accessed via the File protocol. Also try loading an FTP site to see the `location.protocol` value for that type of URL.

Related Item: `location.href` property

search

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Perhaps you've noticed the long, cryptic URL that appears in the Location/Address field of your browser whenever you ask one of the World Wide Web search services to look up matches for items you enter in the keyword field. The URL starts the regular way — with protocol, host, and pathname values. But following the more traditional URL are search commands that are submitted to the search engine (typically, a CGI program running on the server). You can retrieve or set that trailing search query by using the `location.search` property.

Each search engine has its own formula for query submissions based on the designs of the HTML forms that obtain details from users. These search queries come in an encoded format that appears in anything but plain language. If you plan to script a search query, be sure you fully understand the search engine's format before you start assembling a string to assign to the `location.search` property of a window.

The most common format for search data is a series of name/value pairs. An equal symbol (=) separates a name and its value. Multiple name/value pairs have ampersands (&) between them. You should use the `escape()` function to convert the data to URL-friendly format, especially when the content includes spaces.

The `location.search` property also applies to any part of a URL after the filename, including parameters being sent to CGI programs on the server.

Passing data between pages via URLs

It is not uncommon to want to preserve some pieces of data that exist in one page so that a script in another page can pick up where the script processing left off in the first page. You can achieve persistence across page loads without any server programming through one of three techniques: the `document.cookie` (see Chapter 29, "Document and Body Objects"), variables in framesetting documents, and the search string of a URL. That's really what happens when you visit search and e-commerce sites that return information to your browser. Rather than store, say, your search criteria on the server, they

spit the criteria back to the browser as part of the URL. The next time you activate that URL, the values are sent to the server for processing (for example, to send you the next page of search results for a particular query).

Passing data between pages is not limited to client/server communication. You can use the search string strictly on the client side to pass data from one page to another. Unless some CGI process on the server is programmed to do something with the search string, a web server regurgitates the search string as part of the location data that comes back with a page. A script in the newly loaded page can inspect the search string (via the `location.search` property) and tear it apart to gather the data and put it into script variables. Take a look at Listing 28-6, Listing 28-7, and Listing 28-8 to see a powerful application of this technique.

As mentioned in Chapter 27, "Window and Frame Objects," you can force a particular HTML page to open inside the frameset for which it is designed. But with the help of the search string, you can reuse the same framesetting document to accommodate any number of content pages that go into one of the frames (rather than specifying a separate frameset for each possible combination of pages in the frameset). The listings in this section create a simple example of how to force a page to load in a frameset by passing some information about the page to the frameset. Thus, if a user has a URL to one of the content frames (perhaps it has been bookmarked by right-clicking the frame, or it comes up as a search-engine result), the page appears in its designated frameset the next time the user visits the page.

The fundamental task in this scheme has two parts. The first is in each of the content pages, where a script checks whether the page is loaded inside a frameset. If the frameset is missing, a search string is composed and appended to the URL for the framesetting document. The framesetting document has its own short script that looks for the presence of the search string. If the string is there, the script extracts the search string data and uses it to load that specific page into the content frame of the frameset.

Listing 28-6 is the framesetting document. The `getSearchAsArray()` function is more complete than necessary for this simple example, but you can use it in other instances to convert any number of name/value pairs passed in the search string (in traditional format of `name1=value1&name2=value2&etc.`) into an array whose indexes are the names (making it easier for scripts to extract a specific piece of passed data).

LISTING 28-6

A Smart Frameset

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Example Frameset</title>
      <script type="text/javascript">
      // Convert location.search into an array of values
      // indexed by name.
      function getSearchAsArray()
      {
         var results = new Array();
         var input = unescape(location.search.substr(1));
```

```
        if (input)
        {
           var srchArray = input.split("&");
           var tempArray = new Array();
           for (var i = 0; i < srchArray.length; i++)
           {
              tempArray = srchArray[i].split("=");
              results[tempArray[0]] = tempArray[1];
           }
        }
        return results;
     }

     function loadFrame()
     {
        if (location.search)
        {
           var srchArray = getSearchAsArray();
           if (srchArray["content"])
           {
              self.content.location.href = srchArray["content"];
           }
        }
     }
     </script>
   </head>
   <frameset cols="250,*" onload="loadFrame()">
      <frame name="toc" src="jsb28-07.html" />
      <frame name="content" src="jsb28-08.html" />
   </frameset>
</html>
```

Listing 28-7 is the HTML for the table-of-contents frame. Nothing elaborate goes on here, but you can see how normal navigation works for this simplified frameset. You can also see how this example could be easily built upon to provide a handy table-of-contents feature to a site with multiple sections or pages.

LISTING 28-7

The Table of Contents

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
   <title>Table of Contents</title>
   </head>
   <body bgcolor="#EEEEEE">
      <h3>Table of Contents</h3>
```

continued

LISTING 28-7 *(continued)*

```
      <hr />
      <ul>
         <li><a href="jsb28-08.html" target="content">Page 1</a></li>
         <li><a href="jsb28-08a.html" target="content">Page 2</a></li>
         <li><a href="jsb28-08b.html" target="content">Page 3</a></li>
      </ul>
   </body>
</html>
```

Listing 28-8 shows one of the content pages. As the page loads, the `checkFrameset()` function is invoked. If the window does not load inside a frameset, the script navigates to the framesetting page, passing the current content URL as a search string. Notice that the loading of this page on its own does not get recorded to the browser's history and isn't accessed if the user clicks the Back button.

LISTING 28-8

A Content Page

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Page 1</title>
      <script type="text/javascript">
      function checkFrameset()
      {
         if (parent == window)
         {
            // Use replace() to keep current page out of history
            location.replace("jsb28-06.html?content=" + escape(location.href));
         }
      }

      // Invoke the function
      checkFrameset();
      </script>
   </head>
   <body>
      <h1>Page 1</h1>
      <hr />
   </body>
</html>
```

In practice, we recommend placing the code for the `checkFrameset()` function and the call to it inside an external `.js` library, and linking that library to each content document of the frameset. That's why the function assigns the generic `location.href` property to the search string: You can use it on any content page.

The code in Listing 28-6, Listing 28-7, and Listing 28-8 establishes a frameset containing two frames. In the left frame is a table of contents that allows you to navigate among three different pages, the first of which is initially displayed in the right frame. The interesting thing about the example is how you can specify a new page in the `content` parameter of the search property; the page is then opened within the frameset. For example, the following URL would result in the page `hello.html` being opened in the right frame:

```
jsb28-06.html?content=hello.html
```

In this example URL, the frameset page is first opened due to the inclusion of the file `jsb28-06.html`, whereas the `hello.html` file is specified as the value of the `content` parameter.

Note

While this frameset example is an easy way to demonstrate the uses of the various location object properties, keep in mind that the use of framesets is no longer common programming practice. First, it does not support accessibility. Second, CSS Positioning is the standard for placing content on a webpage. ■

Related Item: `location.href` property

Methods

`assign("URL")`

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

In earlier discussions about the `location` object, I said that you navigate to another page by assigning a new URL to the `location` object or `location.href` property. The `location.assign()` method does the same thing. In fact, when you set the `location` object to a URL, JavaScript silently applies the `assign()` method. No particular penalty or benefit comes from using the `assign()` method except perhaps making your code more understandable to others.

Related Item: `location.href` property

`reload(unconditionalGETBoolean)`

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+
