The `location.reload()` method may be named inappropriately because it makes you think of the Reload/Refresh button in the browser toolbar. The `reload()` method is actually more powerful than the Reload/Refresh button in that it clears form control values that otherwise might survive the Reload/Refresh button. Note that IE for the Mac, Opera, and WebKit browsers such as Safari and Chrome do not preserve form control settings even with a soft reload.

Most form elements retain their screen states when you click Reload/Refresh. Text and `textarea` objects maintain whatever text is inside them; radio buttons and checkboxes maintain their checked status; `select` objects remember which item is selected. About the only items the Reload/Refresh button destroys are global variable values and any settable, but not visible, property (for example, the value of a `hidden input` object). I call this kind of reload a *soft reload.* A *hard reload,* on the other hand, should reset all data associated with a page, including default form selections.

locationObject.reload()

Browsers are frustratingly irregular about the ways they reload a document in the memory cache. In theory, an application of the `location.reload()` method should retrieve the page from the cache if the page is still available there (and the `history.go(0)` method should be even gentler, preserving form element settings). Adding a `true` parameter to the method is supposed to force an *unconditional GET* to the server, ignoring the cached version of the page. Yet when it is crucial for your application to get a page from the cache (for speed) or from the server (to guarantee a fresh copy), the browser behaves just the opposite of the way you want it to behave. Meta tags supposedly designed to prevent caching of a page rarely, if ever, work. Some scripters have had success in reloading the page from the server by setting `location.href` to the URL of the page, plus a slightly different search string (for example, based on a string representation of the `Date` object), so that there is no match for the URL in the cache.

The bottom line is that you should be prepared to try different schemes to achieve the effect you want. Also be prepared not to get the results you want. In other words, learn to live with the fact that you don't really have exacting control over retrieving a fresh page.

Listing 28-9 provides a means of testing the different outcomes of a soft reload versus a hard reload. Open this example page in a browser, and click a radio button. Then enter some new text, and make a choice in the `select` object. Clicking the Soft Reload/Refresh button invokes a method that reloads the document as though you had clicked the browser's Reload/Refresh button. It also preserves the visible properties of form elements. The Hard Reload button invokes the `location.reload()` method, which resets all objects to their default settings.

LISTING 28-9

Hard versus Soft Reloading

```
<!DOCTYPE html>

            <option>Red</option>
            <option>Green</option>
            <option>Blue</option>
         </select></p>
      <hr />
      <input type="button" value="Soft Reload" onclick="softReload()" />
      <input type="button" value="Hard Reload" onclick="hardReload()" />
   </form>
 </body>
</html>
```

Related Item: `history.go()` method

replace("*URL*")

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

In a complex web site, you may have pages that you do not want to appear in the user's history list. For example, a registration sequence may lead the user to one or more intermediate HTML documents that won't make much sense to the user later. Or you may have a one-time introduction page that appears only the first time a user visits your site. You especially don't want users to see these pages again if they use the Back button to return to a previous URL. The `location.replace()` method navigates to another page, but it does not let the current page stay in the queue of pages accessible via the Back button.

Although you cannot prevent a document from appearing in the history list while the user views that page, you can instruct the browser to load another document into the window and replace the current history entry with the entry for the new document. This trick does not empty the history list but removes the current item from the list before the next URL is loaded. Removing the item from the history list prevents users from seeing the page again by clicking the Back button later.

Listing 28-10 shows how to use the `replace()` method to direct a web browser to a new URL. Calling the `location.replace()` method navigates to another URL, similarly to assigning a URL to the location. The difference is that the document doing the calling doesn't appear in the history list after the new document loads. You can verify this by trying to click the Back button to return to the page after clicking Replace Me in Listing 28-10; the button is dimmed because the page no longer exists in the browser history. Also check the history listing (in your browser's usual spot for this information) before and after clicking Replace Me.

LISTING 28-10

Invoking the location.replace() Method

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>location.replace() Method</title>
```

Related Item: `history` object

history Object

Properties	Methods	Event Handler
`current`	`back()`	(None)
`length`	`forward()`	
`next`	`go()`	
`previous`		

Syntax

Accessing `history` object properties or methods:

```
[window.]history.property | method([parameters])
```

About this object

As a user surfs the web, the browser maintains a list of URLs for the most recent stops. This list is represented in the scriptable object model by the `history` object. A script cannot surreptitiously extract actual URLs maintained in this list unless you use signed scripts (in NN4+/Moz; see Chapter 49, "Security and Netscape Signed Scripts" on the CD-ROM), and the user grants permission. Under unsigned conditions, a script can methodically navigate to each URL in the history (by relative number or by stepping back one URL at a time), in which case the user sees the browser navigating on its own as though possessed by a spirit. Good Netiquette dictates that you do not navigate a user outside your web site without the user's explicit permission.

One application for the `history` object and its `back()` or `go()` methods is to provide the equivalent of a Back button in your HTML documents. That button triggers a script that checks for any items in the history list and then goes back one page. Your document doesn't have to know anything about the URL from which the user lands at your page; it delegates the specifics of the navigation back to the browser.

The behavior of the Back and Forward buttons is also available through a pair of window methods: `window.back()` and `window.forward()`. The `history` object methods are specific to a frame that is part of the reference. When the `parent.frameName.history.back()` method reaches the end of history for that frame, further invocations of that method are ignored.

IE's history mechanism is not localized to a particular frame of a frameset. Instead, the `history.back()` and `history.forward()` methods mimic the physical act of clicking the toolbar buttons. If you want to ensure cross-browser, if not cross-generational, behavior in a frameset, address references to the `history.back()` and `history.forward()` methods to the parent window.

Opera's history mechanism is also interesting. Let's say that you are developing a web page. You load it into Opera and observe how it behaves. You then edit the page, save it, and go back to Opera to observe the behavior. If you were to click the back button or use any of the methods described in this chapter, you would go back to the previous version of the web page you just edited.

You should use the `history` object and its methods with extreme care. Your design must be smart enough to watch what the user is doing with your pages (for example, by checking the current URL before navigating with these methods). Otherwise, you run the risk of confusing your user by navigating to unexpected places. Your script can also get into trouble because it cannot detect where the current document is in the Back/Forward sequence in history. Your script is also at the mercy of how the browser's history mechanism operates.

Properties

current
next
previous

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari-, Opera+ (current only), Chrome-

To determine where to go when you click the Back and Forward buttons, the browser maintains a list of URLs visited. To someone trying to invade your privacy and see what sites and pages you frequent, this information is valuable. That's why the three properties that expose the actual URLs in the history list are restricted to pages with signed scripts (NN4+/Moz), and whose visitors have given permission to read sensitive browser data (see Chapter 49 on the CD-ROM).

With signed scripts and permission, you can look through the entire array of history entries in any frame or window. Because the list is an array, you can extract individual items by index value. For example, if the array has 10 entries, you can see the fifth item by using normal array indexing methods:

```
var fifthEntry = window.history[4];
```

No property or method exists that directly reveals the index value of the currently loaded URL, but you can script an educated guess by comparing the values of the current, next, and previous properties of the `history` object against the entire list.

We personally don't like some unknown entity watching over our shoulders while we're on the Net, so we respect that same feeling in others and therefore discourage the use of these powers, unless the user is given adequate warning. The signed script permission dialog box does not offer enough detail about the consequences of revealing this level of information. This means that you should explicitly notify users of the fact that you are accessing their history, even when you have implicit permission via a signed script.

Related Item: `history.length` property

length

Value: Number Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Use the `history.length` property to count the items in the history list. Unfortunately, this nugget of information is not particularly helpful in scripting navigation relative to the current location because your script cannot extract anything from the place in the history queue where the current document is located. If the current document is at the top of the list (the most recently loaded), you can calculate relative to that location. But users can use the Go/View menu to jump around the history list as they like. The position of a listing in the history list does not change by virtue of navigating back to that document. A `history.length` of 1, however, indicates that the current document is the first one the user has loaded since starting the browser software.

Listing 28-11 shows how to use the `length` property to notify users of how many pages they've visited.

LISTING 28-11

A Browser History Count

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>History Object</title>
      <script type="text/javascript">
      function showCount()
      {
         var histCount = window.history.length;
         if (histCount > 5)
         {
            alert("My, my, you\'ve been busy. You have visited " + histCount +
               " pages so far.");
         }
         else
         {
            alert("You have been to " + histCount + " Web pages this
               session.");
         }
```

```
        }
      </script>
   </head>
   <body>
      <form>
         <input type="button" name="activity" value="My Activity"
         onclick="showCount()" />
      </form>
   </body>
</html>
```

Related Items: None

Methods

back()
forward()

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Although the names might lead you to believe that these methods mimic the buttons on a browser's toolbar, they do not. The `history.back()` method is window/frame specific, meaning that if you direct successive `back()` methods to a frame within a frameset, the method is ignored when it reaches the first document to be loaded into that frame. The Back button and the `window.back()` method unload the frameset and continue taking you back through the browser's global history.

If you deliberately lead a user to a dead end in your web site, you should make sure that the HTML document provides a way to navigate back to a recognizable spot. Because you can easily create a new window that has no toolbar or menu bar (non-Macintosh browsers), you may end up stranding your users because they have no way of navigating out of a cul-de-sac in such a window. A button in your document should give the user a way back to the last location.

Unless you need to perform some additional processing prior to navigating to the previous location, you can simply place this method as the parameter to the event handler attribute of a button definition. To guarantee compatibility across all browsers, direct this method at the parent document when it's used from within a frameset.

Less likely to be scripted than the `history.back()` action is the method that performs the opposite action: navigating forward one step in the browser's history list. The only time you can confidently use the `history.forward()` method is in balancing the use of the `history.back()` method in the same script — where your script closely keeps track of how many steps the script heads in either direction. Use the `history.forward()` method with extreme caution, and only after performing extensive user testing on your web pages to make sure that you've covered all user possibilities. Similar to navigating backward via `history.back()`, forward progress when using `history.forward()` extends only through the history listing for a given window or frame, not the entire browser history list.

Listing 28-12 and Listing 28-13 provide a little workshop in which you can test the behavior of a variety of forms of backward and forward navigation in different browsers.

        </ul>
     </form>
  </body>
</html>
```

Related Items: `history.go()` method

go(*relativeNumber* | *"URLOrTitleSubstring"*)

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Use the `history.go()` method to script navigation within the history list currently stored in the browser. If you elect to use a URL as a parameter, however, that precise URL must already exist in the history listing. Therefore, do not regard this method as an alternative to setting the `window.location` object to a brand-new URL.

For navigating `n` steps in either direction along the history list, use the `relativeNumber` parameter of the `history.go()` method. This number is an integer value that indicates which item in the list to use, relative to the current location. For example, if the current URL is at the top of the list (that is, the Forward button in the toolbar is dimmed), you need to use the following method to jump to the URL two items backward in the list:

```
history.go(-2);
```

In other words, the current URL is the equivalent of `history.go(0)` (a method that reloads the window). A positive integer indicates a jump that many items forward in the history list. Thus, `history.go(-1)` is the same as `history.back()`, whereas `history.go(1)` is the same as `history.forward()`.

Alternatively, you can specify one of the URLs or document titles stored in the browser's history list (titles appear in the Go/View menu). As security and privacy concerns have increased over time, this variant of the `go()` method has been reined in. It's best not to use the string parameter in your scripting; in fact, none of the current browser versions support this variant.

Like most other history methods, your script finds it difficult to manage the history list or the current URL's spot in the queue. That fact makes it even more difficult for your script to determine intelligently how far to navigate in either direction, or to which specific URL or title matches it should jump. Use this method only for situations in which your web pages are in strict control of the user's activity (or for designing scripts for yourself that automatically crawl around sites according to a fixed regimen). When you give the user control over navigation, you have no guarantee that the history list will be what you expect, and any scripts you write that depend on a `history` object will likely break.

In practice, this method mostly performs a soft reload of the current window using the `0` parameter.

Tip

If you are developing a page for all scriptable browsers, be aware that the reloading of a page with `history.go(0)` in IE often returns to the server to reload the page rather than reloading from the cache. ■

Listing 28-14 contains sample code that demonstrates how to navigate the history list via the `go()` method. Fill in either the number or text field of the page in Listing 28-14, and then click the associated button. The script passes the appropriate kind of data to the `go()` method. Unless you are using an older browser version, using the matching string text box and its button will do nothing. Be sure to use negative numbers for visiting a page earlier in the history.

Note

Mozilla browsers respond only to the integer offset approach to using the `history.go()` method. ■

CHAPTER 29

Document and Body Objects

IN THIS CHAPTER

Accessing arrays of objects contained by the document object

Writing new document content to a window or frame

Using the body element for IE window measurements

User interaction is a vital aspect of client-side JavaScript scripting, and most of the communication between script and user takes place by way of the `document` object and its components. Understanding the scope of the `document` object within each of the object models you support is key to implementing successful cross-browser applications.

Review the `document` object's place within the original object hierarchy. Figure 29-1 shows that the `document` object is a pivotal point for a large percentage of objects. In the W3C DOM, the `document` object plays an even more important role as the container of all element objects delivered with the page: The `document` object is the root of the entire document tree.

In fact, the `document` object and all that it contains is so big that we have divided its discussion into many chapters, each focusing on related object groups. This chapter looks at the `document` object and `body` object (which have conceptual relationships), whereas each of the succeeding chapters in this part of the book details objects contained by the `document` object.

FIGURE 29-1

The basic document object model hierarchy.

Syntax

Accessing `document` object properties or methods:

```
[window.]document.property | method([parameters])
```

About this object

A document object encompasses the totality of what exists inside the content region of a browser window or window frame (excluding toolbars, status lines, and so on). The document is a combination of the content and interface elements that make the web page worth visiting. In modern browsers the document object also serves as the root node of a page's hierarchical tree of nodes — that from which all other nodes grow.

Because the document object isn't explicitly represented in an HTML document by tags or any other notation, the original designers of JavaScript and object models decided to make the document object the portal to many settings that were represented in HTML as belonging to the body element. Therefore, the body element's tag contains attributes for document-wide attributes, such as background color (bgcolor) and link colors in various states (alink, link, and vlink). The original designers decided to have the body element also serve as an HTML container for forms, links, and anchors. The document object, therefore, assumed a majority of the role of the body element. But even then, the document object became the most convenient place to bind some properties that extend beyond the body element, such as the title element and the URL of the link that referred the user to the page. When viewed within the context of the HTML source code, the original document object is somewhat schizophrenic. Even so, the document object has worked well as the basis for references to original object model objects, such as forms, images, and applets.

This, of course, was before every HTML element, including the body element, was exposed as an object through modern object models. Amazingly, even with the IE4+ object model and W3C DOM — both of which treat the body element as an object separate from the document object — script compatibility with the original object model is quite easily accomplished. The document object has assumed a new schizophrenia, splitting its personality between the original object model and the one that places the document object at the root of the hierarchy, quite separate from the body element object it contains. The object knows which face to put on based on the rest of the script syntax that follows it. This means that quite often there are multiple ways to achieve the same reference. For example, you can use the following statement in all scriptable browsers to get the number of form objects in a document:

```
document.forms.length
```

In IE4+, you can also use

```
document.tags["form"].length
```

And in the W3C DOM as implemented in IE5+ and NN6+/Moz/Safari/Opera/Chrome, you can use

```
document.getElementsByTagName("form").length
```

Modern browsers provide a generic approach to accessing elements (getElementsByTagName() method in the W3C DOM) to meet the requirements of object models that expose every HTML (and XML) element as an object.

Promoting the body element to the ranks of exposed objects presented its own challenges to the new object model designers. The body element is the true owner of some properties that the original document object had to take on by default. Most properties that belonged to the original document object were renamed in their transfer to the body element. For example, the original document.alinkColor property is the body.aLink property in the modern model. But the bgColor property has not been renamed. For the sake of code compatibility, modern browsers recognize both properties, even though the W3C DOM has removed the old versions of the properties

for the newly conceived `document` object. Considering the fact that modern browsers are now prevalent, you should be able to stick with the new properties from here on.

Properties

activeElement

Value: Object reference Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera+, Chrome+

Originally just in IE4+, a script can examine the `document.activeElement` property to see which element currently has focus. The value returned is an element object reference. You can use any of the properties and methods listed in Chapter 26 to find out more about the object.

Although the element used to generate a mouse or keyboard event will most likely have focus, don't rely on the `activeElement` property to find out which element generated an event. The IE `event.srcElement` property is far more reliable.

Example

Use The Evaluator (see Chapter 4, "JavaScript Essentials") with IE4+ to experiment with the `activeElement` property. Type the following statement into the top text box:

```
document.activeElement.value
```

After you press the Enter key, the Results box shows the value of the text box you just typed into (the very same expression you just typed). But if you then click the Evaluate button, you will see the `value` property of that button object appear in the Results box.

Related Item: `event.srcElement` property

alinkColor
bgColor
fgColor
linkColor
vlinkColor

Value: Hexadecimal triplet or color name string Mostly Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

These five properties are the script equivalent of the `<body>` tag attributes of the same name (although the property names are case-sensitive). All five settings can be read via the `document.body` object in modern browsers. Values for all color properties can be either the common HTML hexadecimal triplet value (for example, `"#00FF00"`) or any of the standard color names.

Example

We select some color values at random to plug into three settings of the group of ugly colors for Listing 29-1. The smaller window displays a dummy button so that you can see how its display contrasts with color settings. Notice that the script sets the colors of the smaller window by rewriting the entire window's HTML code. After changing colors, the script displays the color values in the original window's textarea. Even though some colors are set with the color constant values, properties come

back in the hexadecimal triplet values. You can experiment to your heart's content by changing color values in the listing. Every time you change the values in the script, save the HTML file and reload it in the browser.

LISTING 29-1

Tweaking the Color of Page Elements

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Color Me</title>
      <script type="text/javascript">
         // may be blocked at load time by browser popup blockers
         var newWindow = window.open("","","height=150,width=300");

         function defaultColors()
         {
            return "bgcolor='#c0c0c0' vlink='#551a8b' link='#0000ff'";
         }

         function uglyColors()
         {
            return "bgcolor='yellow' vlink='pink' link='lawngreen'";
         }

         function showColorValues()
         {
            var result = "";
            result += "bgColor: " + newWindow.document.bgColor + "\n";
            result += "vlinkColor: " + newWindow.document.vlinkColor + "\n";
            result += "linkColor: " + newWindow.document.linkColor + "\n";
            document.forms[0].results.value = result;
         }

         // dynamically writes contents of another window
         function drawPage(colorStyle)
         {
            // work around popup blockers
            if (!newWindow || newWindow.closed)
            {
               newWindow = window.open("","","height=150,width=300");
            }
            var thePage = "";
            thePage += "<html><head><title>Color Sampler<\/title><\/head><body ";
            if (colorStyle == "default")
            {
               thePage += defaultColors();
            }
            else
            {
```

continued

LISTING 29-1 *(continued)*

```
            thePage += uglyColors();
        }
        thePage += ">Just so you can see the variety of items and colors, <a ";
        thePage += "href='http://www.nowhere.com'>here\'s a link<\/a>, and <a
        href='http://home.netscape.com'> here is another link <\/a> you can
        use on-line to visit and see how its color differs from the standard
        link.";
        thePage += "<form>";
        thePage += "<input type='button' name='sample' value='Just a Button'>";
        thePage += "<\/form><\/body><\/html>";
        newWindow.document.write(thePage);
        newWindow.document.close();
        showColorValues();
    }

    // the following works properly only in Windows Navigator
    function setColors(colorStyle)
    {
        if (colorStyle == "default")
        {
            document.bgColor = "#c0c0c0";
        }
        else
        {
            document.bgColor = "yellow";
        }
    }

    // bind the event handlers
    function addEvent(elem, evtType, func)
    {
        if (elem.addEventListener)
        {
            elem.addEventListener(evtType, func, false);
        }
        else if (elem.attachEvent)
        {
            elem.attachEvent("on" + evtType, func);
        }
        else
        {
            elem["on" + evtType] = func;
        }
    }
    addEvent(window, "load", function()
    {
        addEvent(document.getElementById("default1"), "click",
            function(evt) {drawPage("default")});
        addEvent(document.getElementById("weird1"), "click",
            function(evt) {drawPage("ugly")});
```

```
            addEvent(document.getElementById("default2"), "click",
               function(evt) {setColors("default")});
            addEvent(document.getElementById("weird2"), "click",
               function(evt) {setColors("ugly")});
         });
      </script>
   </head>
   <body>
      Try the two color schemes on the document in the small window.
      <form>
         <input type="button" id="default1" name="default" value='Default Colors' />
         <input type="button" id="weird1" name="weird" value="Ugly Colors" />
         <p>
            <textarea name="results" rows="3" cols="20"></textarea>
         </p>
         <hr />
         These buttons change the current document.
         <p>
            <input type="button" id="default2" name="default"
                value='Default Colors' />
            <input type="button" id="weird2" name="weird" value="Ugly Colors" />
         </p>
      </form>
   </body>
</html>
```

Note

The examples in this chapter take advantage of the modern approach to event handling, which involves the `addEventListener()` **(NN6+/Moz/W3C) and** `attachEvent()` **(IE5+) methods. This event-handling technique is explained in detail in Chapter 32, "Event Objects."** ■

Related Items: `body.aLink`, `body.bgColor`, `body.link`, `body.text`, `body.vLink` properties

anchors[]

Value: Array of anchor objects Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Anchor objects (described in Chapter 30, "Link and Anchor Objects") are points in an HTML document marked with `<a name="">` tags. Anchor objects are referenced in URLs by a hash value between the page URL and anchor name. Like other object properties that contain a list of nested objects, the `document.anchors` property delivers an indexed array of anchors in a document. Use the array references to pinpoint a specific anchor for retrieving any anchor property.

Anchor arrays begin their index counts with `0`: The first anchor in a document, then, has the reference `document.anchors[0]`. And, as is true with any built-in array object, you can find out how many entries the array has by checking the `length` property. For example:

```
alert("This document has " + document.anchors.length + " anchors.");
```

***documentObject*.anchors[]**

The `document.anchors` property is read-only. To script navigation to a particular anchor, assign a value to the `window.location` or `window.location.hash` object, as described in the `location` object discussion in Chapter 28, "Location and History Objects."

Example

In Listing 29-2, we append an extra script to Listing 28-1 to demonstrate how to extract the number of anchors in the document. The document dynamically writes the number of anchors found in the document. You will not likely ever need to reveal such information to users of your page, and the `document.anchors` property is not one that you will call frequently. The object model defines it automatically as a document property while defining actual anchor objects.

LISTING 29-2

Using Anchors to Navigate Through a Page

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>document.anchors Property</title>
      <script type="text/javascript">
         function goNextAnchor(where)
         {
            window.location.hash = where;
         }

         // bind the event handlers
         function addEvent(elem, evtType, func)
         {
            if (elem.addEventListener) {
               elem.addEventListener(evtType, func, false);
            }
            else if (elem.attachEvent)
            {
               elem.attachEvent("on" + evtType, func);
            }
            else
            {
               elem["on" + evtType] = func;
            }
         }
         addEvent(window, "load", function()
         {
            addEvent(document.getElementById("next1"), "click",
               function(evt) {goNextAnchor("sec1")});
            addEvent(document.getElementById("next2"), "click",
               function(evt) {goNextAnchor("sec2")});
            addEvent(document.getElementById("next3"), "click",
               function(evt) {goNextAnchor("sec3")});
            addEvent(document.getElementById("next4"), "click",
```

```
            function(evt) {goNextAnchor("start")});
      });
   </script>
</head>
<body>
   <h1><a id="start" name="start">Top</a></h1>
   <form>
      <input type="button" id="next1" name="next" value="NEXT" />
   </form>
   <hr />
   <h1><a id="sec1" name="sec1">Section 1</a></h1>
   <form>
      <input type="button" id="next2" name="next" value="NEXT" />
   </form>
   <hr />
   <h1><a id="sec2" name="sec2">Section 2</a></h1>
   <form>
      <input type="button" id="next3" name="next" value="NEXT" />
   </form>
   <hr />
   <h1><a id="sec3" name="sec3">Section 3</a></h1>
   <form>
      <input type="button" id="next4" name="next" value="BACK TO TOP" />
   </form>
   <hr />
   <p>
      <script type="text/javascript">
        document.write("<i>There are " +
                       document.anchors.length +
                       " anchors defined for this document<\/i>")
      </script>
   </p>
</body>
</html>
```

Related Items: `anchor`, `location` objects; `document.links` property

applets[]

Value: Array of applet objects Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `applets` property refers to Java applets defined in a document by the `<applet>` tag. An applet is not officially an object in the document until the applet loads completely.

Most of the work you do with Java applets from JavaScript takes place through the methods and variables defined inside the applet. Although you can reference an applet according to its indexed array position within the `applets` array, you will more likely use the applet object's name in the reference to avoid any confusion.

Example

The `document.applets` property is defined automatically as the browser builds the object model for a document that contains applet objects. You will rarely access this property, except to determine how many applet objects a document has, as in this example:

```
var numApplets = document.applets.length;
```

Related Item: `applet` object

baseURI

Value: String   Read-Only

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `baseURI` property reveals the absolute base URI of the document. You can check the base URI of a document in the Evaluator (see Chapter 4, "JavaScript Essentials") by entering the following:

```
document.baseURI
```

Related Item: `document.documentURI` property

bgColor

(See `alinkColor`)

body

Value: `body` element object   Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.body` property is a shortcut reference to the `body` element object in modern object models. As you can see in the discussion of the `body` element object later in this chapter, that object has many key properties that govern the look of the entire page. Because the `document` object is the root of all references within any window or frame, the `document.body` property is easier to use to get to the `body` properties than the longer references normally used to access HTML element objects in both the IE4+ and W3C object models.

Example

Use The Evaluator (see Chapter 4, "JavaScript Essentials") to examine properties of the `body` element object. First, to prove that the `document.body` is the same as the element object that comes back from longer references, enter the following statement into the top text box with either IE5+, NN6+/Moz, or some other W3C browser:

```
document.body == document.getElementsByTagName("body")[0]
```

Next, check out the `body` object's property listings later in this chapter and enter the listings into the top text box to review their results. For example:

```
document.body.bgColor
document.body.tagName
```

The main point to take from this example is that the `document.body` reference provides a simpler and more direct means of accessing a document's `body` object without having to use the `getElementsByTagName()` method.

Related Item: `body element` object

charset

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera+, Chrome+

The `charset` property reveals the character set originally used by the browser (IE4+) to render the current document (the NN6+/Moz version of this property is called `characterSet`). You can find possible values for this property at

```
ftp://ftp.isi.edu/in-notes/iana/assignments/character-sets
```

Each browser and operating system has its own default character set. Values may also be set through a `<meta>` tag.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `charset` property. To see the default setting applied to the page, enter the following statement into the top text box:

```
document.charset
```

If you are running IE5+ for Windows and you enter the following statement, the browser will apply a different character set to the page:

```
document.charset = "iso-8859-2"
```

If your version of Windows does not have that character set installed in the system, the browser may ask permission to download and install the character set.

Related Items: `characterSet`, `defaultCharset` properties

characterSet

Value: String Read/Write

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `characterSet` property reveals the character set used by the browser to render the current document (the IE version of this property is called `charset`). You can find possible values for this property at

```
http://www.iana.org/assignments/character-sets
```

Each browser and operating system has its own default character set. Values may also be set through a `<meta>` tag.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `characterSet` property in NN6+/Moz. To see the default setting applied to the page, enter the following statement into the top text box:

```
document.characterSet
```

Related Item: `charset` property

compatMode

Value: String Read-Only

Compatibility: WinIE6+, MacIE6+, NN7+, Moz+, Safari+, Opera+, Chrome+

The `compatMode` property reveals the compatibility mode for the document, as determined by the `DOCTYPE` element's content. The value for this property can be one of the following string constants: `BackCompat` or `CSS1Compat`. The default setting for the `compatMode` property is `BackCompat`, which means that the document is not W3C standards-compliant; in other words, the document is in Quirks mode. Otherwise the document is in Strict mode and is W3C standards-compliant. By *standards-compliant* I'm referring to the CSS1 standard.

Example

You may find it useful to check the compatibility mode of a document in order to carry out processing specific to one of the modes. Following is an example of how you might branch to carry out processing for backward-compatible documents:

```
if (document.compatMode == "BackCompat") {
   // perform backward compatible processing
}
```

Related Items: *Standards Compatibility Modes* (see Chapter 4, "JavaScript Essentials")

contentType

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari-, Opera-, Chrome-

The `contentType` property holds the content type (MIME type) of the document. For a normal HTML document, the value of this property is `text/html`.

cookie

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The cookie mechanism in a web browser lets you store small pieces of information on the client computer in a reasonably secure manner. In other words, when you need some tidbit of information to persist at the client level while either loading diverse HTML documents or moving from one session to another, the cookie mechanism saves the day. The cookie is commonly used as a means to store the username and password you enter into a password-protected web site. The first time you enter this

information into a form, the server-side form processing program has the browser write the information back to a cookie on your hard disk (usually after encrypting the password). Rather than bothering you to enter the username and password the next time you access the site, the server searches the cookie data stored for that particular server and extracts the username and password for automatic validation processing behind the scenes.

Other applications of the cookie include storing user preferences and information about the user's previous visit to the site. Preferences may include font styles or sizes and whether the user prefers viewing content inside a frameset or not. As shown in Chapter 57, "Application: Intelligent 'Updated' Flags" (on the CD-ROM), a time stamp of the previous visit can allow a coded HTML page to display highlighted images next to content that has changed since the user's last visit, even if you have updated the page several times in the interim. Rather than hard-wiring new flags for *your* last visit, the scripts highlight what's new for the visitor.

The cookie file

Allowing some foreign server program to read from and write to your hard disk may give you pause, but browser cookie mechanisms don't just open up your drive's directory for the world to see (and to corrupt). Instead, the cookie mechanism provides access to a type of text file (Internet Explorer) or just one special text file (browsers other than IE) located in a platform-specific spot on your drive.

In Mozilla-based browsers, for example, the cookie file is named `cookies.txt` and is located in a directory (whose name ends in `.slt`) within the browser's profile area. In Windows, that location is `C:\\Windows\Application Data\Mozilla\Profiles\[profilename]\`; in Mac OSX, the location is `[user]/Library/Mozilla/Profiles/[profilename]/`. Internet Explorer for Windows uses a different filing system: all cookies for each domain are saved in a domain-specific file inside the `C:\\Windows\Temporary Internet Files\` directory. Filenames begin with `Cookie:` and include the username and domain of the server that wrote the cookie. Safari cookies are recorded in an XML file named `Cookies.plist` within the `[user]/Library/Cookies/` directory. Opera cookies are recorded in a binary file named `cookies4.dat` within the `[user]\Application Data\Opera\Opera` directory. Google Chrome cookies are recorded in a SQLite database file named `Cookies` within the `[user]\Local Settings\Application Data\Google\Chrome\User Data\Default` directory. Be aware that if you are testing with Google Chrome, your code will not work unless the files are coming from an HTTP server. Chrome intentionally disables cookies on `file:///` documents.

A cookie file is a text file. If curiosity drives you to open a cookie file, we recommend that you do so only with a copy saved in another directory or folder. Any alteration to the existing file can mess up whatever valuable cookies are stored there for sites you regularly visit. The data format for cookie files differs across browsers, in line with the different methodologies used for filing cookies. Inside the Mozilla file (after a few comment lines warning you not to manually alter the file) are lines of tab-delimited text. Each return-delimited line contains one cookie's information. The cookie file is just like a text listing of a database. In each of the IE cookie files, the same data points are stored for a cookie as for Mozilla, but the items are in a return-delimited list. The structure of these files is of no importance to scripting cookies, because all browsers utilize the same syntax for reading and writing cookies through the `document.cookie` property.

Note

As you experiment with browser's cookies, you will be tempted to look into the cookie file after a script writes some data to the cookie. The cookie file usually will not contain the newly written data, because in most browsers cookies are transferred to disk only when the user quits the browser; conversely, the cookie file is read into the browser's memory when it is launched. While you read, write, and delete cookies during a browser session, all activity is performed in memory (to speed up the process) to be saved later. ■

A cookie record

Among the fields of each cookie record are the following (not necessarily in this order):

- Domain of the server that created the cookie
- Information on whether you need a secure HTTP connection to access the cookie
- Pathname of URL(s) capable of accessing the cookie
- Expiration date of the cookie
- Name of the cookie entry
- String data associated with the cookie entry

Note that cookies are domain-specific. In other words, if one domain creates a cookie, another domain cannot access it through the browser's cookie mechanism behind your back. That reason is why it's generally safe to store what we call *throwaway passwords* (the username/password pairs required to access some free registration-required sites) in cookies. Moreover, sites that store passwords in a cookie usually do so as encrypted strings, making it more difficult for someone to hijack the cookie file from your unattended PC and figure out what your personal password scheme may be.

Cookies also have expiration dates. Because some browsers may allow no more than a fixed number of cookies (1000 in Firefox), the cookie file can get pretty full over the years. Therefore, if a cookie needs to persist past the current browser session, it should have an expiration date established by the cookie writer. Browsers automatically clean out any expired cookies.

Not all cookies have to last beyond the current session, however. In fact, a scenario in which you use cookies temporarily while working your way through a web site is quite typical. Many shopping sites employ one or more temporary cookie records to behave as the shopping cart for recording items you intend to purchase. These items are copied to the order form at checkout time. But after you submit the order form to the server, that client-side data has no particular value. As it turns out, if your script does not specify an expiration date, the browser keeps the cookie fresh in memory without writing it to the cookie file. When you quit the browser, that cookie data disappears as expected.

JavaScript access

Scripted access to cookies from JavaScript is limited to setting the cookie (with a number of optional parameters) and getting the cookie data (but with none of the parameters).

The original object model defines cookies as properties of documents, but this description is somewhat misleading. If you use the default path to set a cookie (that is, the current directory of the document whose script sets the cookie in the first place), all documents in that same server directory have read and write access to the cookie. A benefit of this arrangement is that if you have a scripted application that contains multiple documents, all documents served from the same directory can share the cookie data. Modern browsers, however, impose a limit of 20 named cookie entries (that is, one name/value pair) for any domain. If your cookie requirements are extensive, you need to fashion ways of concatenating cookie data. (We do this in the Decision Helper application in Chapter 58 on the CD-ROM.)

Saving cookies

To write cookie data to the cookie file, you use a simple JavaScript assignment operator with the `document.cookie` property. But the formatting of the data is crucial to achieving success. Here is the syntax for assigning a value to a cookie (optional items are in brackets; placeholders for data you supply are in italics):

```
document.cookie = "cookieName=cookieData
        [; expires=timeInGMTString]
```

```
[; path=pathName]
[; domain=domainName]
[; secure]"
```

Let's examine each of the properties individually.

Name/Data

Each cookie must have a name and a string value (even if that value is an empty string). Such name/value pairs are fairly common in HTML, but they look odd in an assignment statement. For example, if you want to save the string "Fred" to a cookie named "userName," the JavaScript statement is

```
document.cookie = "userName=Fred";
```

If the browser sees no existing cookie in the current domain with this name, it automatically creates the cookie entry for you; if the named cookie already exists, the browser replaces the old data with the new data. Retrieving the `document.cookie` property at this point yields the following string:

```
userName=Fred
```

You can omit all the other cookie-setting properties, in which case the browser uses default values, as explained in a following section. For temporary cookies (those that don't have to persist beyond the current browser session), the name/value pair is usually all you need.

The entire name/value pair must be a single string with no semicolons, commas, or character spaces. To take care of spaces between words, preprocess the value with the JavaScript `encodeURIComponent()` function, which URI-encodes the spaces as `%20` — and then be sure to convert the value to restore the human-readable spaces (through `decodeURIComponent()`) when you retrieve the cookie later.

You cannot save a JavaScript array or object to a cookie. But with the help of the `Array.join()` method, you can convert an array to a string; use `String.split()` to re-create the array after reading the cookie at a later time.

Expires

Expiration dates, when supplied, must be passed as Greenwich Mean Time (GMT) strings (see Chapter 17, "The Date Object," about time data). To calculate an expiration date based on today's date, use the JavaScript `Date` object as follows:

```
var exp = new Date();
var oneYearFromNow = exp.getTime() + (365 * 24 * 60 * 60 * 1000);
exp.setTime(oneYearFromNow);
```

Since the `getTime()` and `setTime()` methods operate in milliseconds, the year you're adding to the current date must be converted to milliseconds. After making the calculation, the date is converted to the accepted GMT string format:

```
document.cookie = "userName=Fred; expires=" + exp.toGMTString();
```

In the cookie file, the expiration date and time is stored as a numeric value (in seconds), but to set it, you need to supply the time in GMT format. You can delete a cookie before it expires by setting the

named cookie's expiration date to a time and date earlier than the current time and date. The safest expiration parameter is

```
expires=Thu, 01-Jan-70 00:00:01 GMT;
```

Omitting the expiration date signals to the browser that this cookie is temporary. The browser never writes it to the cookie file and forgets it when you quit the browser.

Path

For client-side cookies, the default path setting (the current directory) is usually the best choice. You can, of course, create a duplicate copy of a cookie with a separate path (and domain) so that the same data is available to a document located in another area of your site (or the Web).

Domain

To help synchronize cookie data with a particular document (or group of documents), the browser matches the domain of the current document with the domain values of cookie entries in the cookie file. Therefore, if you were to display a list of all cookie data contained in a `document.cookie` property, you would get back all the name-value cookie pairs from the cookie file whose domain parameter matches that of the current document.

Unless you expect the document to be replicated in another server within your domain, you can usually omit the `domain` parameter when saving a cookie. Default behavior automatically supplies the domain of the current document to the cookie file entry. Be aware that a domain setting must have at least two periods, such as

```
.google.com
.hotwired.com
```

Or, you can write an entire URL to the domain, including the `http://` protocol.

SECURE

If you omit the `SECURE` parameter when saving a cookie, you imply that the cookie data is accessible to any document or server-side program from your site that meets the other domain- and path-matching properties. For client-side scripting of cookies, you should omit this parameter when saving a cookie.

Retrieving cookie data

Cookie data retrieved through JavaScript arrives as one string, which contains the whole name-data pair. Even though the cookie file stores other parameters for each cookie, you can retrieve only the name-data pairs through JavaScript. Moreover, when two or more (up to a maximum of 20) cookies meet the current domain criteria, these cookies are also lumped into that string, delimited by a semicolon and space. For example, a `document.cookie` string may look like this:

```
userName=Fred; password=NikL2sPacU
```

In other words, you cannot treat named cookies as objects. Instead, you must parse the entire cookie string, extracting the data from the desired name-data pair.

When you know that you're dealing with only one cookie (and that no more will ever be added to the domain), you can customize the extraction based on known data, such as the cookie name. For example, with a cookie name that is seven characters long, you can extract the data with a statement such as this:

```
var data = decodeURIComponent(document.cookie.substring
     (7,document.cookie.length));
```

The first parameter of the `substring()` method includes the equal sign to separate the name from the data; this is where the 7 comes from in the code. This example works with single cookies only because it assumes that the cookie starts at the beginning of the cookie file, which may not be the case if the file contains multiple cookies.

A better approach to cookie extraction is to create a general-purpose function that can work with single- or multiple-entry cookies. For example:

```
function getCookieData(labelName) {
   var labelLen = labelName.length;
   // read cookie property only once for speed
   var cookieData = document.cookie;
   var cLen = cookieData.length;
   var i = 0;
   var cEnd;
   while (i < cLen) {
      var j = i + labelLen;
      if (cookieData.substring(i,j) == labelName) {
         cEnd = cookieData.indexOf(";",j);
         if (cEnd == -1) {
            cEnd = cookieData.length;
         }
         return decodeURIComponent(cookieData.substring(j+1, cEnd));
      }
      i++;
   }
   return "";
}
```

Calls to this function pass the label name of the desired cookie as a parameter. The function parses the entire cookie string, chipping away any mismatched entries (through the semicolons) until it finds the cookie name.

If all of this cookie code still makes your head hurt, you can turn to a set of functions devised by experienced JavaScripter and web site designer Bill Dortch of hIdaho Design. His cookie functions provide generic access to cookies that you can use in all of your cookie-related pages. Listing 29-3 shows Bill's cookie functions, which include a variety of safety nets for date calculation bugs that appeared in some legacy versions of Netscape Navigator. The code is updated with modern URL encoding and decoding methods. Don't be put off by the length of the listing: Most of the lines are comments.

LISTING 29-3

Bill Dortch's Cookie Functions

      <script type="text/javascript">
      //
      //  Cookie Functions -- "Night of the Living Cookie" Version (25-Jul-96)
      //
      //  Written by:  Bill Dortch, hIdaho Design
      //  The following functions are released to the public domain.
      //
      //  This version takes a more aggressive approach to deleting
      //  cookies.  Previous versions set the expiration date to one
      //  millisecond prior to the current time; however, this method
      //  did not work in Netscape 2.02 (though it does in earlier and
      //  later versions), resulting in "zombie" cookies that would not
      //  die.  DeleteCookie now sets the expiration date to the earliest
      //  usable date (one second into 1970), and sets the cookie's value
      //  to null for good measure.
      //
      //  Also, this version adds optional path and domain parameters to
      //  the DeleteCookie function.  If you specify a path and/or domain
      //  when creating (setting) a cookie**, you must specify the same
      //  path/domain when deleting it, or deletion will not occur.
      //
      //  The FixCookieDate function must now be called explicitly to
      //  correct for the 2.x Mac date bug.  This function should be
      //  called *once* after a Date object is created and before it
      //  is passed (as an expiration date) to SetCookie.  Because the
      //  Mac date bug affects all dates, not just those passed to
      //  SetCookie, you might want to make it a habit to call
      //  FixCookieDate any time you create a new Date object:
      //
      //    var theDate = new Date();
      //    FixCookieDate (theDate);
      //
      //  Calling FixCookieDate has no effect on platforms other than
      //  the Mac, so there is no need to determine the user's platform
      //  prior to calling it.
      //
      //  This version also incorporates several minor coding improvements.
      //
      //  **Note that it is possible to set multiple cookies with the same
      //  name but different (nested) paths.  For example:
      //
      //    SetCookie ("color","red",null,"/outer");
      //    SetCookie ("color","blue",null,"/outer/inner");
```

```
//
//  However, GetCookie cannot distinguish between these and will return
//  the first cookie that matches a given name.  It is therefore
//  recommended that you *not* use the same name for cookies with
//  different paths.  (Bear in mind that there is *always* a path
//  associated with a cookie; if you don't explicitly specify one,
//  the path of the setting document is used.)
//
//  Revision History:
//
//    "JavaScript Bible 6th Edition" Version (28-July-2006)
//      - Replaced deprecated escape()/unescape() functions with
//        encodeURI() and decodeURI() functions
//
//    "Toss Your Cookies" Version (22-Mar-96)
//      - Added FixCookieDate() function to correct for Mac date bug
//
//    "Second Helping" Version (21-Jan-96)
//      - Added path, domain and secure parameters to SetCookie
//      - Replaced home-rolled encode/decode functions with
//        new (then) escape/unescape functions
//
//    "Free Cookies" Version (December 95)
//
//
//  For information on the significance of cookie parameters,
//  and on cookies in general, please refer to the official cookie
//  spec, at:
//
//      http://www.netscape.com/newsref/std/cookie_spec.html
//
//********************************************************************
//
// "Internal" function to return the decoded value of a cookie
//
function getCookieVal (offset)
{
  var endstr = document.cookie.indexOf (";", offset);
    if (endstr == -1)
    {
      endstr = document.cookie.length;
    }
  return decodeURI(document.cookie.substring(offset, endstr));
}

//
//  Function to correct for 2.x Mac date bug.  Call this function to
//  fix a date object prior to passing it to SetCookie.
//  IMPORTANT:  This function should only be called *once* for
//  any given date object!  See example at the end of this document.
//
```

continued

LISTING 29-3 *(continued)*

```
function FixCookieDate (date)
{
  var base = new Date(0);
  var skew = base.getTime(); // dawn of (Unix) time - should be 0
    if (skew > 0)
    {  // Except on the Mac - ahead of its time
       date.setTime (date.getTime() - skew);
    }
}

//
//  Function to return the value of the cookie specified by "name".
//    name - String object containing the cookie name.
//    returns - String object containing the cookie value, or null if
//      the cookie does not exist.
//
function GetCookie (name)
{
   var arg = name + "=";
   var alen = arg.length;
   var clen = document.cookie.length;
   var i = 0;
   while (i < clen)
   {
     var j = i + alen;
       if (document.cookie.substring(i, j) == arg)
       {
          return getCookieVal (j);
       }
     i = document.cookie.indexOf(" ", i) + 1;
       if (i == 0)
       {
          break;
       }
   }
   return null;
}

//
//  Function to create or update a cookie.
//    name - String object containing the cookie name.
//    value - String object containing the cookie value.  May contain
//      any valid string characters.
//    [expires] - Date object containing the expiration data of the
//      cookie.  If omitted or null, expires the cookie at the end of the
//      current session.
//    [path] - String object indicating the path for which the cookie is
//      valid.
//      If omitted or null, uses the path of the calling document.
```

```
//    [domain] - String object indicating the domain for which the cookie
//      is valid. If omitted or null, uses the domain of the calling
//      document.
//    [secure] - Boolean (true/false) value indicating whether cookie
//      transmission requires a secure channel (HTTPS).
//
//  The first two parameters are required.  The others, if supplied, must
//  be passed in the order listed above.  To omit an unused optional
//  field, use null as a place holder.  For example, to call SetCookie
//  using name, value and path, you would code:
//
//      SetCookie ("myCookieName", "myCookieValue", null, "/");
//
//  Note that trailing omitted parameters do not require a placeholder.
//
//  To set a secure cookie for path "/myPath", that expires after the
//  current session, you might code:
//
//      SetCookie (myCookieVar, cookieValueVar, null, "/myPath", null,
//         true);
//
function SetCookie (name,value,expires,path,domain,secure)
{
   document.cookie = name + "=" + encodeURIComponent (value) +
      ((expires) ? "; expires=" + expires.toGMTString() : "") +
      ((path) ? "; path=" + path : "") +
      ((domain) ? "; domain=" + domain : "") +
      ((secure) ? "; secure" : "");
}

//  Function to delete a cookie. (Sets expiration date to start of epoch)
//    name -   String object containing the cookie name
//    path -   String object containing the path of the cookie to delete.
//             This MUST be the same as the path used to create the
//             cookie, or null/omitted if
//             no path was specified when creating the cookie.
//    domain - String object containing the domain of the cookie to
//             delete.  This MUST be the same as the domain used to
//             create the cookie, or null/omitted if no domain was
//             specified when creating the cookie.
//
function DeleteCookie (name,path,domain)
{
   if (GetCookie(name))
   {
      document.cookie = name + "=" +
         ((path) ? "; path=" + path : "") +
         ((domain) ? "; domain=" + domain : "") +
         "; expires=Thu, 01-Jan-70 00:00:01 GMT";
   }
}
```

continued

LISTING 29-3 *(continued)*

```
      //
      //  Examples
      //
      var expdate = new Date ();
      FixCookieDate (expdate); // Correct for Mac date bug (call only once)
      expdate.setTime (expdate.getTime() + (24 * 60 * 60 * 1000)); // 24 hrs
      SetCookie ("ccpath", "http://www.hidaho.com/colorcenter/", expdate);
      SetCookie ("ccname", "hIdaho Design ColorCenter", expdate);
      SetCookie ("tempvar", "This is a temporary cookie.");
      SetCookie ("ubiquitous", "This cookie will work anywhere in this ↩
         domain",null,"/");
      SetCookie ("paranoid", "This cookie requires secure ↩
         communications",expdate,"/",null,true);
      SetCookie ("goner", "This cookie must die!");
      document.write (document.cookie + "<br>");
      DeleteCookie ("goner");
      document.write (document.cookie + "<br>");
      document.write ("ccpath = " + GetCookie("ccpath") + "<br>");
      document.write ("ccname = " + GetCookie("ccname") + "<br>");
      document.write ("tempvar = " + GetCookie("tempvar") + "<br>");
      </script>
   </body>
</html>
```

Extra batches

You may design a site that needs more than 20 cookies for a given domain. For example, in a shopping site, you never know how many items a customer may load into the shopping cart cookie.

Because each named cookie stores plain text, you can create your own text-based data structures to accommodate multiple pieces of information per cookie. (But also watch out for a practical limit of 2,000 characters per name/value pair within the 4,000 character maximum for any domain's combined cookies.) The trick is determining a delimiter character that won't be used by any of the data in the cookie. In Decision Helper (in Chapter 58), for example, we use a period to separate multiple integers stored in a cookie.

With the delimiter character established, you must then write functions that concatenate these "subcookies" into single cookie strings and extract them on the other side. It's a bit more work, but well worth the effort, to have the power of persistent data on the client.

Example

Experiment with the last group of statements in Listing 29-3 to create, retrieve, and delete cookies. You can also experiment with The Evaluator by assigning a name/value pair string to `document.cookie`, and then examining the value of the `cookie` property.

Related Items: `String` object methods (see Chapter 15, "The String Object")

`defaultCharset`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera-, Chrome+

The `defaultCharset` property reveals the character set used by the browser to render the current document. You can find possible values for this property at

```
http://www.iana.org/assignments/character-sets
```

Each browser and operating system has its own default character set. Values may also be set through a `<meta>` tag. The difference between the `defaultCharset` and `charset` properties is not clear, especially because both are read/write (although modifying the `defaultCharset` property has no visual effect on the page). However, if your scripts temporarily modify the `charset` property, you can use the `defaultCharset` property to return to the original character set:

```
document.charset = document.defaultCharset;
```

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `defaultCharset` property. To see the default setting applied to the page, enter the following statement into the top text box:

```
document.defaultCharset
```

Related Items: `charset`, `characterSet` properties

`defaultView`

Value: `window` or `frame` object reference Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `defaultView` property returns a reference to the object serving as the viewer for the document. The viewer is responsible for rendering the document, and in Mozilla the object returned in the `defaultView` property is the `window` or `frame` object that contains the document. This W3C DOM Level 2 property provides access to the computed CSS values being applied to any HTML element (through the `document.defaultView.getComputedStyle()` method).

Related Items: `window` and `frame` properties; `window.getComputedStyle()` method

`designMode`

Value: String Read/Write

Compatibility: WinIE5+, MacIE-, NN7.1, Moz1.4+, Safari+, Opera+, Chrome+

The `designMode` property is applicable for IE only when WinIE5+ technology is being used as a component in another application. The property controls whether the browser module is being used for HTML editing. Modifying the property from within a typical HTML page in the IE5+ browser has no effect. But on the Mozilla side, the property can be used to turn an `iframe` element's `document` object into an HTML editable document. Visit `http://www.mozilla.org/editor` for current details and examples.

doctype

Value: `DocumentType` object reference Read-Only

Compatibility: WinIE+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `doctype` property comes from the W3C Core DOM and returns a `DocumentType` object — a representation of the Document Type Definition (DTD) information for the document. The `DocumentType` object (if one is explicitly defined in the source code) is the first child node of the root document node (and is thus a sibling to the `HTML` element). In IE, this property is only supported in XML documents; HTML documents always return `null`.

Table 29-1 shows the typical `DocumentType` object property list and values for a generic HTML page. Future DOM specifications will allow these properties to be read/write.

Related Items: `Node` object (see Chapter 25, "Document Object Model Essentials")

Example

Take a look at the `document.doctype` object by entering the following line of code in the bottom text field of the Evaluator web page (see Chapter 4):

```
document.doctype
```

TABLE 29-1

DocumentType Object in NN6+/Moz

Property	Value
baseURI	http://www.dannyg.com/index.html
entities	null
internalSubset	null
name	HTML
nodeName	HTML
nodeType	10
notations	null
publicId	-//W3C//DTD XHTML 1.0 Transitional//EN
systemId	http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd

If you pay close attention you'll notice that the `publicId` property is actually set to `-//W3C//DTD HTML 4.01 Transitional//EN`, which is different from the value shown in Table 29-1. This reveals the fact that the Evaluator page declares itself as an HTML 4.01 document.

documentElement

Value: HTML or XML element object reference Read-Only

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `documentElement` property returns a reference to the HTML (or XML) element object that contains all of the content of the current document. The naming of this property is a bit misleading, because the root document node is not an element, but its only child node is the HTML (or XML) element for the page. At best, you can think of this property as providing scripts with an *element face* to the `document` object and document node associated with the page currently loaded in the browser.

The `document.documentElement` object represents the `html` element for a page, whereas `docoument.body` represents the `body` element. This explains why `document.body` is a child of the `document.documentElement` object.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to examine the behavior of the `documentElement` property. In IE5+/W3C, enter the following statement into the top text field:

```
document.documentElement.tagName
```

The result is `HTML`, as expected.

Related Item: `ownerDocument` property (see Chapter 26, "Generic HTML Element Objects")

documentURI

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN8+, Moz1.7+, Safari+, Opera+, Chrome+

The `documentURI` property contains the location of the document. This is the W3C DOM Level 3 equivalent of the non-W3C DOM `location.href` property. Use The Evaluator (Chapter 4) to view the document URI by entering the following:

```
document.documentURI
```

Related Item: `document.baseURI` property

domain

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Security restrictions can get in the way of sites that have more than one server at their domain. Because some objects, especially the `location` object, prevent access to properties of other servers displayed in other frames, legitimate access to those properties is blocked. For example, it's not uncommon for popular sites to have their usual public access site on a server named something such as `www.popular.com`. If a page on that server includes a front end to a site search engine located at `search.popular.com`, visitors who use browsers with these domain restrictions security restrictions are denied access.

To guard against that eventuality, a script in documents from two servers can instruct the browser to think both servers are the same. In the preceding example, you would set the `document.domain` property in both documents to `popular.com`. Without specifically setting the property, the default value includes the server name as well, thus causing a mismatch between hostnames.

Before you start thinking that you can spoof your way into other servers, be aware that you can set the `document.domain` property only to servers with the same domain (following the two-dot rule) as the document doing the setting. Therefore, documents originating only from *xxx*`.popular.com` can set their `document.domain` properties to `popular.com` server.

Related Items: `window.open()` method; `window.location` object; security (see Chapter 49, "Security and Netscape Signed Scripts" on the CD-ROM)

embeds[]

Value: Array of `embed` element objects Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Although now supplanted by the `<object>` tag, the `<embed>` tag used to be the markup that loaded data requiring a plug-in application to play or display. The `document.embeds` property is an array of `embed` element objects within the document:

```
var count = document.embeds.length;
```

Related Item: `embed` element object (see Chapter 44, "Embedded Objects")

expando

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

Microsoft calls any custom property that is not a native property of the `document` object an *expando* property. By default, most objects in recent generations of browsers allow scripts to add new properties of objects as a way to temporarily store data without explicitly defining global variables. For example, if you want to maintain an independent counter of how often a function is invoked, you can create a custom property of the `document` object and use it as the storage facility:

```
document.counter = 0;
```

IE4+ enables you to control whether the `document` object is capable of accepting `expando` properties. The default value of the `document.expando` property is `true`, thus allowing custom properties. But the potential downside to this permissiveness, especially during the page construction phase, is that a misspelled native property name is gladly accepted by the `document` object. You may not be aware of why the title bar of the browser window doesn't change when you assign a new string to the `document.Title` property (which, in the case-sensitive world of JavaScript, is distinct from the native `document.title` property).

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `document.expando` property in IE4+. Begin by proving that the `document` object can normally accept custom properties. Type the following statement into the top text field:

```
document.spooky = "Boo!"
```

This property is now set and stays that way until the page is either reloaded or unloaded.

Now freeze the `document` object's properties with the following statement:

```
document.expando = false
```

If you try to add a new property, such as the following, you receive an error:

```
document.happy = "tra la"
```

Interestingly, even though `document.expando` is turned off, the first custom property is still accessible and modifiable.

Related Item: `prototype` property of custom objects (see Chapter 23, "Function Objects and Custom Objects")

fgColor

(See `alinkColor`)

fileCreatedDate
fileModifiedDate
fileSize

Value: String, Integer (fileSize) Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

These three IE-specific properties return information about the file that holds the current document. The first two properties (not implemented in MacIE) reveal the dates on which the current document's file was created and modified. For an unmodified file, its creation and modified dates are the same. The `fileSize` property reveals the number of bytes of the file.

Date values returned for the first two properties are in a format similar to mm/dd/yyyy. Note, however, that the values contain only the date and not the time. In any case, you can use the values as the parameter to a `new Date()` constructor function. You can then use date calculations for such information as the number of days between the current day and the most recent modification.

Not all servers may provide the proper date or size information about a file, or in a format that IE can interpret. Test your implementation on the deployment server to ensure compatibility.

Also, be aware that these properties can be read-only for a file that is loaded in the browser. JavaScript by itself cannot get this information about files that are on the server, but not loaded into the browser.

Example

Listing 29-4 dynamically generates several pieces of content relating to the creation and modification dates of the file, as well as its size. More importantly, the listing demonstrates how to turn a value returned by the file date properties into a genuine date object that can be used for date calculations. In the case of Listing 29-4, the calculation is the number of full days between the creation date and the day someone views the file. Notice that the dynamically generated content is added very simply through the `innerText` properties of carefully located `span` elements in the body content.

LISTING 29-4

Displaying File Information for a Web Page

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">

Related Item: `lastModified` property

forms[]

Value: Array Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

As we show in Chapter 34, "Form and Related Objects," which is dedicated to the `form` object, an HTML form (anything defined inside a `<form>...</form>` tag pair) is a JavaScript object unto itself. You can create a valid reference to a form according to its name (assigned through a form's `name` attribute). For example, if a document contains the following form definition:

```
<form name="phoneData">
   input item definitions
</form>
```

then your scripts can refer to the form object by name:

```
document.phoneData
```

However, a `document` object also tracks its forms in another way: as an array of `form` objects. The first item of a `document.forms` array is the form that loaded first (it was foremost from the top of the HTML code). If your document defines one form, the `forms` property is an array one entry in length; with three separate forms in the document, the array is three entries long.

Use standard array notation to reference a particular form from the `document.forms` array. For example, the first form in a document (the zeroth entry of the `document.forms` array) is referenced as

```
document.forms[0]
```

Any of the form object's properties or methods are available by appending the desired property or method name to the reference. For example, to retrieve the value of an input text field named `homePhone` from the second form of a document, the reference you use is

```
document.forms[1].homePhone.value
```

One advantage to using the `document.forms` property for addressing a form object or element instead of the actual form name is that you may be able to generate a library of generalizable scripts that know how to cycle through all available forms in a document and then hunt for a form that has some special element and property. The following script fragment (part of a *repeat loop* described more

fully in Chapter 21, "Control Structures and Exception Handling") uses a loop-counting variable (i) to help the script check all forms in a document:

```
for (var i = 0; i < document.forms.length; i++) {
   if (document.forms[i]. ... ) {
      statements
   }
}
```

One more variation on forms array references enables you to substitute the name of a form (as a string) for the `forms` array index. For example, the form named `phoneData` can be referenced as:

```
document.forms["phoneData"]
```

If you take a lot of care in assigning names to objects, you will likely prefer the `document.formName` style of referencing forms. In this book, you see both indexed array and form name style references. The advantage of using name references is that even if you redesign the page and change the order of forms in the document, references to the named forms will still be valid, whereas the index numbers of the forms will have changed. Also see the discussion in Chapter 34, "Form and Related Objects," of the `form` object and how to pass a form's data to a function.

Example

The document in Listing 29-5 is set up to display an alert dialog box that simulates navigation to a particular music site, based on the selected status of the blues check box. The user input here is divided into two forms: one form with the check box and the other form with the button that does the navigation. A block of copy fills the space in between. Clicking the bottom button (in the second form) triggers the function that fetches the checked property of the blues check box by using the `document.forms[i]` array as part of the address.

LISTING 29-5

A Simple Form Example

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>document.forms example</title>
      <script type="text/javascript">
         function goMusic()
         {
            if (document.forms[0].bluish.checked)
            {
               alert("Now going to the Blues music area...");
            }
            else
            {
               alert("Now going to the Rock music area...");
            }
         }
```

```
        // bind the event handlers
        function addEvent(elem, evtType, func)
        {
           if (elem.addEventListener)
           {
              elem.addEventListener(evtType, func, false);
           }
           else if (elem.attachEvent)
           {
              elem.attachEvent("on" + evtType, func);
           }
           else
           {
              elem["on" + evtType] = func;
           }
        }
        addEvent(window, "load", function()
        {
           addEvent(document.getElementById("visit"), "click", goMusic);
        });
      </script>
   </head>
   <body>
      <form name="theBlues">
         <input type="checkbox" name="bluish" />Check here if you've got the
         blues.
      </form>
      <hr />
      M<br />
      o<br />
      r<br />
      e<br />
      <br />
      C<br />
      o<br />
      p<br />
      y<br />
      <hr />
      <form name="visit">
         <input type="button" id="visit" value="Visit music site" />
      </form>
   </body>
</html>
```

Related Item: `form` object (see Chapter 34, “Form and Related Objects”)

frames[]

Value: Array Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera+, Chrome-

The `document.frames` property is similar to the `window.frames` property, but its association with the `document` object may seem a bit illogical at times. The objects contained by the array returned from the property are window objects, which means they are the window objects of any defined `frame` elements (from a framesetting document) or `iframe` elements (from a plain HTML document). Distinguishing the window objects from the `iframe` element objects is important. Window objects have different properties and methods from the `frame` and `iframe` element objects. The latter's properties typically represent the attributes for those element's tags. If a document contains no `iframe` elements, the `document.frames` array length is zero.

Although you can access an individual frame object through the typical array syntax (for example, `document.frames[0]`), you can also use alternate syntax that Microsoft provides for collections of objects. The index number can also be placed inside parentheses, as in:

```
document.frames(0)
```

Moreover, if the frames have values assigned to their `name` attributes, you can use the name (in string form) as a parameter:

```
document.frames("contents")
```

And if the collection of frames has more than one frame with the same name, you must take special care. Using the duplicated name as a parameter forces the reference to return a collection of frame objects that share that name. Or, you can limit the returned value to a single instance of the duplicate-named frames by specifying an optional second parameter indicating the index. For example, if a document has two `iframe` elements with the name `contents`, a script could reference the second `window` object as:

```
document.frames("contents", 1)
```

For the sake of cross-browser compatibility, my preference for referencing frame window objects is through the `window.frames` property.

Example

See Listings 27-7 and 27-8 for examples of using the `frames` property with window objects.

Related Item: `window.frames` property

height
width

Value: Integer — Read-Only

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari+, Opera-, Chrome+

The `height` and `width` properties provide the pixel dimensions of the content within the current window (or frame). If the document's content is smaller than the size of the browser's content region, the dimensions returned by these properties include the blank space to the right or bottom edges of the content area of the window. But if the content extends beyond the viewable edges of the content region, the dimensions include the unseen content as well. The corresponding measures in Internet Explorer are the `document.body.scrollHeight` and `document.body.scrollWidth` properties. These IE properties are also supported by most modern browsers.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to examine the `height` and `width` properties of that document. Enter the following statement into the top text box and click the Evaluate button:

```
"height=" + document.height + "; width=" + document.width
```

Resize the window so that you see both vertical and horizontal scroll bars in the browser window and click the Evaluate button again. If either or both numbers get smaller, the values in the Results box are the exact size of the space occupied by the document. But if you expand the window to well beyond where the scroll bars are needed, the values extend to the number of pixels in each dimension of the window's content region.

Related Items: `document.body.scrollHeight`, `document.body.scrollWidth` properties

images[]

Value: Array Read-Only

Compatibility: WinIE4+, MacIE3+, NN3+, Moz+, Safari+, Opera+, Chrome+

With images treated as first-class objects, beginning with NN3 and IE4, it's only natural for a document to maintain an array of all the image tags defined on the page (just as it does for links and anchors). The primary importance of having images as objects is that you can modify their content (the source file associated with the rectangular space of the image) on-the-fly. You can find details about the `image` object in Chapter 31, "Image, Area, Map, and Canvas Objects."

Use image array references to pinpoint a specific image for the retrieval of any image property, or for assigning a new image file to its `src` property. Image arrays begin their index counts with `0`: The first image in a document has the reference `document.images[0]`. And, as with any array object, you can find out how many images the array contains by checking the `length` property. For example:

```
var imageCount = document.images.length;
```

Images can also have names, so if you prefer, you can refer to the image object by its name, as in

```
var imageLoaded = document.imageName.complete;
```

or

```
var imageLoaded = document.images[imageName].complete;
```

The `document.images` array is a useful guide to knowing whether a browser supports swappable images. Any browser that treats an `img` element as an object always forms a `document.images` array in the page. If no images are defined in the page, the array is still there, but its length is zero. The array's existence, however, is the clue about image object compatibility. Because the `document.images` array evaluates to an array object when present, the expression can be used as a conditional expression for branching to statements that involve image swapping:

```
if (document.images) {
   // image swapping or precaching here
}
```

Browsers that don't have this property (legacy and, potentially, mobile) evaluate `document.images` as `undefined`, and thus the condition is treated as a `false` value.

Example

The `document.images` property is defined automatically as the browser builds the object model for a document that contains image objects. See the discussion about the `Image` object in Chapter 31, for reference examples.

Related Item: `Image` object (see Chapter 31, "Image, Area, Map, and Canvas Objects")

`implementation`

Value: Object Read-Only

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The Core W3C DOM defines the `document.implementation` property as an avenue to let scripts find out what DOM features (that is, modules of the DOM standard) are implemented for the current environment. Although the object returned by the property (a `DOMImplementation` object) has no properties, it has a method, `hasFeature()`, which lets scripts find out, for example, whether the environment supports HTML or just XML. The first parameter of the `hasFeature()` method is the feature in the form of a string. The second parameter is a string form of the version number. The method returns a Boolean value.

The "Conformance" section of the W3C DOM specification governs the module names. (The standard also allows browser-specific features to be tested through the `hasFeature()` method.) Module names include strings such as `HTML`, `XML`, `MouseEvents`, and so on.

Version numbering for W3C DOM modules corresponds to the W3C DOM level. Thus, the version for the XML DOM module in DOM Level 2 is known as `2.0`. Note that versions refer to DOM modules and not, for example, the separate HTML standard.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `document.implementation.hasFeature()` method. Enter the following statements one at a time into the top text field and examine the results:

```
document.implementation.hasFeature("HTML","1.0")
document.implementation.hasFeature("HTML","2.0")
document.implementation.hasFeature("HTML","3.0")
document.implementation.hasFeature("CSS","2.0")
document.implementation.hasFeature("CSS2","2.0")
```

Feel free to try other values. For some reason, as of version 7, Internet Explorer returns false for some features that it indeed supports, such as CSS 2.0. In other words, it's probably not a good idea to place a lot of trust in the IE results of the `hasFeature()` method, at least for the time being.

`inputEncoding`

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari+, Opera-, Chrome+

The input encoding of a document is the character encoding that is in effect at the time when the document is parsed. For example, ISO-8859-1 is a common character encoding that you may see reported by the `inputEncoding` property.

lastModified

Value: Date string Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Every disk file maintains a modified time stamp, and most (but not all) servers are configured to expose this information to a browser accessing a file. This information is available by reading the `document.lastModified` property. If your server supplies this information to the client, you can use the value of this property to present this information for readers of your web page. The script automatically updates the value for you, rather than requiring you to hand-code the HTML line every time you modify the home page. Be aware that if you are testing with Safari or Google Chrome, your code will not work unless the files are coming from an HTTP server.

If the value returned to you displays itself as a date in 1969, it means that you are positioned somewhere west of GMT, or Greenwich Mean Time (some number of time zones west of GMT at 1 January 1970), and the server is not providing the proper data when it serves the file. Sometimes server configuration can fix the problem, but not always.

The returned value is not a date object, but rather a straight string consisting of the time and date, as recorded by the document's file system. The format of the string varies from browser to browser and version to version. You can, however, usually convert the date string to a JavaScript date object and use the date object's methods to extract selected elements for recompilation into readable form. Listing 29-6 shows an example.

Even local file systems don't necessarily provide the correct data for every browser to interpret. But put that same file on a UNIX or Windows web server, and the date appears correctly when accessed through the Net.

Example

Experiment with the `document.lastModified` property with Listing 29-6. But also be prepared for inaccurate readings depending on the location of the file.

LISTING 29-6

Putting a Time Stamp on a Page

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Time Stamper</title>
   </head>
   <body>
      <center>
         <h1>GiantCo Home Page</h1>
      </center>
      <script type="text/javascript">
         update = new Date(document.lastModified);
         theMonth = update.getMonth() + 1;
         theDate = update.getDate();
```

continued

LISTING 29-6 *(continued)*

```
         theYear = update.getFullYear();
         document.writeln("<I>Last updated:" +
                          theMonth + "/" + theDate +
                          "/" + theYear + "<\/I>");
      </script>
      <hr />
   </body>
</html>
```

As noted at great length in the `Date` object discussion in Chapter 17, you should be aware that date formats vary greatly from country to country. Some of these formats use a different order for date elements. When you hard-code a date format, it may take a form that is unfamiliar to other users of your page.

Related Item: `Date` object (see Chapter 17, "The Date Object")

layers[]

Value: Array Read-Only

Compatibility: WinIE-, MacIE-, NN4, Moz-, Safari-, Opera-, Chrome-

The `layer` object is the NN4 way of exposing positioned elements to the object model. Thus, the `document.layers` property is an array of positioned elements in the document. The `layer` object and `document.layers` property are orphaned in NN4, and their importance is all but gone now that Mozilla has taken over. Chapter 43 includes several examples of how to carry out similar functionality as the `document.layers` property using the standard W3C DOM.

Related Item: `layer` object (see Chapter 43, "Positioned Objects")

linkColor

(See `alinkColor`)

links[]

Value: Array Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `document.links` property is similar to the `document.anchors` property, except that the objects maintained by the array are link objects — items created with `<a href="">` tags. Use the array references to pinpoint a specific link for retrieving any link property, such as the target window specified in the link's HTML definition.

Link arrays begin their index counts with `0`: The first link in a document has the reference `document.links[0]`. And, as with any array object, you can find out how many entries the array has by checking the `length` property. For example:

```
var linkCount = document.links.length;
```

Entries in the `document.links` property are full-fledged `location` objects, which means you have the same properties available to each member of the `links[]` array as you do in the `location` object.

Example

The `document.links` property is defined automatically as the browser builds the object model for a document that contains link objects. You rarely access this property, except to determine the number of link objects in the document.

Related Items: `link` object; `document.anchors` property

location
URL

Value: String — Read/Write and Read-Only (see text)

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The `document.URL` property is similar to the `window.location` property. A `location` object, you may recall from Chapter 28, "Location and History Objects," consists of a number of properties regarding the document currently loaded in a window or frame. Assigning a new URL to the `location` object (or `location.href` property) tells the browser to load the page from that URL into the frame. The `document.URL` property, on the other hand, is simply a string (read-only in Navigator, Mozilla, and Safari) that reveals the URL of the current document. The value may be important to your script, but the property does not have the object power of the `window.location` object. You cannot change (assign another value to) this property value because a document has only one URL: its location on the Net (or your hard disk) where the file exists, and what protocol is required to get it.

This may seem like a fine distinction, and it is. The reference you use (`window.location` object or `document.URL` property) depends on what you are trying to accomplish specifically with the script. If the script is changing the content of a window by loading a new URL, you have no choice but to assign a value to the `window.location` object. Similarly, if the script is concerned with the component parts of a URL, the properties of the `location` object provide the simplest avenue to that information. To retrieve the URL of a document in string form (whether it is in the current window or in another frame), you can use either the `document.URL` property or the `window.location.href` property.

Note

The `document.URL` property replaces the old `document.location` property, which is still supported in most browsers. ■

Example

HTML documents in Listings 29-7 through 29-9 create a test lab that enables you to experiment with viewing the `document.URL` property for different windows and frames in a multiframe environment. Results are displayed in a table, with an additional listing of the `document.title` property to help you identify documents being referred to. The same security restrictions that apply to retrieving `window.location` object properties also apply to retrieving the `document.URL` property from another window or frame.

LISTING 29-7

A Simple Frameset for the URL Example

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>document.URL Reader</title>
   </head>
   <frameset rows="60%,40%">
      <frame name="Frame1" src="jsb29-09.html" />
      <frame name="Frame2" src="jsb29-08.html" />
   </frameset>
</html>
```

LISTING 29-8

Showing Location Information for Different Contexts

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>URL Property Reader</title>
      <script type="text/javascript">
         function fillTopFrame()
         {
            newURL=prompt("Enter the URL of a document to show in the top frame:","");
            if (newURL != null && newURL != "")
            {
               top.frames[0].location = newURL;
            }
         }

         function showLoc(item)
         {
            var windName = item.value;
            var theRef = windName + ".document";
            item.form.dLoc.value = decodeURIComponent(eval(theRef + ".URL"));
            item.form.dTitle.value = decodeURIComponent(eval(theRef + ".title"));
         }

         // bind the event handlers
         function addEvent(elem, evtType, func)
         {
            if (elem.addEventListener)
            {
```

```
               elem.addEventListener(evtType, func, false);
            }
            else if (elem.attachEvent)
            {
               elem.attachEvent("on" + evtType, func);
            }
            else
            {
               elem["on" + evtType] = func;
            }
         }
         addEvent(window, "load", function()
         {
            addEvent(document.getElementById("opener"), "click", fillTopFrame);
            addEvent(document.getElementById("parent"), "click",
               function(evt) {showLoc(document.getElementById("parent"));});
            addEvent(document.getElementById("upper"), "click",
               function(evt) {showLoc(document.getElementById("upper"));});
            addEvent(document.getElementById("this"), "click",
               function(evt) {showLoc(document.getElementById("this"));});
         });
      </script>
   </head>
   <body>
      Click the "Open URL" button to enter the location of an HTML document to
      display in the upper frame of this window.

               value="top.frames[0]" />
            Upper frame
            <input type="radio" name="whichFrame" id="this" value="top.frames[1]" />
            This frame
         </p>
         <table border="2">
            <tr>
               <td align="right">document.URL:</td>
               <td><textarea name="dLoc" rows="3" cols="30" wrap="soft">
                   </textarea>
               </td>
            </tr>
            <tr>
               <td align="right">document.title:</td>
               <td><textarea name="dTitle" rows="3" cols="30" wrap="soft">
                   </textarea>
```

continued

LISTING 29-8 *(continued)*

```
          </td>
        </tr>
      </table>
    </form>
  </body>
</html>
```

LISTING 29-9

A Placeholder Page for the URL Example

```
<!DOCTYPE html>
<html>
  <head>
    <meta http-equiv="content-type" content="text/html;charset=utf-8">
    <title>Opening Placeholder</title>
  </head>
  <body>
    Initial place holder. Experiment with other URLs for this frame (see
    below).
  </body>
</html>
```

Related Items: `location` object; `location.href`, `URLUnencoded` properties

media

Value: String — Read/Write

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `document.media` property indicates the output medium for which content is formatted. The property actually returns an empty string as of IE7, but the intention appears to be to provide a way to use scripting to set the equivalent of the CSS2 `@media` rule (one of the so-called *at* rules because of the at symbol). This style sheet rule allows browsers to assign separate styles for each type of output device on which the page is rendered (for example, perhaps a different font for a printer versus the screen). In practice, however, this property is not modifiable, at least through IE8.

Related Items: None

mimeType

Value: String — Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Although this property is readable in WinIE5+, its value is not, strictly speaking, a MIME type, at least not in traditional MIME format. Moreover, the results are inconsistent between IE versions 5, 6,

7, and 8. Perhaps this property will be of more use in an XML, rather than an HTML, document environment. In any case, this property in no way exposes supported MIME types in the current browser.

namePropPlaceholder

Value: String Read-Only

Compatibility: WinIE6+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `nameProp` property returns a string containing the title of the document, which is the same as `document.title`. If the document doesn't have a title, `nameProp` contains an empty string.

Related Item: `title` property

namespaces[]

Value: Array of `namespace` objects Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

A `namespace` object can dynamically import an XML-based IE Element Behavior. The `namespaces` property returns an array of all `namespace` objects defined in the current document.

Related Items: None

parentWindow

Value: `window` object reference Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera+, Chrome-

The `document.parentWindow` property returns a reference to the `window` object containing the current document. The value is the same as any reference to the current window.

Example

To prove that the `parentWindow` property points to the document's window, you can enter the following statement into the top text field of The Evaluator (see Chapter 4, "JavaScript Essentials"):

```
document.parentWindow == self
```

This expression evaluates to `true` only if both references are of the same object.

Related Item: `window` object

plugins[]

Value: Array Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `document.plugins` property returns the same array of `embed` element objects that you get from the `document.embeds` property. This property has been deprecated in favor of `document.embeds`.

Related Item: `document.embeds` property

protocol

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The IE-specific `document.protocol` property returns the plain-language version of the protocol that was used to access the current document. For example, if the file is accessed from a web server, the property returns `Hypertext Transfer Protocol`. This property differs from the `location.protocol` property, which returns the portion of the URL that includes the often more cryptic protocol abbreviation (for example, `http:`). As a general rule, you want to hide all of this stuff from a web application user.

Example

If you use The Evaluator (Chapter 4, "JavaScript Essentials") to test the `document.protocol` property, you will find that it displays `File Protocol` in the results because you are accessing the listing from a local hard disk or CD-ROM. However, if you upload the Evaluator web page to a web server and access it from there, you will see the expected `Hypertext Transfer Protocol` result.

Related Item: `location.protocol` property

referrer

Value: String Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

When a link from one document leads to another, the second document can, under JavaScript control, reveal the URL of the document containing the link. The `document.referrer` property contains a string of that URL. This feature can be a useful tool for customizing the content of pages based on the previous location the user was visiting within your site. A referrer contains a value only when the user reaches the current page through a link. Any other method of navigation (such as through the history, bookmarks, or by manually entering a URL) sets this property to an empty string.

Caution

The `document.referrer` property usually returns an empty string unless the files are retrieved from a web server. ■

Example

This demonstration requires two documents (and you'll need to access the documents from a web server). The first document, in Listing 29-10, simply contains one line of text as a link to the second document. In the second document, shown in Listing 29-11, a script verifies the document from which the user came through a link. If the script knows about that link, it displays a message relevant to the experience the user had at the first document. Also try opening Listing 29-11 in a new browser window from the Open File command in the File menu to see how the script won't recognize the referrer.

LISTING 29-10

An Example Referrer Page

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>document.referrer Property 1</title>
   </head>
   <body>
      <h1><a href="jsb29-11.html">Visit my sister document</a></h1>
   </body>
</html>
```

LISTING 29-11

Determining the Referrer when a Page Is Visited Through a Link

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>document.referrer Property 2</title>
   </head>
   <body>
      <h1>
         <script type="text/javascript">
            alert(document.referrer.length + "    :    " + document.referrer);
               if (document.referrer.length > 0 &&
                   document.referrer.indexOf("jsb29-10.html") != -1)
               {
                  document.write("How is my brother document?");
               }
               else
               {
                  document.write("Hello, and thank you for stopping by.");
            }
         </script>
      </h1>
   </body>
</html>
```

Related Item: `link` object

`scripts[]`

Value: Array　　　　Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera+, Chrome+

Originally IE-specific, the `document.scripts` property returns an array of all `script` element objects in the current document. You can reference an individual `script` element object to read not only the properties it shares with all HTML element objects (see Chapter 26, "Generic HTML Element Objects"), but also script-specific properties, such as `defer`, `src`, and `htmlFor`. The actual scripting is accessible through either the `innerText` or `text` properties for any `script` element object.

Although the `document.scripts` array is read-only, many properties of individual `script` element objects are modifiable. Adding or removing `script` elements impacts the length of the `document.scripts` array. Don't forget, too, that if your scripts need to access a specific `script` element object, you can assign an `id` attribute to it and reference the element directly.

This property is the same as the W3C browser expression `document .getElementsByTagName("script")`, which returns an array of the same objects.

Example

You can experiment with the `document.scripts` array in The Evaluator (Chapter 4, "JavaScript Essentials"). For example, you can see that only one `script` element object is in the Evaluator page if you enter the following statement into the top text field:

```
document.scripts.length
```

If you want to view all of the properties of that lone `script` element object, enter the following statement into the bottom text field:

```
document.scripts[0]
```

Among the properties are both `innerText` and `text`. If you assign an empty string to either property, the scripts are wiped out from the object model, but not from the browser. The scripts disappear because after they were loaded, they were cached outside of the object model. Therefore, if you enter the following statement into the top field:

```
document.scripts[0].text = ""
```

the script contents are gone from the object model, yet subsequent clicks of the Evaluate and List Properties buttons (which invoke functions of the `script` element object) still work.

Related Item: `script` element object (Chapter 40, "HTML Directive Objects")

security

Value: String Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `security` property reveals information about a security certificate, if one is associated with the current document.

Related Items: none

selection

Value: Object Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera+, Chrome-

The `document.selection` property returns a `selection` object whose content is represented in the browser window as a body text selection. That selection can be explicitly performed by the

user (by clicking and dragging across some text) or created under script control through the WinIE `TextRange` object (see Chapter 33). Because script action on a selection (for example, finding the next instance of selected text) is performed through the `TextRange` object, converting a selection to a `TextRange` object using the `document.selection.createRange()` method is common practice. See the `selection` object in Chapter 33 for more details.

Be aware that you cannot script interaction with text selections through user interface elements, such as buttons. Clicking a button gives focus to the button and deselects the selection. Use other events, such as `document.onmouseup` to trigger actions on a selection.

Example

Refer to Listings 26-36 and 26-44 in Chapter 26 to see the `document.selection` property in action for script-controlled copying and pasting (WinIE only).

Related Items: `selection`, `TextRange` objects

strictErrorChecking

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari-, Opera-, Chrome-

The `strictErrorChecking` property reveals the error-checking mode for the document. More specifically, if the property is set to `true` (the default), exceptions and errors related to DOM operations are reported. Otherwise, DOM-related exceptions may not be thrown, and errors may not be reported.

styleSheets[]

Value: Array Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.styleSheets` array consists of references to all `style` element objects in the document. Not included in this array are style sheets that are assigned to elements by way of the `style` attribute inside a tag, or linked in through `link` elements. See Chapter 38 for details about the `styleSheet` object.

Related Item: `styleSheet` object (see Chapter 38, "Style Sheet and Style Objects")

title

Value: String Read-Only and Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

A document's title is the text that appears between the `<title>...</title>` tag pair in an HTML document's `head` portion. The title usually appears in the title bar of the browser window in a single-frame presentation, or in a tabbed pane within a multi-paned browser window. Only the title of the topmost framesetting document appears as the title of a multiframe window. Even so, the `title` property for an individual document within a frame is available through scripting. For example, if two frames are available (`UpperFrame` and `LowerFrame`), a script in the document occupying the `LowerFrame` frame can reference the `title` property of the other frame's document, such as this:

```
parent.UpperFrame.document.title
```

The `document.title` property is a holdover from the original document object model. HTML elements in recent browsers have an entirely different application of the `title` property (see Chapter 26). In modern browsers (IE4+/W3C/Moz/Safari/Opera/Chrome), you should address the document's title by way of the `title` element object directly.

Related Items: `history` object

URL

(See `location`)

URLUnencoded

Value: String Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz+, Safari+, Opera+, Chrome+

The `document.URL` property returns a URL-encoded string, meaning that non-alphanumeric characters in the URL are converted to URL-friendly characters (for example, a space becomes `%20`). You can always use the `decodeURI()` function on the value returned by the `document.URL` property, although in IE the `URLUnencoded` property does that for you. If there are no URL-encoded characters in the URL, then both properties return identical strings.

Related Items: `document.URL` property

vlinkColor

(See `alinkColor`)

width

(See `height`)

xmlEncoding
xmlStandalone
xmlVersion

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari+, Opera-, Chrome+

These three properties reveal information about the document as it pertains to XML. More specifically, they convey the XML encoding of the document, whether or not the document is a standalone XML document, and the XML version number of the document, respectively. If any of the property values cannot be determined, their values remain `null`.

Methods

captureEvents(*eventTypeList*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN4+, Moz-, Safari-, Opera-, Chrome-

In Navigator 4 only, the natural propagation of an event is downward from the `window` object, through the `document` object, and eventually reaching its target. For example, if you click a button, the `click` event first reaches the `window` object; then it goes to the `document` object; if the button is defined within a layer, the event also filters through that layer; eventually (in a split second) the event reaches the button, where an `onclick` event handler is ready to act on that click.

Event capture with different syntax has been standardized in the W3C DOM and is implemented in W3C browsers, such as Firefox and Camino (Mozilla). More specifically, the W3C event capture model introduces the concept of an event listener, which enables you to bind an event handler function to an event. See the `addEventListener()` method in Chapter 26 for the W3C counterpart to the NN4 `captureEvents()` method. Also, see Chapter 32 for more details on the combination of event capture and event bubbling in the W3C DOM.

clear()

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Ever since NN2, the `document.clear()` method was intended to clear the current document from the browser window. This method is quite impractical, because you typically need some further scripts to execute after you clear the document, but if the scripts are gone, nothing else happens.

In practice, the `document.clear()` method never did what it was supposed to do (and in earlier browsers easily caused browser crashes). We strongly recommend against using `document.clear()`, even in preparation for generating a new page's content with `document.write()`. The `document.write()` method clears the original document from the window before adding new content. If you truly want to empty a window or frame, then use `document.write()` to write a blank HTML document or to load an empty HTML document from the server.

Related Items: `document.close()`, `document.write()`, `document.writeln()` methods

close()

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Whenever a layout stream is opened to a window through the `document.open()` method or through either of the document writing methods (which also open the layout stream), you must close the stream after the document is written. This causes the `Layout:Complete` and `Done` messages to appear in the status line (although you may experience some bugs in the status message on some platforms). The document-closing step is very important to prepare the window for the next potential round of replenishment with new script-assembled HTML. If you don't close the document, subsequent writing is appended to the bottom of the document.

Some or all of the data specified for the window won't display properly until you invoke the `document.close()` method, especially when images are being drawn as part of the document stream. A common symptom is the momentary appearance and then disappearance of the document parts. If you see such behavior, look for a missing `document.close()` method after the last `document.write()` method.

Fixing the Sticky Wait Cursor

From time to time, various browsers fail to restore the cursor to normal after `document.write()` and `document.close()` (and some other content-modifying scripts). The cursor stubbornly remains in the wait mode, or the progress bar keeps spinning when, in truth, all processing has been completed. Albeit ugly, one workaround that we have found effective is to force an extra `document.close()` via a `javascript:` pseudo-URL (just adding another `document.close()` to your script doesn't do the trick). For use within a frameset, the `javascript:` URL must be directed to the top of the frameset hierarchy, whereas the `document.close()` method is aimed at the frame that had its content changed. For example, if the change is made to a frame named `content`, create a function, such as the following:

```
function recloseDoc() {
   top.location.href =
      "javascript:void (parent.content.document.close())";
}
```

If you place this function in the framesetting document, scripts that modify the content frame can invoke this script after any operation that prevents the normal cursor from appearing.

Example

Before you experiment with the `document.close()` method, be sure you understand the `document.write()` method described later in this chapter. After that, make a separate set of the three documents for that method's example (Listings 29-14 through 29-16 in a different directory or folder). In the `takePulse()` function listing, comment out the `document.close()` statement, as shown here:

```
msg += "<p>Make it a great day!</body></html>";
parent.frames[1].document.write(msg);
//parent.frames[1].document.close();
```

Now try the pages on your browser. You see that each click of the upper button appends text to the bottom frame, without first removing the previous text. The reason is that the previous layout stream was never closed. The document thinks that you're still writing to it. Also, without properly closing the stream, the last line of text may not appear in the most recently written batch.

Related Items: `document.open()`, `document.clear()`, `document.write()`, `document.writeln()` methods

createAttribute("*attributeName*")

Returns: Attribute object reference

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.createAttribute()` method generates an attribute node object (formally known as an `Attr` object in W3C DOM terminology) and returns a reference to the newly created object. Invoking the method assigns only the name of the attribute, so it is up to your script to assign a value to the object's `nodeValue` property and then plug the new attribute into an existing element through

that element's `setAttributeNode()` method (described in Chapter 26). The following sequence generates an attribute that becomes an attribute of a `table` element:

```
var newAttr = document.createAttribute("width");
newAttr.nodeValue = "80%";
document.getElementById("myTable").setAttributeNode(newAttr);
```

Attributes do not always have to be attributes known to the HTML standard, because the method also works for XML elements, which have custom attributes.

Example

To create an attribute and inspect its properties, enter the following text into the top text box of The Evaluator (Chapter 4, "JavaScript Essentials"):

```
a = document.createAttribute("author")
```

Now enter `a` into the bottom text box to inspect the properties of an `Attr` object.

Related Items: `setAttributeNode()` method (see Chapter 26, "Generic HTML Element Objects")

createCDATASection("*data*")

Returns: CDATA section object reference

Compatibility: WinIE-, MacIE5, NN7+, Moz+, Safari+, Opera+, Chrome+

The `document.createCDATASection()` method generates a CDATA section node for whatever string you pass as the parameter. The value of the new node becomes the string that you pass.

createComment("*commentText*")

Returns: Comment object reference

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.createComment()` method creates an instance of a comment node. Upon creation, the node is in memory and available to be inserted into the document via any node's `appendChild()` or `insertBefore()` method.

Related Items: `appendChild()`, `insertBefore()` methods

createDocumentFragment()

Returns: Document fragment object reference

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.createDocumentFragment()` method creates an instance of an empty document fragment node. This node serves as a holder that can be used to assemble a sequence of nodes in memory. After creating and assembling nodes into the document fragment, the entire fragment can be inserted into the document tree.

A document fragment is particularly helpful when your scripts assemble an arbitrary sequence of element and text nodes. By providing a parent node for all content within, the fragment node supplies the necessary parent node context for W3C DOM node methods, such as `appendChild()`, during the content assembly process. If you then append or insert the document fragment node to an

element in the rendered document tree, the fragment wrapper disappears, leaving just its content in the desired location in the document. Therefore, a typical usage pattern for a document fragment is to begin by creating an empty fragment node (through the `createDocumentFragment()` method), populate it at will with newly created element or text nodes or both, and then use the appropriate node method on a document tree's element to append, insert, or replace, using the fragment node as the source material.

Related Items: None

`createElement("tagName")`
`createElementNS("namespaceURI", "`*`tagName`*`")`

Returns: Element object reference

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.createElement()` and `document.createElementNS()` methods generate an element object for whatever HTML (or XML) tag name you pass as the parameter. An object created in this manner is not officially part of the current document node tree because it has not yet been placed into the document. But these methods are the way you begin assembling an element object that eventually gets inserted into the document. The `createElementNS()` method is identical to `createElement()`, except that the latter method accepts an extra parameter that you use to pass a namespace URI for the element. Additionally, the tag name that you specify when creating an element via `createElementNS()` must be a qualified name. Note, however, that `createElementNS()` is not supported in Internet Explorer through version 8.

The returned value is a reference to the object. Properties of that object include all properties (set to default values) that the browser's object model defines for that element object. Your scripts can then address the object through this reference to set the object's properties. Typically, you do this before the object is inserted into the document, especially because otherwise read-only properties can be modified before the element is inserted into the document.

After the object is inserted into the document, the original reference (for example, a global variable used to store the value returned from the `createElement()` method) still points to the object, even while it is in the document and being displayed for the user. To demonstrate this effect, consider the following statements that create a simple paragraph element containing a text node:

```
var newText = document.createTextNode("Four score and seven years ago...");
var newElem = document.createElement("p");
newElem.id = "newestP";
newElem.appendChild(newText);
document.body.appendChild(newElem);
```

At this point, the new paragraph is visible in the document. But you can now modify, for example, the style of the paragraph by addressing either the element in the `document` object model or the variable that holds the reference to the object you created:

```
newElem.style.fontSize = "20pt";
```

or

```
document.getElementById("newestP").style.fontSize = "20pt";
```

The two references are inextricably connected and always point to the exact same object. Therefore, if you want to use a script to generate a series of similar elements (for example, a bunch of `li` list item

elements), then you can use `createElement()` to make the first one and set all properties that the items have in common. Then use `cloneNode()` to make a new copy, which you can then treat as a separate element (and probably assign unique IDs to each element).

When scripting in the W3C DOM environment, you may rely on `document.createElement()` frequently to generate new content for a page or portion thereof (unless you prefer to use the convenience `innerHTML` property to add content in the form of strings of HTML). In a strict W3C DOM environment, creating new elements is not a matter of assembling HTML strings, but rather creating genuine element (and text node) objects.

Example

Chapter 26, "Generic HTML Element Objects," contains numerous examples of the `document.createElement()` method in concert with methods that add or replace content to a document. See Listings 26-10, 26-21, 26-22, 26-28, 26-29, and 26-31.

Related Item: `document.createTextNode()` method

createEvent("*eventType*")

Returns: Event object reference

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.createEvent()` method creates an instance of a W3C DOM `Event` object of the specified event category. Upon creation, the generic event must be initialized as a particular event type, and any other relevant properties set for the event. After successfully initializing the event, you can fire it through a call to the `dispatchEvent()` method.

Event types recognized by Mozilla are `KeyEvents`, `MouseEvents`, `MutationEvents`, and `UIEvents`. Beginning with Mozilla 1.7.5, the following additional types may also be used: `Event`, `KeyboardEvent`, `MouseEvent`, `MutationEvent`, `MutationNameEvent`, `TextEvent`, `UIEvent`. The process of initializing each of these event types requires its own series of parameters in the associated `initEvent()` method. See Chapter 32 for more details.

Example

Following is an example of how you might create an event, initialize it to a specific event type, and send it to a given element:

```
var evt = document.createEvent("MouseEvents");
evt.initEvent("mouseup", true, true);
document.getElementById("myButton").dispatchEvent(evt);
```

Related Items: `createEventObject()` method; W3C DOM event object (see Chapter 32, "Event Objects")

createEventObject([*eventObject*])

Returns: `event` object

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The IE-specific `createEventObject()` method creates an `event` object, which can then be passed as a parameter to the `fireEvent()` method of any element object. The `event` object created by this event is just like an `event` object created by a user or system action.

An optional parameter enables you to base the new event on an existing `event` object. In other words, the properties of the newly created `event` object pick up all the properties of the `event` object passed as a parameter, which then enables you to modify properties of your choice. If you provide no parameter to the method, then you must fill the essential properties manually. For more about the properties of an `event` object, see Chapter 32.

Example

See the discussion of the `fireEvent()` method in Chapter 26 for an example of the sequence to follow when creating an event to fire on an element.

Related Items: `createEvent()` method; `fireEvent()` method (see Chapter 26); `event` object (see Chapter 32)

createNSResolver(*nodeResolver*)

Returns: XPath namespace resolver object reference

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `createNSResolver()` method is used in the context of XPath to alter a node so that it can resolve namespaces. This is necessary as part of the evaluation of an XPath expression. The only parameter is the node that is to serve as the basis for the namespace resolver.

Related Item: `evaluate()` method

createRange()

Returns: `Range` object reference

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.createRange()` method creates an empty W3C DOM `Range` object with the boundary points of the range collapsed to the point before the first character of the rendered body text.

Related Item: `Range` object

createStyleSheet(["*URL*"[, *index*]])

Returns: `styleSheet` object reference

Compatibility: WinIE4+, MacIE4, NN-, Moz-, Safari-, Opera-, Chrome-

The IE-specific `createStyleSheet()` method creates a `styleSheet` object, a type of object that includes `style` element objects as well as style sheets that are imported into a document through the `link` element. Thus, you can dynamically load an external style sheet even after a page has loaded.

Unlike the other create methods entering W3C DOM usage, the `createStyleSheet()` method not only creates the style sheet, but it inserts the object into the document object model immediately. Thus, any style sheet rules that belong (or are assigned to) that object take effect on the page right away. If you'd rather create a style sheet and delay its deployment, you should use the `createElement()` method and element object assembly techniques.

If you don't specify any parameters to the method in WinIE, an empty `styleSheet` object is created. It is assumed that you will then use `styleSheet` object methods, such as `addRule()` to add the details to the style sheet. To link in an external style sheet file, assign the file's URL to

the first parameter of the method. The newly imported style sheet is appended to the end of the `document.styleSheets` array of `styleSheet` objects. An optional second parameter lets you specify precisely where in the sequence of style sheet elements the newly linked style sheet should be inserted. A style sheet rule for any given selector is overridden by a style sheet for the same selector that appears later in the sequence of style sheets in a document.

Example

Listing 29-12 demonstrates adding an internal and external style sheet to a document. For the internal addition, the `addStyle1()` function invokes `document.createStyleSheet()` and adds a rule governing the `p` elements of the page. In the `addStyle2()` function, an external file is loaded. That file contains the following two style rules:

```
h2 {font-size:20pt; color:blue;}
p  {color:blue;}
```

Notice that by specifying a position of zero for the imported style sheet, the addition of the internal style sheet always comes afterward in `styleSheet` object sequence. Thus, except when you deploy only the external style sheet, the red text color of the `p` elements override the blue color of the external style sheet. If you remove the second parameter of the `createStyleSheet()` method in `addStyle2()`, the external style sheet is appended to the end of the list. If it is the last style sheet to be added, the blue color prevails. Repeatedly clicking the buttons in this example continues to add the style sheets to the document.

LISTING 29-12

Creating and Applying Style Sheets

Related Item: `styleSheet` object (see Chapter 38, “Style Sheet and Style Objects”)

createTextNode("*text*")

Returns: Object

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

A text node is a W3C DOM object that contains body text without any HTML (or XML) tags, but is usually contained by (meaning, is a child of) an HTML (or XML) element. Without the IE `innerText` convenience property for modifying the text of an element, the W3C DOM relies on the node hierarchy of a document (Mozilla exceeds the W3C DOM by providing an `innerHTML`

property, which you can use to replace text in an element). To insert or replace text inside an HTML element in the W3C DOM way, you create the text node and then use methods of the parent element (for example, `appendChild()`, `insertBefore()`, and `replaceChild()`, all described in Chapter 26) to modify the document's content. To generate a fresh text node, use `document.createTextNode()`.

The sole parameter of the `createTextNode()` method is a string whose text becomes the `nodeValue` of the text node object returned by the method. You can also create an empty text node (passing an empty string) and assign a string to the `nodeValue` of the object later. As soon as the text node is present in the document object model, scripts can simply change the `nodeValue` property to modify the text of an existing element. For more details on the role of text nodes in the W3C DOM, see Chapter 25, "Document Object Model Essentials."

Example

Although Chapters 25 and 26 (Listing 26-21, for instance) provide numerous examples of the `createTextNode()` method at work, using The Evaluator is instructive to see just what the method generates in IE5+/W3C. You can use one of the built-in global variables of The Evaluator to hold a reference to a newly generated text node by entering the following statement into the top text field:

```
a = document.createTextNode("Hello")
```

The Results box shows that an object was created. Now, look at the properties of the object by entering `a` into the bottom text field. The precise listings of properties varies between IE5+ and W3C browsers, but the W3C DOM properties that they share in common indicate that the object is a node type 3 with a node name of `#text`. No parents, children, or siblings exist yet because the object created here is not part of the document hierarchy tree until it is explicitly added to the document.

To see how insertion works, enter the following statement into the top text field to append the text node to the `myP` paragraph:

```
document.getElementById("myP").appendChild(a)
```

The word *Hello* appears at the end of the simple paragraph lower on the page. Now you can modify the text of that node either through the reference, from the point of view of the containing `p` element, or through the global variable reference for the newly created node:

```
document.getElementById("myP").lastChild.nodeValue = "Howdy"
```

or

```
a.nodeValue = "Howdy"
```

Related Item: `document.createElement()` method

createTreeWalker(*rootNode, whatToShow, filterFunction, entityRefExpansion*)

Returns: `TreeWalker` object reference

Compatibility: WinIE-, MacIE-, NN7+, Moz1.4+, Safari+, Opera+, Chrome+

The `document.createTreeWalker()` method creates an instance of a `TreeWalker` object that can be used to navigate the document tree. The first parameter to the method indicates the node in

the document that is to serve as the root node of the tree. The second parameter is an integer constant that specifies one of several built-in filters for selecting nodes to be included in the tree. Following are the possible acceptable values for this parameter:

NodeFilter.SHOW_ALL	NodeFilter.SHOW_ATTRIBUTE
NodeFilter.SHOW_CDATA_SECTION	NodeFilter.SHOW_COMMENT
NodeFilter.SHOW_DOCUMENT	NodeFilter.SHOW_DOCUMENT_FRAGMENT
NodeFilter.SHOW_DOCUMENT_TYPE	NodeFilter.SHOW_ELEMENT
NodeFilter.SHOW_ENTITY	NodeFilter.SHOW_ENTITY_REFERENCE
NodeFilter.SHOW_NOTATION	NodeFilter.SHOW_PROCESSING_INSTRUCTION
NodeFilter.SHOW_TEXT	

The third parameter to the `createNodeIterator()` method is a reference to a filter function that can filter nodes even further than the `whatToShow` parameter. This function must accept a single node and return an integer value based upon one of the following constants: `NodeFilter.FILTER_ACCEPT`, `NodeFilter.FILTER_REJECT`, or `NodeFilter.FILTER_SKIP`. The idea is that you code the function to perform a test on each node and return an indicator value that lets the node iterator know whether or not to include the node in the tree. Your function doesn't loop through nodes. The `TreeWalker` object mechanism repetitively invokes the function as needed to look for the presence of whatever characteristic you wish to use as a filter.

The final parameter to the method is a Boolean value that determines whether or not the content of entity reference nodes should be treated as hierarchical nodes. This parameter applies primarily to XML documents.

Related Items: `TreeWalker` object

elementFromPoint(*x*, *y*)

Returns: Element object reference

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera+, Chrome+

Originally IE-specific, the `elementFromPoint()` method returns a reference to whatever element object occupies the point whose integer coordinates are supplied as parameters to the method. The coordinate plane is that of the document, whose top-left corner is at point `0,0`. This coordinate plane can be very helpful in interactive designs that need to calculate collision detection between positioned objects or mouse events.

When more than one object occupies the same point (for example, one element is positioned atop another), the element with the highest z-index value is returned. A positioned element always wins when placed atop a normal body-level element. And if multiple overlapping positioned elements have the same z-index value (or none by default), the element that comes last in the source code order is returned for the coordinate that they share in common.

Example

Listing 29-13 is a document that contains many different types of elements, each of which has an ID attribute assigned to it. The `onmouseover` event handler for the `document` object invokes a

function that finds out which element the cursor is over when the event fires. Note that the event coordinates are `event.clientX` and `event.clientY`, which use the same coordinate plane as the page for their point of reference. As you roll the mouse over every element, its ID appears on the page. Some elements, such as `br` and `tr`, occupy no space in the document, so you cannot get their IDs to appear. On a typical browser screen size, a positioned element rests atop one of the paragraph elements so that you can see how the `elementFromPoint()` method handles overlapping elements. If you scroll the page, the coordinates for the event and the page's elements stay in sync.

Related Items: `event.clientX`, `event.clientY` properties; positioned objects (see Chapter 43, “Positioned Objects”)

`evaluate("expression", contextNode, resolver, type, result)`

Returns: XPath result object reference

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `document.evaluate()` method evaluates an XPath expression and returns an XPath result object (`XPathResult`). The most important parameter to this method is the first one, which contains the actual XPath expression as a string. The second parameter is the context node to which the expression applies, whereas the third parameter is the namespace resolver (see the `createNSResolver()` method). The `resolver` parameter can be specified as `null` as long as there aren't any namespace prefixes used within the expression.

The `type` parameter determines the type of the result of the expression and is specified as one of the XPath result types, such as 0 for any type, 1 for number, 2 for string, and so forth. Finally, a reusable `result` object can be specified in the last parameter, which will then be modified and returned from the method as the result of the expression.

Related Item: `createNSResolver()` method

`execCommand("`*`commandName`*`"[, `*`UIFlag`*`] [, `*`param`*`])`

Returns: Boolean

Compatibility: WinIE4+, MacIE-, NN7.1+, Moz1.3+, Safari1.3+, Opera+, Chrome+

The execCommand() method is the JavaScript gateway to a set of commands that is outside of the methods defined for objects in the object model. A series of related methods (queryCommandEnable() and others) also facilitate management of these commands.

The syntax for the execCommand() method requires at least one parameter, a string version of the command name. Command names are not case-sensitive. An optional second parameter is a Boolean flag to instruct the command to display any user interface artifacts that may be associated with the command. The default is false. For the third parameter, some commands require that an attribute value be passed for the command to work. For example, to set the font size of a text range, the syntax is

```
myRange.execCommand("FontSize", true, 5);
```

The execCommand() method returns Boolean true if the command is successful; false if not successful. Some commands can return values (for example, finding out the font name of a selection), but those are accessed through the queryCommandValue() method.

In Internet Explorer, most of these commands operate on body text selections that are TextRange objects. As described in Chapter 33, a TextRange object must be created under script control. But a TextRange object can be created in response to a user selecting some text in the document. Because a TextRange object is independent of the element hierarchy (indeed, a TextRange can spread across multiple nodes), it cannot respond to style sheet specifications. Thus, many of the commands that can operate on a TextRange object have to do with formatting or modifying the text. For a list of commands that work exclusively on TextRange objects, see the TextRange.execCommand() method in Chapter 33.

Although many of the commands intended for the TextRange also work when invoked from the document object, in this section the focus is on those commands that have scope over the entire document. Table 29-2 lists those few commands that work with the document. Also listed are many commands that work exclusively on text selections in the document, whether the selections are made manually by the user or with the help of the TextRange object (see Chapter 33).

Mozilla 1.4 and Safari 1.3 added a feature that allows scripts to turn an iframe element's document object into an HTML editable document. Here is an example of how to center the selected text in an iframe with an ID of msg:

```
document.getElementById("msg").contentDocument.execCommand("JustifyCenter");
```

Note that the contentDocument property is used to access the iframe as a document. Visit http://www.mozilla.org/editor for additional details and examples of the document.execCommand() method.

Example

You can find many examples of the execCommand() method for the TextRange object in Chapter 33. But you can try out the document-specific commands in The Evaluator (see Chapter 4) in Internet Explorer if you like. Try each of the following statements in the top text box and click the Evaluate button:

```
document.execCommand("Refresh")
document.execCommand("SelectAll")
document.execCommand("Unselect")
```

TABLE 29-2

document.execCommand() Commands

Command	Parameter	Description
BackColor	Color String	Encloses the current selection with a font element whose style attribute sets the background-color style to the parameter value.
CreateBookmark	Anchor String	Encloses the current selection (or text range) with an anchor element whose name attribute is set to the parameter value.
CreateLink	URL String	Encloses the current selection with an a element whose href attribute is set to the parameter value.
decreaseFontSize	none	Encloses the current selection with a small element.
Delete	none	Deletes the current selection from the document.
FontName	Font Face(s)	Encloses the current selection with a font element whose face attribute is set to the parameter value.
FontSize	Size String	Encloses the current selection with a font element whose size attribute is set to the parameter value.
foreColor	Color String	Encloses the current selection with a font element whose color attribute is set to the parameter value.
FormatBlock	Block Element String	Encloses the current selection with the specified block element. IE only supports the h1 through h6, address and pre block elements. Other browsers support all block elements.
increaseFontSize	none	Encloses the current selection with a big element.
Indent	None	Indents the current selection.
InsertHorizontalRule	Id String	Encloses the current selection in an hr element, whose id attribute is set to the parameter value.
InsertImage	Id String	Encloses the current selection in an img element, whose id attribute is set to the parameter value.
InsertParagraph	Id String	Encloses the current selection in an p element, whose id attribute is set to the parameter value.
JustifyCenter	None	Centers the current selection.
JustifyFull	None	Full-justifies the current selection.
JustifyLeft	None	Left-justifies the current selection.
JustifyRight	None	Right-justifies the current selection.
Outdent	None	Outdents the current selection.

TABLE 29-2 *(continued)*

Command	Parameter	Description
`Refresh`	None	Reloads the page.
`RemoveFormat`	None	Removes formatting for the current selection.
`SelectAll`	None	Selects all text of the document.
`UnBookmark`	None	Removes anchor tags that surround the current selection.
`Unlink`	None	Removes link tags that surround the current selection.
`Unselect`	None	Deselects the current selection anywhere in the document.

All methods return `true` in the Results box.

Because any way you can evaluate a statement in The Evaluator forces a body selection to become de-selected before the evaluation takes place, you can't experiment this way with the selection-oriented commands.

Related Items: `queryCommandEnabled()`, `queryCommandIndterm()`, `queryCommandState()`, `queryCommandSupported()`, `queryCommandText()`, `queryCommandValue()` methods

getElementById("*elementID*")

Returns: Element object reference

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.getElementById()` method is the W3C DOM syntax for retrieving a reference to any element in a document that has a unique identifier assigned to its `id` attribute. If the document contains more than one instance of an ID, the method returns a reference to the first element in source code order with that ID. Because this method is such an important avenue to writing references to objects that are to be modified under script control, you can see how important it is to assign unique IDs to elements.

This method's name is quite a finger twister for scripters, especially compared to the IE4+ convention of letting a reference to any element begin simply with the object's ID. However, the `getElementById()` method is the modern way of acquiring an element's reference for W3C DOM-compatible browsers, including IE. When you type this method, be sure to use a lowercase `d` as the last character of the method name.

Unlike some other element-oriented methods (for example, `getElementsByTagName()`), which can be invoked on any element in a document, the `getElementById()` method works exclusively with the `document` object.

Example

You can find many examples of this method in use throughout this book, but you can take a closer look at how it works by experimenting in The Evaluator (Chapter 4, "JavaScript Essentials"). A number of elements in The Evaluator have IDs assigned to them, so that you can use the method to inspect the objects and their properties. Enter the following statements into both the top and bottom text

fields of The Evaluator. Results from the top field are references to the objects; results from the bottom field are lists of properties for the particular object.

```
document.getElementById("myP")
document.getElementById("myEM")
document.getElementById("myTitle")
document.getElementById("myScript")
```

Related Item: `getElementsByTagName()` method (see Chapter 26, "Generic HTML Element Objects")

getElementsByName("*elementName*")

Returns: Array

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `document.getElementsByName()` method returns an array of references to objects whose `name` attribute is assigned the element name passed as the method's attribute. Although other browsers recognize `name` attributes even for elements that don't have them by default, IE does not. Therefore, for maximum cross-browser compatibility, use this method only to locate elements that have `name` attributes defined for them by default, such as form control elements. If the element does not exist in the document, the method returns an array of zero length.

For the most part, you are best served by using IDs on elements and the `getElementById()` method to unearth references to individual objects. But some elements, especially the `input` element of type radio, use the `name` attribute to group elements together. In that case, a call to `getElementsByName()` returns an array of all elements that share the name — facilitating perhaps a `for` loop that inspects the `checked` property of a radio button group. Thus, instead of using the old-fashioned approach by way of the containing form object:

```
var buttonGroup = document.forms[0].radioGroupName;
```

you can retrieve the array more directly:

```
var buttonGroup = document.getElementsByName(radioGroupName);
```

In the latter case, you operate independently of the containing form object's index number or name. This assumes, of course, that a group name is not shared elsewhere on the page, which would certainly lead to confusion.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to test out the `getElementsByName()` method. All form elements in the upper part of the page have names associated with them. Enter the following statements into the top text field and observe the results:

```
document.getElementsByName("output")
document.getElementsByName("speed").length
document.getElementsByName("speed")[0].value
```

You can also explore all of the properties of the text field by typing the following expression into the bottom field:

```
document.getElementsByName("speed")[0]
```

Related Items: document.getElementsById(), getElementsByTagName() methods

importNode(node, deep)

Returns: Node object reference

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The document.importNode() method imports a node from another document object into the current document object. A copy of the original node is made when the node is imported, meaning that the original node remains unchanged. The second parameter to the method is a Boolean value that determines whether or not the node's entire subtree is imported (true) or just the node itself (false).

open(["*mimeType*"] [,"*replace*"])

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Opening a document is different from opening a window. In the case of a window, you're creating a new object, both on the screen and in the browser's memory. Opening a document, on the other hand, tells the browser to get ready to accept some data for display in the window named or implied in the reference to the document.open() method. (For example, parent.frames[1] .document.open() may refer to a different frame in a frameset, whereas document.open() implies the current window or frame.) Therefore, the method name may mislead newcomers because the document.open() method has nothing to do with loading documents from the web server or hard disk. Rather, this method is a prelude to sending data to a window through the document.write() or document.writeln() methods. In a sense, the document.open() method merely opens the valve of a pipe; the other methods send the data down the pipe like a stream, and the document.close() method closes that valve as soon as the page's data has been sent in full.

The document.open() method is optional because a document.write() method that attempts to write to a closed document automatically clears the old document and opens the stream for a new one. Whether or not you use the document.open() method, be sure to use the document.close() method after all the writing has taken place.

An optional parameter to the document.open() method enables you to specify the nature of the data being sent to the window. A MIME (Multipurpose Internet Mail Extension) type is a specification for transferring and representing multimedia data on the Internet (originally for mail transmission, but now applicable to all Internet data exchanges). You've seen MIME depictions in the list of helper applications in your browser's preferences settings. A pair of data type names separated by a slash represents a MIME type (such as text/html and image/gif). When you specify a MIME type as a parameter to the document.open() method, you're instructing the browser about the kind of data it is about to receive, so that it knows how to render the data. Common values that most browsers accept are:

```
text/html
text/plain
image/gif
image/jpeg
image/xbm
```

If you omit the parameter, JavaScript assumes the most popular type, `text/html` — the kind of data you typically assemble in a script prior to writing to the window. The `text/html` type includes any images that the HTML references. Specifying any of the image types means that you have the raw binary representation of the image that you want to appear in the new document — possible, but unlikely.

Another possibility is to direct the output of a `write()` method to a plug-in. For the `mimeType` parameter, specify the plug-in's MIME type (for example, `application/x-director` for Shockwave). Again, the data you write to a plug-in must be in a form that it knows how to handle. The same mechanism also works for writing data directly to a helper application.

Note

IE accepts only the `text/html` MIME type parameter. ■

Modern browsers include a second, optional parameter to the method: `replace`. This parameter does for the `document.open()` method what the `replace()` method does for the `location` object. For `document.open()`, it means that the new document you are about to write replaces the previous document in the window or frame, with the end result that the replaced window or frame's history is not recorded.

Example

You can see an example of where the `document.open()` method fits in the scheme of dynamically creating content for another frame in the discussion of the `document.write()` method later in this chapter.

Related Items: `document.close()`, `document.clear()`, `document.write()`, `document.writeln()` methods

queryCommandEnabled("*commandName*")
queryCommandIndterm("*commandName*")
queryCommandState("*commandName*")
queryCommandSupported("*commandName*")
queryCommandText("*commandName*")
queryCommandValue("*commandName*")

Returns: Various values

Compatibility: WinIE4+, MacIE-, NN7.1, Moz1.3+, Safari+, Opera+, Chrome+

These six methods lend further support to the `execCommand()` method for `document` and `TextRange` objects. If you choose to use the `execCommand()` method to achieve some stylistic change on a text selection, you can use some of these query methods to make sure the browser supports the desired command and to retrieve any returned values. Table 29-3 summarizes the purpose and returned values for each of the query methods. Note that browser support for these seven methods is uneven.

Because the `execCommand()` method cannot be invoked on a page while it is still loading, any such invocations that may collide with the loading of a page should check with `queryCommandEnabled()` prior to invoking the command. Validating that the browser version

running the script supports the desired command is also a good idea. Therefore, you may want to wrap any command call with the following conditional structure:

```
if (document.queryCommandEnabled(commandName) &&
    document.queryCommandSupported(commandName)) {
    //  ...
}
```

TABLE 29-3

Query Commands

queryCommand	Returns	Description
`Enabled`	Boolean	Reveals whether the `document` or `TextRange` object is in a suitable state to be invoked.
`Indterm`	Boolean	Reveals whether the command is in an indeterminate state.
`CommandState`	Boolean | `null`	Reveals whether the command has been completed (`true`), is still working (`false`), or is in an indeterminate state (`null`).
`Supported`	Boolean	Reveals whether the command is supported in the current browser.
`Text`	String	Returns any text that may be returned by a command.
`Value`	Varies	Returns whatever value (if any) is returned by a command.

When using a command to read information about a selection, use the `queryCommandText()` or `queryCommandValue()` methods to catch that information (recall that the `execCommand()` method itself returns a Boolean value regardless of the specific command invoked).

Example

See the examples for these methods covered under the `TextRange` object in Chapter 33, "Body Text Objects."

Related Items: `TextRange` object (see Chapter 33); `execCommand()` method

recalc([*allFlag*])

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

IE5 introduced the concept of dynamic properties. With the help of the `setExpression()` method of all elements and the `expression()` style sheet value, you can establish dependencies between object properties and potentially dynamic properties, such as a window's size or a draggable element's

location. After those dependencies are established, the `document.recalc()` method causes those dependencies to be recalculated — usually in response to some user action, such as resizing a window or dragging an element.

The optional parameter is a Boolean value. The default value, `false`, means that the recalculations are performed only on expressions for which the browser has detected any change since the last recalculation. If you specify `true`, however, all expressions are recalculated, whether they have changed or not.

Mozilla 1.4 includes a feature that allows scripts to turn an `iframe` element's document object into an HTML editable document. Part of the scripting incorporates the `document.execCommand()` and related methods. Visit `http://www.mozilla.org/editor` for current details and examples.

Example

You can see an example of `recalc()` in Listing 26-32 for the `setExpression()` method. In that example, the dependencies are between the current time and properties of standard element objects.

Related Items: `getExpression()`, `removeExpression()`, `setExpression()` methods (see Chapter 26, "Generic HTML Element Objects")

releaseEvents(*eventTypeList*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN4+, Moz-, Safari-, Opera-, Chrome-

In NN4+, as soon as you enable event capture for a particular event type in a document, that capture remains in effect until the page unloads or you specifically disable the capture. You can turn off event capture for each event via the `releaseEvents()` method. See Chapter 32, "Event Objects," for more details on event capture and release.

Related Items: `captureEvents()`, `routeEvent()` methods

routeEvent([*eventObject*])

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN4+, Moz-, Safari-, Opera-, Chrome-

If you capture a particular event type in NN4, your script may need to perform some limited processing on that event before letting it reach its intended target. To let an event pass through the object hierarchy to its target, you use the `routeEvent()` method, passing as a parameter the event object being handled in the current function. See Chapter 32, "Event Objects," for more details on event processing.

Related Items: `captureEvents()`, `releaseEvents()` methods

write("*string1*" [,"*string2*" ... [, "*stringn*"]])
writeln("*string1*" [,"*string2*" ... [, "*stringn*"]])

Returns: Boolean `true` if successful

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Both of these methods send text to a document for display in its window. The only difference between the two methods is that `document.writeln()` appends a carriage return to the end of the string it sends to the document. This carriage return is helpful for formatting source code when viewed through the browser's source view window. For new lines in rendered HTML that is generated by these methods, you must still write a `<br>` to insert a line break.

A common, incorrect conclusion that many JavaScript newcomers make is that these methods enable a script to modify the contents of an existing document, which is not true. As soon as a document has loaded into a window (or frame), the only fully backward-compatible text that you can modify without reloading or rewriting the entire page is the content of `text` and `textarea` objects. In IE4+, you can modify HTML and text through the `innerHTML`, `innerText`, `outerHTML`, and `outerText` properties of any element. For W3C DOM–compatible browsers, you can modify an element's text by setting its `nodeValue` or `innerHTML` properties. The preferred approach for modifying the content of a node involves strict adherence to the W3C DOM, which requires creating and inserting or replacing new elements, as described in Chapter 26, and demonstrated in examples throughout this chapter and the rest of the book.

The two safest ways to use the `document.write()` and `document.writeln()` methods are to:

- Write some or all of the page's content by way of scripts embedded in the document
- Send HTML code either to a new window or to a separate frame in a multiframe window

For the first case, you essentially interlace script segments within your HTML. The scripts run as the document loads, writing whatever scripted HTML content you like. This task is exactly what you did in `script1.html` in Chapter 3, "Selecting and Using Your Tools." This task is also how you can have one page generate browser-specific HTML when a particular class of browser requires unique syntax.

In the latter case, a script can gather input from the user in one frame and then algorithmically determine the layout and content destined for another frame. The script assembles the HTML code for the other frame as a string variable (including all necessary HTML tags). Before the script can write anything to the frame, it can optionally open the layout stream (to close the current document in that frame) with the `parent.frameName.document.open()` method. In the next step, a `parent.frameName.document.write()` method pours the entire string into the other frame. Finally, a `parent.frameName.document.close()` method ensures that the total data stream is written to the window. Such a frame looks just the same as if it were created by a source document on the server rather than on-the-fly in memory. The `document` object of that window or frame is a full citizen as a standard `document` object. You can, therefore, even include scripts as part of the HTML specification for one of these temporary HTML pages.

After an HTML document (containing a script that is going to write via the `write()` or `writeln()` methods) loads completely, the page's incoming stream closes automatically. If you then attempt to apply a series of `document.write()` statements, the first `document.write()` method completely removes all vestiges of the original document. That includes all of its objects and scripted variable values. Therefore, if you try to assemble a new page with a series of `document.write()` statements, the script and variables from the original page will be gone before the second `document.write()` statement executes. To get around this potential problem, assemble the content for the new screen as one string variable, and then pass that variable as the parameter to a single `document.write()` statement. Also be sure to include a `document.close()` statement in the next line of script.

Assembling HTML in a script to be written via the `document.write()` method often requires skill in concatenating string values and nesting strings. A number of JavaScript `String` object shortcuts facilitate the formatting of text with HTML tags (see Chapter 15, "The String Object," for details).

If you are writing to a different frame or window, you are free to use multiple `document.write()` statements if you like. Whether your script sends lots of small strings via multiple `document.write()` methods, or assembles a larger string to be sent through one `document.write()` method, depends partly on the situation and partly on your own scripting style. From a performance standpoint, a fairly standard procedure is to do more preliminary work in memory and place as few I/O (input/output) calls as possible. On the other hand, making a difficult-to-track mistake is easier in string concatenation when you assemble longer strings. You should use the system that's most comfortable for you.

You may see another little-known way of passing parameters to these methods. Instead of concatenating string values with the plus (+) operator, you can also bring string values together by separating them with commas, in which case the strings appear to be arguments to the `document.write()` method. For example, the following two statements produce the same results:

```
document.write("Today is " + new Date());
document.write("Today is ",new Date());
```

Neither form is better than the other, so use the one that feels more comfortable to your existing programming style.

Note

Dynamically generating scripts requires an extra trick, especially in NN. The root of the problem is that if you try code such as `document.write("<script></script>")`, the browser interprets the end script tag as the end of the script that is doing the writing. You have to trick the browser by separating the end tag into a couple of components. Escaping the forward slash also helps. For example, if you want to load a different `.js` file for each class of browser, the code looks similar to the following:

```
// variable 'browserVer' is a browser-specific string
// and 'page' is the HTML your script is accumulating
// for document.write()
page += "<script type='text/javascript' src='" +
        browseVer + ".js'><" + "\/script>"; ■
```

Using the `document.open()`, `document.write()`, and `document.close()` methods to display images in a document requires some small extra steps. First, any URL assignments that you write via `document.write()` must be complete (not relative) URL references. Alternatively, you can write the `<base>` tag for the dynamically generated page so that its `href` attribute value matches that of the file that is writing the page.

The other image trick is to be sure to specify `height` and `width` attributes for every image, scripted or otherwise. Document-rendering performance is improved on all platforms, because the values help the browser lay out elements even before their details are loaded.

In addition to the `document.write()` example that follows (see Listings 29-14 through 29-16), you can find fuller implementations that use this method to assemble images and bar charts in many of the applications in Chapters 52 through 61 on the CD-ROM. Because you can assemble any valid HTML as a string to be written to a window or frame, a customized, on-the-fly document can be as elaborate as the most complex HTML document that you can imagine.

Example

The example in Listings 29-14 through 29-16 demonstrates several important points about using the `document.write()` and `document.writeln()` methods for writing to another frame. First is

the fact that you can write any HTML code to a frame, and the browser accepts it as if the source code came from an HTML file somewhere. In the example, we assemble a complete HTML document, including basic HTML tags for completeness.

LISTING 29-14

A Frameset for the Document Writing Example

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Writin' to the doc</title>
   </head>
   <frameset rows="50%,50%">
      <frame name="Frame1" src="jsb29-15.html" />
      <frame name="Frame2" src="jsb29-16.html" />
   </frameset>
</html>
```

LISTING 29-15

Writing a Document Based upon User Input

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Document Write Controller</title>
      <script type="text/javascript">
         function takePulse(form)
         {
            var msg = "<html><head><title>On The Fly with " +
                      form.yourName.value + "<\/title><\/head>";
            msg += "<body bgcolor='salmon'><h1>Good Day " +
                    form.yourName.value +
                   "!<\/h1><hr />";
            for (var i = 0; i < form.how.length; i++)
            {
               if (form.how[i].checked)
               {
                  msg += form.how[i].value;
                  break;
               }
            }
            msg += "<br />Make it a great day!<\/body><\/html>";
            parent.Frame2.document.write(msg);
            parent.Frame2.document.close();
         }
```

continued

LISTING 29-15 *(continued)*

```
      function getTitle()
      {
        alert("Lower frame document.title is now:" + parent.Frame2.document.title);
      }

      // bind the event handlers
      function addEvent(elem, evtType, func)
      {
         if (elem.addEventListener)
         {
            elem.addEventListener(evtType, func, false);
         }
         else if (elem.attachEvent)
         {
            elem.attachEvent("on" + evtType, func);
         }
         else
         {
            elem["on" + evtType] = func;
         }
      }
      addEvent(window, "load", function()
      {
         addEvent(document.getElementById("enter"), "click",
                  function(evt)
                  {takePulse(document.getElementById("enter").form)
                  });
         addEvent(document.getElementById("peek"), "click", getTitle);
      });
   </script>
</head>
<body>
   Fill in a name, and select how that person feels today. Then click "Write
   To Below" to see the results in the bottom frame.
   <form>
      Enter your first name:
      <input type="text" name="yourName" value="Dave" />
      <p>How are you today?
         <input type="radio" name="how"
                value="I hope that feeling continues forever."
                checked="checked" />
         Swell
         <input type="radio" name="how"
                value="You may be on your way to feeling Swell" />
         Pretty Good
         <input type="radio" name="how"
                value="Things can only get better from here." />So-So
      </p>
      <p><input type="button" id="enter" name="enter" value="Write To Below" /></p>
```

```
      <hr />
      <input type="button" id="peek" name="peek" value="Check Lower Frame Title" />
    </form>
  </body>
</html>
```

LISTING 29-16

A Placeholder Page for the Document Writing Example

```
<!DOCTYPE html>
<html>
  <head>
    <meta http-equiv="content-type" content="text/html;charset=utf-8">
    <title>Placeholder</title>
  </head>
  <body>
  </body>
</html>
```

It is important to note that this example customizes the content of the document based on user input. This customization makes the experience of working with your web page feel far more interactive to the user — yet you're doing it without any server-side programs.

The second point we want to bring home is that the document created in the separate frame by the `document.write()` method is a genuine `document` object. In this example, the `<title>` tag of the written document changes if you redraw the lower frame after changing the entry of the name field in the upper frame. If you click the lower button after updating the bottom frame, you see that the `document.title` property has, indeed, changed to reflect the `<title>` tag written to the browser in the course of displaying the frame's page. The fact that you can artificially create full-fledged, JavaScript `document` objects on the fly represents one of the most important powers of serverless CGI scripting (for information delivery to the user) with JavaScript. You have much to take advantage of here if your imagination is up to the task.

Note that you can easily modify Listing 29-15 to write the results to the same frame as the document containing the field and buttons. Instead of specifying the lower frame:

```
parent.frames[1].document.open();
parent.frames[1].document.write(msg);
parent.frames[1].document.close();
```

The code simply can use:

```
document.open();
document.write(msg);
document.close();
```

This code would replace the form document with the results and not require any frames in the first place. Because the code assembles all of the content for the new document into one variable value, that data survive the one `document.write()` method.

The frameset document (see Listing 29-14) creates a blank frame by loading a blank document (see Listing 29-16). An alternative that we highly recommend is to have the framesetting document fill the frame with a blank document of its own creation. See the section “Blank frames” in Chapter 27, “Window and Frame Objects,” for further details about this technique.

Related Items: `document.open()`; `document.close()`; `document.clear()` methods

Event handlers

onselectionchange

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onselectionchange` event can be triggered by numerous user actions, although all of those actions occur on elements that are under the influence of the WinIE5.5+ edit mode.

Related Item: `oncontrolselect` event handler

onstop

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `onstop` event fires in WinIE5+ when the user clicks the browser’s Stop button. Use this event handler to stop potentially runaway script execution on a page, because the Stop button does not otherwise control scripts after a page has loaded. If you are having a problem with a runaway repeat loop during development, you can temporarily use this event handler to let you stop the script for debugging.

Example

Listing 29-17 provides a simple example of an intentional infinitely looping script. In case you load this page into a browser other than IE5+, you can click the Halt Counter button to stop the looping. The Halt Counter button, as well as the `onstop` event handler, invokes the same function.

LISTING 29-17

Stopping a Script Using the onstop Event Handler

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>onStop Event Handler</title>
      <script type="text/javascript">
         var counter = 0;
         var timerID;
         function startCounter()
         {
            document.forms[0].display.value = ++counter;
            //clearTimeout(timerID)
            timerID = setTimeout("startCounter()", 10);
         }
         function haltCounter()
```

```
        {
           clearTimeout(timerID);
           counter = 0;
        }

        // bind the event handlers
        function addEvent(elem, evtType, func)
        {
           if (elem.addEventListener)
           {
              elem.addEventListener(evtType, func, false);
           }
           else if (elem.attachEvent)
           {
              elem.attachEvent("on" + evtType, func);
           }
           else
           {
              elem["on" + evtType] = func;
           }
        }
        addEvent(window, "load", function()
        {
           addEvent(document, "stop", haltCounter);
           addEvent(document.getElementById("start"), "click", startCounter);
           addEvent(document.getElementById("halt"), "click", haltCounter);
        });
     </script>
  </head>
  <body>
     <h1>onStop Event Handler</h1>
     <hr />
     <p>Click the browser's Stop button (in IE) to stop the script counter.</p>
     <form>
        <p><input type="text" name="display" /></p>
        <input type="button" id="start" value="Start Counter" />
        <input type="button" id="halt" value="Halt Counter" />
     </form>
  </body>
</html>
```

Syntax

Accessing body element object properties or methods:

```
[window.] document.body.property | method([parameters])
```

About this object

In object models that reveal HTML element objects, the body element object is the primary container of the content that visitors see on the page. The body contains all rendered HTML. This special place in the node hierarchy gives the body object some unique powers, especially in the IE object model.

As if to signify the special relationship, both the IE and W3C object models provide the same shortcut reference to the body element: document.body. As a first-class HTML element object (as evidenced by the long lists of properties, methods, and event handlers covered in Chapter 26), you are also free to use other syntaxes to reach the body element.

You are certainly familiar with several body element attributes that govern body-wide content appearance, such as link colors (in three states) and background (color or image). But IE and NN/Mozilla (and the W3C so far) have some very different ideas about the body element's role in scripting documents. Many methods and properties that NN/Mozilla considers to be the domain of the window (for example, scrolling, inside window dimensions, and so forth), IE puts into the hands of the body element object. Therefore, whereas NN/Mozilla scrolls the window (and whatever it may contain), IE scrolls the body (inside whatever window it lives). And because the body element

fills the entire viewable area of a browser window or frame, that viewable rectangle is determined in IE by the body's `scrollHeight` and `scrollWidth` properties, whereas NN4+/Moz features `window.innerHeight` and `window.innerWidth` properties. This distinction is important to point out because when you are scripting window- or document-wide appearance factors, you may have to look for properties and methods for the `window` or `body` element object, depending on your target browser(s).

Note

Use caution when referencing the `document.body` object while the page is loading. The object may not officially exist until the page has completely loaded. If you need to set some initial properties through scripting, do so in response to the `onload` event handler located in the `<body>` tag. Attempts at setting `body` element object properties in immediate scripts inside the `head` element may result in error messages about the object not being found. ■

Properties

alink
bgColor
link
text
vLink

Value: Hexadecimal triplet or color name string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `aLink`, `link`, and `vLink` properties replaced the ancient `document` properties `alinkColor`, `linkColor`, and `vlinkColor`. The `bgColor` property is the same as the old `document.bgColor` property, while the `text` property replaced the `document.fgColor` property. These properties serve as the scripted equivalents of the HTML attributes for the `body` element — the new property names more closely align themselves with the HTML attributes than the old property names.

We use past tense when referring to these properties because CSS has largely made them obsolete. Granted, they still work, but will likely fall into disuse as web developers continue to embrace style sheets as the preferred means of altering color in web pages. Link colors that are set through pseudo-class selectors in style sheets (as `style` attributes of the `body` element) must be accessed through the `style` property for the `body` object.

background

Value: URL string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `background` property enables you to set or get the URL for the background image (if any) assigned to the `body` element. A `body` element's background image overlays the background color in case both attributes or properties are set. To remove an image from the document's background, set the `document.body.background` property to an empty string.

Similar to the properties that provide access to colors on the page, the background image in modern web pages should be set through style sheets, as opposed to the `body.background` property. In that case, you access the background programmatically through the `style` property of the `body` object.

bgColor

(See aLink)

bgProperties

Value: String constant Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The IE-specific bgProperties property is an alternative way of adjusting whether the background image should remain fixed when the user scrolls the document or scroll with the document. Initial settings for this behavior should be done through the background-attachment CSS attribute and modified under script control by way of the body element's style.backgroundAttachment property.

No matter which way you reference this property, the only allowable values are the string constants scroll (the default) or fixed.

Example

Both of the following statements change the default behavior of background image scrolling in IE4+:

```
document.body.bgProperties = "fixed";
```

or

```
document.body.style.backgroundAttachment = "fixed";
```

The added benefit of using the style sheet version is that it also works in NN6+/Moz and other W3C browsers.

Related Item: body.background property

bottomMargin
leftMargin
rightMargin
topMargin

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The four IE-specific margin properties are alternatives to setting the corresponding four margin style sheet attributes for the body element (body.style.marginBottom, and so on). Style sheet margins represent blank space between the edge of an element's content and its next outermost container. In the case of the body element, that container is an invisible document container.

Of the four properties, only the one for the bottom margin may be confusing, if the content does not fill the vertical space of a window or frame. The margin value is not automatically increased to accommodate the extra blank space.

Example

Both of the following statements change the default left margin in IE4+. The style sheet version has an added benefit — it also works in NN6+/Moz and other W3C browsers.

```
document.body.leftMargin = 30;
```

and

```
document.body.style.marginLeft = 30;
```

Related Item: `style` object

`leftMargin`

(See `bottomMargin`)

`link`

(See `aLink`)

`noWrap`

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `nowrap` property enables you to modify the `body` element behavior normally set through the HTML `nowrap` attribute. Because the property name is a negative, the Boolean logic needed to control it can get confusing.

The default behavior for a `body` element is for text to wrap within the width of the window or frame. This behavior occurs when the value of `noWrap` is its default value of `false`. By turning `noWrap` to `true`, a line of text continues to render past the right edge of the window or frame until the HTML contains a line break (or end of paragraph). If the text continues on past the right edge of the window, the window (or frame) gains a horizontal scroll bar (unless, of course, a frame is set to not scroll).

By and large, users don't like to scroll in any direction if they don't have to. Unless you have a special need to keep single lines intact, let the default behavior rule the day.

Example

To change the word-wrapping behavior from the default, the statement is:

```
document.body.noWrap = true;
```

Related Items: None

`rightMargin`

(See `bottomMargin`)

`scroll`

Value: Constant string Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The IE-specific `scroll` property provides scripted access to the IE-specific `scroll` attribute of a `body` element. By default, an IE `body` element displays a vertical scroll bar even if the height of the content does not warrant it; a horizontal scroll bar appears only when the content is forced to be wider than the window or frame. You can make sure that both scroll bars are hidden by setting the `scroll` attribute to `no` or changing it through a script. Possible values for this property are the constant strings `yes` and `no`.

Except for `frame` attributes and NN4+/Moz-signed scripts, other browsers do not provide facilities for turning off scroll bars under script control. You can generate a new window (via the `window.open()` method) and specify that its scroll bars be hidden.

Example

To change the scroll bar appearance from the default, the statement is:

```
document.body.scroll = "no";
```

Related Items: `window.scrollbars` property; `window.open()` method

scrollLeft
scrollTop

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN7+, Moz+, Safari+, Opera+, Chrome+

Even though the `scrollLeft` and `scrollTop` properties of the `body` object are the same as those for generic HTML element objects, they play an important role in determining the placement of positioned elements (described more fully in Chapter 43). Because the mouse event and element position properties tend to be relative to the visible content region of the browser window, you must take the scrolling values of the `document.body` object into account when assigning an absolute position. Values for both of these properties are integers representing pixels.

Example

Listing 29-18 is an unusual construction that creates a frameset and the content for each of the two frames, all within a single HTML document. In the left frame of the frameset are two fields that are ready to show the pixel values of the right frame's `xOffset` and `yOffset` properties. The content of the right frame is a 30-row table of fixed width (800 pixels). Mouse-click events are captured by the document level (see Chapter 32), allowing you to click any table or cell border, or outside the table, to trigger the `showOffsets()` function in the right frame. That function is a simple script that displays the page offset values in their respective fields in the left frame.

LISTING 29-18

Determining Scroll Values

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Master of all Windows</title>
      <script type="text/javascript">
         function leftFrame()
         {
            var output = "<html><body><h3>Body Scroll Values<\/h3><hr />\n";
            output += "<form>body.scrollLeft:<input type='text' ";
            output += "name='xOffset' size=4 /><br />\n";
            output += "body.scrollTop:<input type='text' ";
            output += "name='yOffset' size=4 /><br />\n";
            output += "<\/form><\/body><\/html>";
```

```
         return output;
      }

      function rightFrame()
      {
         var output = "<html><head><script type='text/javascript'>\n";
         output += "function showOffsets() {\n";
         output += "parent.readout.document.forms[0].xOffset.value ";
         output += "= document.body.scrollLeft\n";
         output += "parent.readout.document.forms[0].yOffset.value ";
         output += "= document.body.scrollTop\n}\n";
         output += "document.onclick = showOffsets\n";
         output += "<\/script><\/head><body><h3>Content Page<\/h3>\n";
         output += "Scroll this frame and click on a table border to view ";
         output += "page offset values.<br /><hr />\n";
         output += "<table border=5 width=800>";
         var oneRow = "<td>Cell 1<\/td><td>Cell 2<\/td><td>Cell ";
         oneRow += "3<\/td><td>Cell 4<\/td><td>Cell 5<\/td>";
         for (var i = 1; i <= 30; i++)
         {
            output += "<tr><td><b>Row " + i + "<\/b><\/td>" + oneRow + "<\/tr>";
         }
         output += "<\/table><\/body><\/html>";
         return output;
      }
   </script>
 </head>
 <frameset cols="30%,70%">
   <frame name="readout" src="javascript:parent.leftFrame()" />
   <frame name="display" src="javascript:parent.rightFrame()" />
 </frameset>
</html>
```

Related Items: `window.pageXOffset`, `window.pageYOffset` properties

`text`

(See `aLink`)

`topMargin`

(See `bottomMargin`)

`vLink`

(See `aLink`)

Methods

`createControlRange()`

Returns: Array

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

This method creates a control range in WinIE5+ browsers. Control ranges are used for control-based selection, as opposed to text-based selection made possible by text ranges. The method only applies to documents in edit mode. In regular document view mode, the `createControlRange()` method returns an empty array.

`createTextRange()`

Returns: Object

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `body` element object is the most common object used to generate a `TextRange` object in IE4+, especially when the text you are about to manipulate is part of the document's body text. The initial `TextRange` object returned from the `createTextRange()` method encompasses the entire `body` element's HTML and body text. Further action on the returned object is required to set the start and end point of the range. See the discussion of the `TextRange` object in Chapter 33 for more details.

Example

See Listing 30-10 for an example of the `createTextRange()` method in action.

Related Item: `TextRange` object (see Chapter 33, "Body Text Objects")

`doScroll(["`*`scrollAction`*`"])`

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Use the `doScroll()` method to simulate user action on the scroll bars inside a window or frame that holds the current document. This method comes in handy if you are creating your own scroll bars in place of the standard system scroll bars. Scrolling is instantaneous, however, rather than animated, even if the Display control panel is set for animated scrolling. The parameter for this method is one of the string constant values shown in Table 29-4. Occasionally, in practice, the longer scroll action names more closely simulate an actual click on the scroll bar component, whereas the shortcut versions may scroll at a slightly different increment.

Unlike scrolling to a specific pixel location (by setting the `body` element's `scrollTop` and `scrollLeft` properties), the `doScroll()` method depends entirely on the spatial relationship between the body content and the window or frame size. Also, the `doScroll()` method triggers the `onscroll` event handler for the `body` element object.

Be aware that scripted modifications to body content can alter these spatial relationships. IE is prone to being sluggish in updating all of its internal dimensions after content has been altered. Should you attempt to invoke the `doScroll()` method after such a layout modification, the scroll may not be performed as expected. You may find the common trick of using `setTimeout()` to delay the invocation of the `doScroll()` method by a fraction of a second.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `doScroll()` method in IE5+. Size the browser window so that at least the vertical scroll bar is active (meaning it has a

thumb region). Enter the following statement into the top text field and press the Enter key a few times to simulate clicking the PgDn key:

```
document.body.doScroll()
```

Return to the top of the page, and now do the same for scrolling by the increment of the scroll bar down arrow:

```
document.body.doScroll("down")
```

TABLE 29-4

document.body.doScroll() Parameters

Long Parameter	Short Parameter	Scroll Action Simulates
`scrollbarDown`	`down`	Clicking the down arrow.
`scrollbarHThumb`	n/a	Clicking the horizontal scroll bar thumb (no scrolling action).
`scrollbarLeft`	`left`	Clicking the left arrow.
`scrollbarPageDown`	`pageDown`	Clicking the page down area or pressing PgDn (default).
`scrollbarPageLeft`	`pageLeft`	Clicking the page left area.
`scrollbarPageRight`	`pageRight`	Clicking the page right area.
`scrollbarPageUp`	`pageUp`	Clicking the page up area or pressing PgUp.
`scrollbarRight`	`right`	Clicking the right arrow.
`scrollbarUp`	`up`	Clicking the up arrow.
`scrollbarVThumb`	n/a	Clicking the vertical scroll bar thumb (no scrolling action).

You can also experiment with upward scrolling. Enter the desired statement in the top text field and leave the text cursor in the field. Manually scroll to the bottom of the page and then press Enter to activate the command.

Event handlers

onafterprint
onbeforeprint
onscroll

(See these event handlers for the `window` object, Chapter 27, “Window and Frame Objects.”)

TreeWalker Object

Property	Method	Event Handler
currentNode	firstChild()	
expandEntityReference	lastChild()	
filter	nextNode()	
root	nextSibling()	
whatToShow	parentNode()	
	previousNode()	
	previousSibling()	

Syntax

Creating a `TreeWalker` object:

```
var treewalk = document.createTreeWalker(document, whatToShow,
   filterFunction, entityRefExpansion);
```

Accessing `TreeWalker` object properties and methods:

```
TreeWalker.property | method([parameters])
```

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

About this object

The `TreeWalker` object serves as a container for a list of nodes that meet the criteria defined by the `document.createTreeWalker()` method, which is used to create the object. The list of nodes contained by a `TreeWalker` object conforms to the same hierarchical structure of the document from which they are referenced. The `TreeWalker` object provides a means of navigating through this list of nodes based on their inherent tree-like structure.

You can think of the `TreeWalker` object as somewhat of an iterator object since its main purpose is to provide a means of stepping through nodes in a list. However, in this case the list is a hierarchical tree, as opposed to a linear list. The `TreeWalker` object maintains a pointer inside the list of nodes that always points to the current node. Whenever you navigate through the list using the `TreeWalker` object, the navigation is always relative to the pointer. For example, referencing the previous or next node through calls to the `previousNode()` or `nextNode()` methods depends upon the current position of the node pointer in the tree.

Use the `document.createTreeWalker()` method to create a `TreeWalker` object for a particular document. This method requires a user function that serves as a filter for nodes selected to be part of the tree. A reference to the function is the third parameter of the method call. The return value of this user function can be one of three constant values, which indicate the status of the current node: `NodeFilter.FILTER_ACCEPT`, `NodeFilter.FILTER_REJECT`,

or `NodeFilter.FILTER_SKIP`. The difference between `NodeFilter.FILTER_REJECT` and `NodeFilter.FILTER_SKIP` is that descendents of skipped nodes may still qualify as part of the tree, whereas rejected nodes and their descendents are excluded altogether. Following is an example of a user function you could use to create a `TreeWalker` object:

```
function ratingAttrFilter(node)
{
   if (node.hasAttribute("rating"))
   {
      return NodeFilter.FILTER_ACCEPT;
   }
   return NodeFilter.FILTER_REJECT;
}
```

In this example function, only nodes containing an attribute named `rating` are allowed through the filter, which means that only those nodes will get added to the list (tree). With this function in place, you then call the `document.createTreeWalker()` method to create the `TreeWalker` object:

```
var myTreeWalker = document.createTreeWalker(document, NodeFilter.SHOW_ELEMENT,
                   ratingAttrFilter, false);
```

Now that the `TreeWalker` object is created, you can use its properties and methods to access individual nodes and navigate through the list.

Properties

currentNode

Value: Node reference Read/Write

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `currentNode` property returns a reference to the current node, which sits at the location of the tree's node pointer. Although you can use the `currentNode` property to access the current node, you can also use it to set the current node.

Example

To assign a node to the current position in the tree, just create an assignment statement using the `currentNode` property:

```
myTreeWalker.currentNode = document.getElementById("info");
```

Related Item: `root` property

expandEntityReference
filter
root
whatToShow

Value: See text Read-Only

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

These properties reflect the parameter values passed into the `document.createTreeWalker()` method upon the creation of the `TreeWalker` object.

Related Item: `document.createTreeWalker()` method

Methods

firstChild()
lastChild()
nextSibling()
parentNode()
previousSibling()

Returns: Node reference

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

These methods return references to nodes within the hierarchy of the tree-like list of nodes contained by the `TreeWalker` object. There is a parent-child relationship among all of the nodes in the tree, and these functions are used to obtain node references based upon this relationship. The node pointer within the tree moves to the new node whenever you use one of these methods to navigate to a given node. This means you can access the new node as the current node after calling one of these navigation methods.

Example

The following code shows how to obtain the tag name of the parent node of the current node in the `TreeWalker` object:

```
if (myTreeWalker.parentNode())
{
   var parentTag = myTreeWalker.currentNode.tagName;
}
```

Related Items: `nextNode()`, `previousNode()` methods

nextNode()
previousNode()

Returns: Node reference

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `nextNode()` and `previousNode()` methods navigate back and forth in the list of nodes contained by the `TreeWalker` object. It's important to note that these methods operate on the node list as if it had been flattened from a tree into a linear sequence of nodes. Both methods move the internal node pointer to the next or previous node, respectively.

Example

The following code demonstrates both the node filter function and a typical function you could use to display (in a series of alert windows, perhaps for debugging purposes) the IDs of all elements

inside the body that have `id` attributes assigned. The `nextNode()` method is called first to advance the `TreeWalker`'s node pointer to the first node of the collection, and then iteratively (inside a `do-while` construction) to obtain the next node that passes the node filter's test.

```
function idFilter(node)
{
   if (node.hasAttribute("id"))
   {
      return NodeFilter.FILTER_ACCEPT;
   }
   return NodeFilter.FILTER_SKIP;
}

function showIds()
{
   var tw =
   document.createTreeWalker(document.body, NodeFilter.SHOW_ELEMENT,
      idFilter, false);
   // make sure TreeWalker contains at least one node, and go to it if true
   if (tw.nextNode())
   {
      do
      {
         alert(tw.currentNode.id);
      } while (tw.nextNode());
   }
}
```

Related Item: `parentNode()` method

CHAPTER

30

Link and Anchor Objects

IN THIS CHAPTER

Differences among link, anchor, and a element objects

Scripting a link to invoke a script function

Scripting a link to swap an image on mouse rollovers

The Web is based on the notion that the world's information can be strung together by way of the *hyperlink* — the clickable hunk of text or image that enables an inquisitive reader to navigate to a further explanation or related material. Of all the document objects you work with in JavaScript, the link is the one that makes that connection. Anchors provide guideposts to specific locations within documents.

As scriptable objects going back to the first scriptable browsers, links and anchors are comparatively simple devices. But this simplicity belies their significance in the entire scheme of the Web. Under script control, links can be far more powerful than mere tethers to locations on the Web.

In modern browsers, the notion of separating links and anchors as similar yet distinctly different objects begins to fade. The association of the word *link* with objects is potentially confused by the newer browsers' recognition of the `link` element (see Chapter 40, "HTML Directive Objects"), which has an entirely different purpose as a scriptable object. Taking the place of the anchor and link objects is an HTML element object representing the element created by the `<a>` tag. As an element object, the `a` element assumes all the properties, methods, and event handlers are associated with all HTML element objects in modern object models. To begin making that transition, this chapter treats all three types of objects at the same time.

Anchor, Link, and a Element Objects

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Syntax

Accessing Link Object Properties:

```
(all)      [window.]document.links[index].property
```

Accessing a element object properties:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
    method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

A little scripting history can help you understand where the link and anchor objects came from and how the `a` element object evolved from them.

Using the terminology of the original object model, the anchor and link objects are both created in the object model from the `<a>` tag. What distinguishes a link from an anchor is the presence of the `href` attribute in the tag. Without an `href` attribute, the element is an anchor object, which has only a single property (`name`) in modern browsers. A link, on the other hand, is much more alive as an object — all because of the inclusion of an `href` attribute, which usually points to a URL to load into a window or frame.

When object models treat HTML elements as objects, both the anchor and link objects are subsumed by the `a` element object. Even so, one important characteristic from the original object holds true: All `a` element objects that behave as link objects (by virtue of the presence of an `href` attribute) are members of the `document.links` property array. Therefore, if your scripts need to inspect or modify properties of all link objects on a page, they can do so by way of a `for` loop through the array of link objects. This is true even if you script solely for modern browsers and want to, say, change a style attribute of all links (for example, change their `style.textDecoration` property from `none` to `underline`). The fact that the same element can have different behaviors depending on the existence of one attribute makes us think of the `a` element object as potentially two different animals. Therefore, when you see separate references to the link and anchor objects, you know the distinction between the two is important.

Scripting newcomers are often confused about the purpose of the `target` attribute of an `a` element when they want a scripted link to act on a different frame or window. Under plain HTML, the `target` attribute points to the frame or window into which the new document (the one assigned to the `href` attribute) is to load, leaving the current window or frame intact. But if you intend to use event handlers to navigate (by setting the `location.href` property), the `target` attribute does not apply to the scripted action. Instead, assign the new URL to the `location.href` property of the desired frame or window. For example, if one frame contains a table of contents consisting entirely of links, the `onclick` event handlers of those links can load other pages into the `main` frame by assigning the URL to the `parent.main.location.href` property. You must also cancel the default behavior of any link, as described in the discussion of the generic `onclick` event handler in Chapter 26.

When you want a click of the link (whether the link consists of text or an image) to initiate an action without actually navigating to another URL, you can use a special technique — the `javascript:` pseudo-URL — to direct the URL to a JavaScript function. The URL `javascript:functionName()` is a valid parameter for the `href` attribute (and not just in the link object). You can also add a special `void` operator that guarantees that the called function does not trigger any true linking action (`href="javascript: void someFunction()"`). Specifying an empty string for the `href` attribute yields an FTP-like file listing for the client computer — an undesirable artifact. Don't forget, too, that if the URL leads to a type of file that initiates a browser helper application (for example, playing a QuickTime movie), the helper app or plug-in loads and plays without changing the page in the browser window.

Note

Usage of the `javascript:` pseudo-URL is controversial. There is no published industry standard that supports it, even though most browsers do. It is also unfriendly to users who visit the page with scripting disabled or unavailable (for example, browsers designed for visually impaired users), because the links won't do anything, leading to frustration. You should also be aware that search engines won't follow these types of links when they work their way through a site. ■

A single link can change the content of more than one frame at the same time with the help of JavaScript. If you want only JavaScript-enabled browsers to act on such links, one approach is to use a `javascript:` pseudo-URL to invoke a function that changes the `location.href` properties of multiple frames. For example, consider the following function, which changes the content of two frames:

```
function navFrames(url1, url2)
{
   parent.product.location.href = url1;
   parent.accessories.location.href = url2;
}
```

Then you can have a `javascript:` pseudo-URL invoke this multipurpose function, and pass the specifics for the link as parameters:

```
<a href="javascript: void navFrames('products/gizmo344.html',
 'access/access344.html')">Deluxe Super Gizmo</a>
```

Or, if you want one link to do something for everyone, but something extra for JavaScript-enabled browsers (an approach that is desirable when designing a page for accessibility), you can combine the standard link behavior with an `onclick` event handler to take care of both situations:

```
function setAccessFrame(url)
{
   parent.accessories.location.href = url;
}
...
<a href="products/gizmo344.html" target="product"
onclick="setAccessFrame('access/access344.html')">Deluxe Super Gizmo</a>
```

Note

The property assignment event handling technique in the previous example is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) method. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." ■

Notice here that the `target` attribute is necessary for the standard link behavior, whereas the script assigns a URL to a frame's `location.href` property.

One additional technique allows a single link tag to operate for both scriptable and nonscriptable browsers. For nonscriptable browsers, establish a genuine URL to navigate from the link. Then make sure that the link's `onclick` event handler evaluates to `return false` or cancels the default action. At click time, a scriptable browser executes the event handler and ignores the `href` attribute; a non-scriptable browser ignores the event handler and follows the link. See the discussion of the generic `onclick` event handler in Chapter 26 for more details.

Properties

charset

Value: String Read/Write

Compatibility: WinIE6+, MacIE6+, NN6+, Moz+, Safari+, Opera+, Chrome+

The charset property represents the HTML 4 charset attribute of an a element. It advises the browser of the character set used by the document to which the href attribute points. The value is a string of one of the character set codes from the registry at http://www.iana.org/assignments/character-sets. The most commonly used character set on the Web is called ISO-8859-5.

coords
shape

Value: Strings Read/Write

Compatibility: WinIE6+, MacIE6+, NN6+, Moz+, Safari+, Opera+, Chrome+

HTML 4 provides specifications for a elements that accommodate different shapes (rect, circle, and poly) and coordinates when the link surrounds an image. Although the coords and shape properties are present for a element objects in all W3C DOM–compatible browsers, active support for the feature is not present in NN6.

hash
host
hostname
pathname
port
protocol
search

Value: Strings Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

This large set of properties is identical to the same-named properties of the location object (see Chapter 28, "Location and History Objects"). All properties are components of the URL that is assigned to the link object's href attribute. Although none of these properties appears in the W3C DOM specification for the a element object, the properties survive in modern browsers for backward compatibility. If you want to script the change of the destination for a link, try modifying the value of the object's href property, rather than modifying individual components of the URL.

Related Item: location object

href

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The href property (included in the W3C DOM) is the URL of the destination of an a element equipped to act as a link. URLs can be relative or absolute.

In W3C DOM–compatible browsers, you can turn an anchor object into a link object by assigning a value to the href property, even if the a element has no href attribute in the HTML that loads from the server. Naturally, this conversion is temporary, and it lasts only as long as the page is loaded in the browser. When you assign a value to the href property of an a element that surrounds text, the text assumes the appearance of a link (either the default appearance or whatever style you assign to links).

Related Item: location object

hreflang

Value: String Read/Write

Compatibility: WinIE6+, MacIE6+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `hreflang` property advises the browser (if the browser takes advantage of it) about the written language used for the content to which the `a` element's `href` attribute points. Values for this property must be in the form of the standard language codes (for example, `en-us` for U.S. English).

Methods

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `Methods` property (note the uppercase *M*) represents the HTML 4 `methods` attribute for an `a` element. Values for this attribute and property serve as advisory instructions to the browser about which HTTP method(s) to use for accessing the destination document. This is a rare case in which an HTML 4 attribute is not echoed in the W3C DOM. In any case, although IE4+ supports the property, the IE browsers do nothing special with the information.

mimeType

Value: String Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

This property is used to obtain the MIME type of the document linked to by the `a` element. The HTML 4 and W3C DOM specifications define a `type` attribute and `type` property, instead of `mimeType`. The property is a read-only property and, therefore, has no control over the MIME type of the destination document. Interestingly, the IE8 MSDN documentation for the `a` object does not list this attribute, although IE8 does continue to support it.

Related Item: `a.type` property

name

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Although a `name` attribute is optional for an `a` element serving solely as a link object, it is required for an anchor object. This value is exposed to scripting via the `name` property. Although it is unlikely that you will need to change the value by scripting, you can use this property as a way to identify a link object from among the `document.links` arrays in a repeat loop. For example:

```
for (var i = 0; i < document.links.length; i++)
{
   if (document.links[i].name == "bottom"
   {
      // statements dealing with the link named "bottom"
   }
}
```

If this code makes it inside the `if` clause, you know you've found a link with the name `bottom`.

nameProp

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-

The IE-specific `nameProp` property is a convenience property that retrieves the segment of the `href` to the right of the rightmost forward slash character of the URL. Most typically, this value is the name of the file from a URL. But if the URL also includes a port number, that number is returned as part of the `nameProp` value.

rel
rev

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `rel` and `rev` properties define relationships in the forward and back directions with respect to the destination document of the `a` element. In other words, you're describing how a link relates to the document to which it points, as well as how the document relates back. For example, in a table-of-contents page, each link to a chapter might have its `rel` attribute set to `chapter`, whereas its `rev` attribute might be set to `contents`. Browsers have yet to exploit most of the potential of these attributes and properties.

A long list of values is predefined for these properties, based on the corresponding attribute values specified in HTML 4. If the browser does nothing with a particular value, the value is ignored. You can string together multiple values in a space-delimited list inside a single string. Accepted values are as follows:

alternate	contents	index	start
appendix	copyright	next	stylesheet
bookmark	glossary	prev	subsection
chapter	help	section	

target

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

An important property of the link object is the `target`. This value reflects the window name supplied to the `target` attribute in the `a` element.

You can temporarily change the target for a link. But as with most transient object properties, the setting does not survive soft reloads. Rather than alter the target this way, you can safely force the target change by letting the `href` attribute call a `javascript:functionName()` psuedo-URL in which the function assigns a document to the desired `window.location`. If you have done extensive HTML authoring before, you will find it hard to break the habit of relying on the `target` attribute.

Another drawback to the `target` attribute is the fact that it isn't supported by the strict XHTML DTD. So if you develop XHTML pages that must validate with the strict DTD, you will not be able

to include a `target` attribute in your `<a>` tags. Instead, use the page's `onload` event handler or the `a` element's `onclick` event handler to invoke a function that assigns the desired value to the `target` property. In this case, you are using a JavaScript property to sidestep a limitation associated with an HTML attribute.

Related Item: `document.links` property

type

Value: String　　　　Read/Write

Compatibility: WinIE6+, MacIE6+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `type` property represents the HTML 4 `type` attribute, which specifies the MIME type for the content of the destination document to which the element's `href` attribute points. This is primarily an advisory property for browsers that wish to, say, display different cursor styles based on the anticipated type of content at the other end of the link. Thus far, browsers do not take advantage of this feature. However, you can assign MIME type values to the attribute (for example, `video/mpeg`) and let scripts read those values for making style changes to the link text after the page loads. IE4+ also implements a similar property in the `mimeType` property.

Related Item: `a.mimeType` property

urn

Value: String　　　　Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `urn` property represents the IE-specific `URN` attribute, which enables authors to use a URN (Uniform Resource Name) for the destination of the `a` element. (See `http://www.ietf.org/rfc/rfc2141.txt` for information about URNs.) This property is not in common use.

CHAPTER

31

Image, Area, Map, and Canvas Objects

IN THIS CHAPTER

How to pre-cache images

Swapping images after a document loads

Creating interactive, client-side image maps

Drawing vector graphics with a canvas

For modern web browsers, images and areas — those items created by the `<img>` and `<area>` tags — are first-class objects that you can script for enhanced interactivity. You can swap the image displayed in an `<img>` tag with other images, perhaps to show the highlighting of an icon button when the cursor rolls atop it. And with scriptable client-side area maps, pages can be smarter about how they respond to users' clicks on image regions.

One further benefit afforded scripters is that they can preload images into the browser's image cache as the page loads. With cached images, the user experiences no delay when the first swap occurs. The need for this capability has diminished slightly with higher bandwidth connections, but it still isn't a bad idea for those users who still rely on connections with speed limitations.

New on the graphical JavaScript scene is the notion of a canvas, which is a graphical region that you can use to carry out graphics operations via JavaScript code. A few browsers already support canvases, so you can get started tinkering with them now.

Image and img Element Objects

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Syntax

Creating an `Image` object:

```
imageObject = new Image([pixelWidth, pixelHeight]);
```

Accessing `img` element and `Image` object properties or methods:

```
(NN3+/IE4+)   [window.]document.imageName. property | method([parameters])
(NN3+/IE4+)   [window.]document.images[index]. property | method([parameters])
(NN3+/IE4+)   [window.]document.images["imageName"]. property |
              method([parameters])
(IE4+)        [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)    [window.]document.getElementById("elemID").property |
              method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

Before getting into detail about images as objects, it's important to understand the distinction between instances of the static `Image` object and `img` element objects. The former exist only in the browser's memory without showing anything to the user; the latter are the elements on the page generated via the `<img>` (or nonsanctioned, but accepted, `<image>`) tag. Scripts use instances of the `Image` object to pre-cache images for a page, but `Image` object instances obviously have fewer applicable properties, methods, and event handlers because they are neither visible on the page nor influenced by tag attributes.

The primary advantage of treating `img` elements as objects is that scripts can change the image that occupies the `img` object's space on the page, even after the document has loaded and displayed an initial image. The key to this scriptability is the `src` property of an image.

In a typical scenario, a page loads with an initial image. That image's tags specify any of the extra attributes, such as `height` and `width` (which help speed the rendering of the page), and specify whether the image uses a client-side image map to make it interactive. (See the `area` object later in this chapter.) As the user spends time on the page, the image can then change (perhaps in response to user action or some timed event in the script), replacing the original image with a new one in the same space. In legacy browsers that support the `img` element object, the height and width of the initial image that loads into the element establishes a fixed-sized rectangular space for the image. Attempts to fit an image of another size into that space forces the image to scale (up or down, as the case may be) to fit the rectangle. But in modern browsers (IE4+/Moz/W3C), a change in the image's size is reflected by an automatic reflow of the page content around the different size. Of course, you might not consider this desirable and choose to pre-size your images to the same size to avoid the automatic reflow of the page content.

The benefit of separate instances of the `Image` object is that a script can create a virtual image to hold a preloaded image. (The image is loaded into the image cache but the browser does not display the image.) The hope is that one or more unseen images will load into memory while the user is busy reading the page or waiting for the page to download. Then, in response to user action on the page, an image can change instantaneously rather than forcing the user to wait for the image to load on demand.

To preload an image, begin by assigning a new, empty `Image` object to a global variable. The new image is created via the constructor function available to the `Image` object:

```
var imageVariable = new Image(width, height);
```

You help the browser allocate memory for the image if you provide the pixel height and width of the pre-cached image as parameters to the constructor function. All that this statement does is create an object in memory whose properties are all empty. To force the browser to load the image into the cache, assign an image file URL to the object's `src` property:

```
var oneImage = new Image(55,68);
oneImage.src = "neatImage.gif";
```

As this image loads, you see the progress in the status bar, just like you would with any image. Later, assign the `src` property of this stored image to the `src` property of the `img` element object that appears on the page:

```
document.images["someImage"].src = oneImage.src;
```

Depending on the type and size of image, you will be amazed at the speedy response of this kind of loading. With small-palette graphics, the image displays instantaneously.

A popular user-interface technique is to change the appearance of an image that represents a clickable button when the user rolls the mouse pointer atop the art. This action assumes that a mouse event fires on an element associated with the object. Image rollovers are most commonly accomplished in two different image states: normal and highlighted. But you may want to increase the number of states to more closely simulate the way clickable buttons work in application programs. In some instances, a third state signifies that the button is switched on. For example, if you use rollovers in a frame for navigational purposes, and the user clicks a button to navigate to the Products area, that button stays selected but in a different style than the rollover highlights. Some designers go one step further by providing a fourth state that appears briefly when the user mouses down an image. Each one of these states requires the download of yet another image, so you have to gauge the effect of the results against the delay in loading the page.

The speed with which image swapping takes place may lead you to consider using this approach for animation. Though this approach may be practical for brief bursts of animation, the many other ways of introducing animation to your web page (such as via GIF89a-standard images, Flash animations, Java applets, and a variety of plug-ins) produce animation that offers better speed control. In fact, swapping preloaded JavaScript image objects for some cartoon-like animations may be too fast. You can build a delay mechanism around the `setInterval()` method, but the precise timing between frames varies with client processor performance.

All browsers that implement the `img` element object also implement the `document.images` array. You can (and probably should) use the availability of this array as a conditional switch before any script statements that work with the `img` element or `Image` object. The construction to use is as follows:

```
if (document.images)
{
   // statements working with images as objects
}
```

Earlier browsers treat the absence of this array as the equivalent of `false` in the `if` clause's conditional statement.

Most of the properties discussed here mirror attributes of the `img` HTML element. For more details on the meanings and implications of attribute values on the rendered content, consult the HTML 4.01 specification (`http://www.w3.org/TR/html4/`), the HTML 5 specification (`http://www.w3.org/TR/html5/`), and Microsoft's extensions for IE (`http://msdn.microsoft.com/en-us/library/ms535259%28VS.85%29.aspx`).

Properties

align

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `align` property defines how the image is oriented in relation to surrounding text content. It is a double-duty property because you can use it to control the vertical or horizontal alignment, depending on the value (and whether the image is influenced by a `float` style attribute). Values are string constants, as follows:

```
absbottom    middle
absmiddle    right
baseline     texttop
bottom       top
left
```

The default alignment for an image is `bottom`. Increasingly, element alignment is handed over to style sheet control. (This is reflected in the corresponding `alignment` attribute's deprecation in HTML 4.01 and nonexistence in HTML 5.) In modern web pages, designers are encouraged to use style sheets, as opposed to element attributes, for presentation details such as alignment.

Listing 31-1 enables you to choose from the different `align` property values as they influence the layout of an image whose HTML is embedded inline with some other text. Resize the window to see different perspectives on word-wrapping on a page and their effects on the alignment choices. Not all browsers provide distinctive alignments for each choice, so experiment in multiple supported browsers.

LISTING 31-1

Testing an Image's align Property

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>img align Property</title>
      <script type="text/javascript">
      function setAlignment(sel)
      {
         document.getElementById("myIMG").align =
            sel.options[sel.selectedIndex].value;
      }
      </script>
   </head>
   <body>
      <h1>img align Property</h1>
      <hr />
      <form>
         Choose the image alignment: <select onchange="setAlignment(this)">
            <option value="absbottom">absbottom</option>
            <option value="absmiddle">absmiddle</option>
```

continued

LISTING 31-1 *(continued)*

```
          <option value="baseline">baseline</option>
          <option value="bottom" selected="selected">bottom</option>
          <option value="left">left</option>
          <option value="middle">middle</option>
          <option value="right">right</option>
          <option value="texttop">texttop</option>
          <option value="top">top</option>
        </select>
      </form>
      <hr />
      <p>Lorem ipsum dolor sit amet, consectetaur adipisicing elit, sed do
        eiusmod tempor incididunt ut labore et dolore magna aliqua.
        <img alt="image" id="myIMG" src="desk1.gif" height="90" width="120" />
        Ut enim adminim veniam, quis nostrud exercitation ullamco laboris nisi ut
        aliquip ex ea commodo consequat.</p>
    </body>
  </html>
```

Related Items: `text-align`, `float` style sheet attributes

alt

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `alt` property enables you to set or modify the text that the browser displays in the image's rectangular space (if height and width are specified in the tag) before the image downloads to the client. Also, if a browser has images turned off (or is incapable of displaying images), the `alt` text helps users identify what is normally displayed in that space. In IE, the `alt` text is displayed when you mouse over the image. You can modify this `alt` text even after the page loads.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to assign a string to the `alt` property of the `document.myIMG` image on the page. First, assign a nonexistent image to the `src` property to remove the existing image:

```
document.myIMG.src = "fred.gif"
```

Scroll down to the image, and you can see that the original image has been replaced with a space for the new, nonexistent, image. Now, assign a string to the `alt` property:

```
document.myIMG.alt = "Fred\'s face"
```

The extra backslash is required to escape the apostrophe inside the string. Scroll down to see the new `alt` text in the image space. This simple test in The Evaluator will work in most browsers. In some browsers, such as Firefox, it will appear to not work. Browsers such as Firefox support

the properties in question, but since the new image is nonexistent, it doesn't replace the original image; because the original image isn't broken, you won't see the effect of changing the alt property.

Related Item: title property

border

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The border property defines the thickness in pixels of a border around an image. Remember that if you wrap an image inside an a element to make use of the mouse events (for rollovers and such), be sure to set the border=0 attribute of the <img> tag to prevent the browser from generating the usual link type of border around the image. Even though the default value of the attribute is zero, surrounding the image with an a element or attaching the image to a client-side image map puts a border around the image.

As with the alignment property, an element's border is increasingly handed over to style sheet control. (This is reflected in the corresponding border attribute's nonexistence in HTML 5.) In modern web pages, designers are encouraged to use style sheets as opposed to element attributes for presentation details such as borders.

Example

Feel free to experiment with the document.myIMG.border property for the image in The Evaluator (Chapter 4, "JavaScript Essentials") by assigning different integer values to the property.

Related Items: isMap, useMap properties

complete

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Sometimes you may want to make sure that an image is not still in the process of loading before allowing another process to take place. This situation is different from waiting for an image to load before triggering some other process (which you can do via the Image object's onload event handler). To verify that the img object displays a completed image, check for the Boolean value of the complete property. To verify that a particular image file has loaded, first find out whether the complete property is true; then compare the src property against the desired filename.

An image's complete property switches to true even if only the specified lowsrc image has finished loading. Do not rely on this property alone for determining whether the src image has loaded if both src and lowsrc attributes are specified in the <img> tag.

One of the best ways to use this property is in an if construction's conditional statement:

```
if (document.myImage.complete)
{
    // statements that work with document.myImage
}
```

***imageObject*.complete**

To experiment with the `image.complete` property, run Listing 31-2. Click the Load NASA Image button. As the image loads, click the Is "it loaded yet?" button to see the status of the `complete` property for the `Image` object. The value is `false` until the loading finishes; then, the value becomes `true`. We deliberately chose to load a large image directly from the NASA web site so that you would have plenty of time to click the "Is it loaded yet?" button several times in order to see the behavior of the `complete` property. You may have to quit and relaunch your browser between trials to clear the image from the cache (or empty the browser's memory cache) if you've been visiting the NASA web site's image gallery.

LISTING 31-2

Scripting image.complete

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>The Complete Property</title>
      <script type="text/javascript">
      function loadIt()
      {
         document.getElementById("result").value = "";
         document.getElementById("theImage").src =
           "http://www.nasa.gov/images/content/402217main_ssc2008-01b_full.jpg" ;
      }
      function checkLoad()
      {
         document.getElementById("result").value =
            document.getElementById("theImage").complete;
      }
      </script>
   </head>
   <body>
      <img id="theImage" alt="image" width="120" height="90" />
      <form>
         <input type="button" value="Load NASA image"
                onclick="loadIt();" />
         <p><input type="button" value="Is it loaded yet?"
                   onclick="checkLoad();" />
            <input id="result" type="text" />
         </p>
         <input type="reset" />
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique in the previous example is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Events Objects." ■

Related Items: `img.src`, `img.lowsrc`, `img.readyState` properties; `onload` event handler

dynsrc

Value: URL string Read/Write

Compatibility: WinIE4-6, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `dynsrc` property is a URL to a video source file, which (in IE) you can play through an `img` element. You can turn a space devoted to a static image into a video viewer by assigning a URL of a valid video source (for example, an `.avi` or `.mpg` file) to the `dynsrc` property of the image element object. Unlike the `src` property of image objects, assigning a URL to the `dynsrc` property does not pre-cache the video.

You may experience buggy behavior in various IE versions when you assign a value to an image's `dynsrc` property after the `img` element renders a `.gif` or `.jpg` image. In WinIE5, the status bar indicates that the video file is still downloading, even though the download is complete. Clicking the Stop button has no effect. WinIE5.5+ may not even load the video file, leaving a blank space, although the property does store the value of the URL. MacIE5 changes between static and motion images with no problems, but playing the video file multiple times causes the `img` element to display black space beyond the element's rectangle.

Related Items: `img.loop`, `img.start` properties

fileCreatedDate
fileModifiedDate
fileUpdatedDate
fileSize

Value: String, Integer (`fileSize`) Read-Only

Compatibility: WinIE4+, MacIE5+, NN-, Moz-, Safari-, Opera-, Chrome-

These four IE-specific properties return information about the file displayed in the `img` element (whether it's a still or animated image). Three of the properties reveal the dates on which the current image's file was created, modified, and updated. For an unmodified file, its creation and modified dates are the same. The updated date of an image is the date on which the image file was last uploaded to the server; the `fileUpdatedDate` property is only supported on WinIE5.5+ and MacIE5. The `fileSize` property reveals the number of bytes of the file.

Date values returned for the first two properties are formatted differently between IE4 and IE5. The former provides a full readout of the day and date; the latter returns a format similar to mm/dd/yyyy. Note, however, that the values contain only the date and not the time. In any case, you can use the values as the parameter to a `new Date()` constructor function. This enables you to then use date calculations for such information as the number of days between the current day and the most recent modification.

Not all servers provide the proper date or size information about a file or in a format that IE can interpret. Test your implementation on the deployment server to ensure compatibility.

Also, be aware that these properties can be read-only for a file that is loaded in the browser. JavaScript by itself cannot get this information about files on the server.

Note

All of these file-related properties are present in the Mac version of IE, but the values are empty. ■

Example

These properties are similar to the same-named properties of the `document` object. You can see these properties in action in Listing 29-4. Make a copy of that listing, and supply an image before modifying the references from the `document` object to the `Image` object to see how these properties work with the `img` element object.

Or, just test them out one at a time using an existing image in the Evaluator (Chapter 4, "JavaScript Essentials"):

```
document.getElementById("myIMG").fileSize
```

Related Items: None

height
width

Value: Integer Read/Write (see text)

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The `height` and `width` properties return and control the pixel height and width of an image object. The property is read/write in all modern browsers that support the `img` element object. However, the net effect of changing these properties varies from browser to browser. For example, if you adjust the `height` property of an image in Mozilla, the browser automatically scales the image within the same proportions as the original. But adjusting the `width` property has no effect on the `height` property. In IE7, the opposite effect is true in regard to `width` and `height`. Any time an image is scaled dynamically, unwanted pixelation can occur in the image, so modify an image's size with extreme care.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `height` and `width` properties. Begin retrieving the default values by entering the following two statements into the top text box:

```
document.myIMG.height
document.myIMG.width
```

Increase the height of the image from its default 90 to 180:

```
document.myIMG.height = 180
```

Next, exaggerate the width:

```
document.myIMG.width = 400
```

View the resulting image.

Related Items: `hspace`, `vspace` properties

`href`

(See `src` property)

`hspace`
`vspace`

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The `hspace` and `vspace` properties control the pixel width of a transparent margin surrounding an image. Specifically, `hspace` controls the margins at the left and right of the image; `vspace` controls the top and bottom margins. Images, by default, have margins of zero pixels.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `hspace` and `vspace` properties. Begin by noticing that the image near the bottom of the page has no margins specified for it and is flush left with the page. Now assign a horizontal margin spacing of 30 pixels:

```
document.myIMG.hspace = 30
```

The image has shifted to the right by 30 pixels. An invisible margin also exists to the right of the image.

Related Items: `height`, `width` properties

`isMap`

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+ Opera+, Chrome+

The `isMap` property enables you to set whether the image should act as a server-side image map. When set as a server-side image map, pixel coordinates of the click are passed as parameters to whatever link `href` surrounds the image. For client-side image maps, see the `useMap` property later in this chapter.

Example

The image in The Evaluator page is not defined as an image map. Thus, if you type the following statement into the top text box, the property returns `false`:

```
document.myIMG.isMap
```

Related Item: `img.useMap` property

`longDesc`

Value: URL string Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `longDesc` property is a URL of a file that is intended to provide a detailed description of the image associated with the `img` element. Current browsers recognize this property, but do not do anything special with the information — whether specified by script or the `longdesc` attribute.

Related Item: `alt` property

loop

Value: Integer Read/Write

Compatibility: WinIE4-6, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `loop` property represents the number of times a video clip playing through the `img` element object should run. After the video plays that number of times, only the first frame of the video appears in the image area. The default value is `1`; but if you set the value to `-1`, the video plays continuously. Unfortunately, setting the property to `0` prior to assigning a URL to the `dynsrc` property does not prevent the movie from playing at least once (except on the Mac, as noted in the `dynsrc` property discussion earlier in this chapter).

Related Item: `dynsrc` property

lowsrc
lowSrc

Value: URL string Read/Write

Compatibility: WinIE4+, MacIE4+, NN3+, Moz-, Safari-, Opera-, Chrome-

For image files that take several seconds to load, modern browsers enable you to specify a lower-resolution image, or some other quick-loading placeholder, to stand in while the big image crawls to the browser. You assign this alternate image via the `lowsrc` attribute in the `<img>` tag. The attribute is reflected in the `lowsrc` property of an image object. While all modern browsers enable you to specify this property or its corresponding HTML attribute, only IE actually displays the specified image.

All compatible browsers recognize the all-lowercase version of this property. NN6 also recognizes a camelCase "S" version of the property, `lowSrc`.

Be aware that in some browsers if you assign a URL to the `lowsrc` attribute, the `complete` property switches to `true` and the `onLoad` event handler fires when the alternate file finishes loading: The browser does not wait for the main `src` file to load.

Example

See Listing 31-4 for the `Image` object's `onload` event handler to see how the source-related properties affect event processing.

Related Items: `img.src`, `img.complete` properties

mimeType

Value: String Read-Only

Compatibility: WinIE6+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `mimeType` property returns a plain-language description of the MIME type for the image, such as `JPEG Image` or `GIF Image`.

Example

You can use the `mimeType` property in Internet Explorer to determine the format of an image, as the following example demonstrates:

```
if (document.myIMG.mimeType.indexOf("JPEG") != -1) {
   // Carry out JPEG-specific processing
}
```

In this example, the `indexOf()` method is used to check for the presence of the phrase `"JPEG"` anywhere in the MIME type string. This works because the string returned in the `mimeType` property for JPEG images is `JPEG Image`.

Related Items: None

`name`

Value: Identifier string Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+ Opera+, Chrome+

The `name` property returns the value assigned to the `name` attribute of an `img` element. Modern browsers allow you to use the ID of the element (`id` attribute) to reference the `img` element object via `document.all` (IE) and `document.getElementById()`. But references in the form of `document.imageName` and `document.images[imageName]` must use only the value assigned to the `name` attribute.

In some designs, it may be convenient to assign numerically sequenced names to `img` elements, such as `img1`, `img2`, and so on. As with any scriptable identifier, the name cannot begin with a numeric character. Rarely, if ever, will you need to change the name of an `img` element object.

Example

You can use The Evaluator (Chapter 4, "JavaScript Essentials") to examine the value returned by the `name` property of the image on that page. Enter the following statement into the top text box:

```
document.myIMG.name
```

Of course, this is redundant because the name is part of the reference to the object.

Related Item: `id` property

`nameProp`

Value: Filename string Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Unlike the `src` property, which returns a complete URL in IE, the IE `nameProp` property returns only the filename, exclusive of protocol and path. If your image-swapping script needs to read the name of the file currently assigned to the image (to determine which image to show next), the `nameProp` property makes it easier to get the actual filename without having to perform extensive parsing of the URL.

Example

You can use The Evaluator Sr. (Chapter 4, "JavaScript Essentials") to compare the results of the `src` and `nameProp` properties in WinIE5+. Enter each of the following statements into the top text box:

```
document.myIMG.src
document.myIMG.nameProp
```

Related Item: `img.src` property

naturalHeight
naturalWidth

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera-, Chrome+

The `naturalHeight` and `naturalWidth` properties return the unscaled height and width of the image, in pixels. These properties are useful in situations where script code or `img` element attributes have scaled an image and you wish to know the image's original size.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `naturalHeight` and `naturalWidth` properties in a Mozilla-based or WebKit-based browser. Begin retrieving the default values by entering the following statement into the top text box:

```
document.myIMG.width
```

Increase the width of the image from its default 120 to 200:

```
document.myIMG.width = 200
```

If you scroll down to the image, you see that the image has scaled in proportion. You can now find out the natural width of the original image by taking a look at the `naturalWidth` property:

```
document.myIMG.naturalWidth
```

The Evaluator will reveal 120 as the natural image width even though the image is currently scaled to 200.

Related Items: `img.height`, `img.width` properties

protocol

Value: String Read-Only

Compatibility: WinIE4+, MacIE5+, NN-, Moz-, Safari-, Opera-, Chrome-

The IE `protocol` property returns only the protocol portion of the complete URL returned by the `src` property. This allows your script, for example, to see if the image is sourced from a local hard drive or a web server. Values returned are not the actual protocol strings; rather, they are descriptions thereof: `HyperText Transfer Protocol` or `File Protocol`.

Example

You can use The Evaluator Sr. (Chapter 4, "JavaScript Essentials") to examine the `protocol` property of the image on the page. Enter the following statement into the top text box:

```
document.myIMG.protocol
```

Related Items: `img.src`, `img.nameProp` properties

src

Value: URL string Read/Write

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

The `src` property is the gateway to precaching images (in instances of the `Image` object that are stored in memory) and performing image swapping (in `img` element objects). Assigning a URL to the `src` property of an image object in memory causes the browser to load the image into the browser's cache (provided the user has the cache turned on). Assigning a URL to the `src` property of an `img` element object causes the element to display the new image. To take advantage of this powerful combination, you preload alternate versions of swappable images into image objects in memory and then assign the `src` property of the `Image` object to the `src` property of the desired `img` element object.

In legacy browsers, the size of the image defined by the original `img` element governs the rectangular space devoted to that image. An attempt to assign an image of a different size to that `img` element object causes the image to rescale to fit the rectangle (usually resulting in a distorted image). In all modern browsers, however, the `img` element object resizes itself to accommodate the image, and the page content reflows around the new size.

Note that when you read the `src` property, it returns a fully formed URL of the image file, including protocol and path. This often makes it inconvenient to let the name of the file guide your script in swapping images in a sequence of your choice. Some other mechanism (such as storing the current filename in a global variable) may be easier to work with (also see the WinIE5+ `nameProp` property).

Example

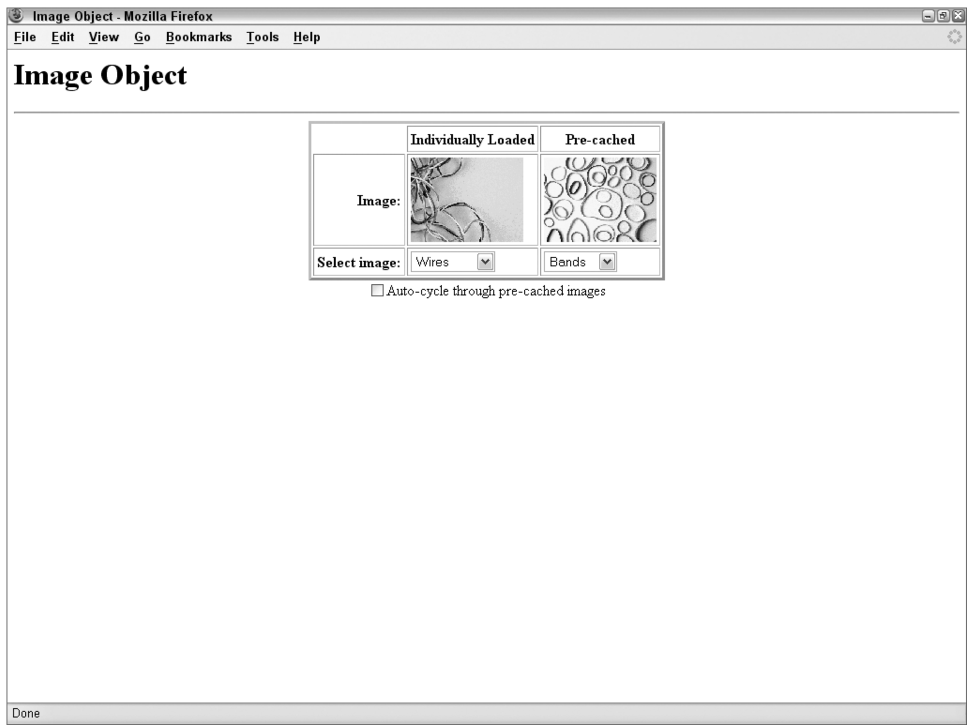
In the following example (see Listing 31-3), you see a few applications of image objects. Of prime importance is a comparison of how pre-cached versus images rendered on-the-fly feel to the user. As a bonus, you see an example of how to set a timer to automatically change the images displayed in an image object. This feature is a popular request among sites that display advertising banners or slide shows.

As the page loads, a global variable is handed an array of image objects. Entries of the array are assigned string names as index values (`"desk1"`, `"desk2"`, and so on). The intention is that these names ultimately will be used as addresses to the array entries. Each image object in the array has a URL assigned to it, which pre-caches the image.

The page (see Figure 31-1) includes two `img` elements: one that displays noncached images and one that displays cached images. Under each image is a `select` element that you can use to select one of four possible image files for each element. The `onchange` event handler for each `select` list invokes a different function to change the noncached (`loadIndividual()`) or cached (`loadCached()`) images. Both of these functions take as their single parameter a reference to the form that contains the `select` elements.

FIGURE 31-1

The image object demonstration page.



To cycle through images at five-second intervals, the `checkTimer()` function looks to see if the timer check box is selected. If so, the `selectedIndex` property of the cached image `select` control is copied and incremented (or reset to zero if the index is at the maximum value). The `select` element is adjusted, so you can now invoke the `loadCached()` function to read the currently selected item and set the image accordingly.

For some extra style points, the `<body>` tag includes an `onunload` event handler that invokes the `resetSelects()` function. This general-purpose function loops through all forms on the page and all elements within each form. For every `select` element, the `selectedIndex` property is reset to zero. Thus, if a user reloads the page, or returns to the page via the Back button, the images start in their original sequence. An `onload` event handler makes sure that the images are in sync with the `select` choices and the `checkTimer()` function is invoked with a five-second delay. Unless the timer check box is checked, however, the cached images don't cycle.

LISTING 31-3

A Scripted Image Object and Rotating Images

```
<!DOCTYPE html>

      var imageDB;
      // pre-cache the 'desk' images
      if (document.images)
      {
         // list array index names for convenience
         var deskImages = new Array("desk1", "desk2", "desk3", "desk4");
         // build image array and pre-cache them
         imageDB = new Array(4);
         for (var i = 0; i < imageDB.length ; i++)
         {
            imageDB[deskImages[i]] = new Image(120,90);
            imageDB[deskImages[i]].src = deskImages[i] + ".gif";
         }
      }
      // change image of 'individual' image
      function loadIndividual(form)
      {
         if (document.images)
         {
            var gifName =
                form.individual.options[form.individual.selectedIndex].value;
            document.getElementById("thumbnail1").src = gifName + ".gif";
         }
      }
      // change image of 'cached' image
      function loadCached(form)
      {
         if (document.images)
         {
            var gifIndex =
                form.cached.options[form.cached.selectedIndex].value;
            document.getElementById("thumbnail2").src = imageDB[gifIndex].src;
         }
      }
      // if switched on, cycle 'cached' image to next in queue
      function checkTimer()
```

continued

imageObject.src

LISTING 31-3 *(continued)*

```
   {
      if (document.images & document.Timer.timerBox.checked)
      {
         var gifIndex = document.selections.cached.selectedIndex;
            if (++gifIndex > imageDB.length - 1)
            {
               gifIndex = 0;
            }
         document.selections.cached.selectedIndex = gifIndex;
         loadCached(document.selections);
         var timeoutID = setTimeout("checkTimer()",5000);
      }
   }
   // reset form controls to defaults on unload
   function resetSelects()
   {
      for (var i = 0; i < document.forms.length; i++)
      {

      <form name="Timer">
         <input type="checkbox" name="timerBox"
         onclick="checkTimer()" />Auto-cycle through pre-cached images
      </form>
    </center>
  </body>
</html>
```

Related Items: `img.lowsrc`, `img.nameProp` properties

start

Value: String Read/Write

Compatibility: WinIE4-6, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `start` property works in conjunction with video clips viewed through the `img` element in IE4+. By default, a clip starts playing (except on the Macintosh) when the image file opens. This follows the default setting of the `start` property: `"fileopen"`. Another recognized value is `"mouseover"`, which prevents the clip from running until the user rolls the mouse pointer atop the image.

Related Items: `img.dynsrc`, `img.loop` properties

useMap

Value: Identifier string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `useMap` property represents the `usemap` attribute of an `img` element, pointing to the name assigned to the `map` element in the page (see Listing 31-6). This `map` element contains the details

about the client-side image map (described later in this chapter). The value for the `useMap` property must include the hash mark that defines an internal HTML reference on the page. If you need to switch between two or more image maps for the same `img` element (for example, you swap images or the user is in a different mode), you can define multiple `map` elements with different names. Then, change the value of the `useMap` property for the `img` element object to associate a different map with the image.

Related Item: `isMap` property

vspace

(See `hspace`)

width

(See `height`)

x
y

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN4, Moz1+, Safari1+, Opera-, Chrome+

A script can retrieve the *x* and *y* coordinates of an `img` element (the top-left corner of the rectangular space occupied by the image) via the `x` and `y` properties. These properties are read-only. They are generally not used, in favor of the `offsetLeft` and `offsetTop` properties of any element, which are also supported in IE.

Related Items: `img.offsetLeft`, `img.offsetTop` properties; `img.scrollIntoView()`, `window.scrollTo()` methods

Event handlers

onabort
onerror

Compatibility: WinIE4+, MacIE4+, NN3+, Moz-, Safari-, Opera-, Chrome-

Your scripts may need to be proactive when a user clicks the Stop button while an image loads or when a network or server problem causes the image transfer to fail. Use the `onabort` event handler to activate a function in the event of a user clicking the Stop button; use the `onerror` event handler for the unexpected transfer snafu. Be aware that while `onerror` works in all browsers, `onabort` does not.

In practice, these event handlers don't supply all the information you may like to have in a script, such as the filename of the image that's loading at the time. If such information is critical to your scripts, the scripts need to store the name of a currently loading image to a variable before they set the image's `src` property. You also don't know the nature of the error that triggers an error event. You can treat such problems by forcing a scripted page to reload or by navigating to an entirely different spot in your web site.

Example

Listing 31-4 includes an `onabort` event handler. If the images already exist in the cache, you must quit and relaunch the browser to try to stop the image from loading. In that example, we provide a

reload option for the entire page. How you handle the exception depends a great deal on your page design. Do your best to smooth over any difficulties that users may encounter.

`onload`

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

An `img` object's `onload` event handler fires when one of three actions occurs: an image's `lowsrc` image finishes loading; in the absence of a `lowsrc` image specification, the `src` image finishes loading; or when each frame of an animated GIF (GIF89a format) appears.

It's important to understand that if you define a `lowsrc` file inside an `<img>` tag, the `img` object receives no further word about the `src` image having completed its loading. If this information is critical to your script, verify the current image file by checking the `src` property of the `Image` object.

Be aware, too, that an `img` element's `onload` event handler may fire before the other elements on the page have completed loading. If the event handler function refers to other elements on the page, the function should verify the existence of other elements prior to addressing them.

Quit and restart your browser, or clear your cache, to get the most from Listing 31-4. As the document first loads, the `lowsrc` image file (the picture of pencil erasers) loads ahead of the NASA image. (Recall that the `lowsrc` property is not supported by all browsers, so you won't necessarily see the pencil erasers loaded ahead of the NASA image.) Again, we deliberately chose to load a large image directly from the NASA web site so that you would have more time to see the behavior of the `onload` event handler. When the erasers are loaded, the `onload` event handler writes "done" to the text field, even though the main image (the NASA image) is not loaded yet.

Syntax

Accessing `area` element object properties:

```
(NN3+/IE4+)     [window.]document.links[index].property
(IE4+)          [window.]document.all.elemID.property | method([parameters])
(IE4+)          [window.]document.all.MAPElemID.areas[index].property |
                method([parameters])
(IE5+/W3C)      [window.]document.getElementById("MAPElemID").areas
                [index].property | method([parameters])
(IE5+/W3C)      [window.]document.getElementById("elemID").property |
                method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

Document object models treat an image map area object as one of the link (`a` element) objects in a document (see the anchor object in Chapter 30, "Link and Anchor Objects"). When you think about it, such treatment is not illogical at all because clicking a map area generally leads the user to another document or anchor location in the same document — a hyperlinked reference.

Although the HTML definitions of links and map areas differ greatly, the earliest scriptable implementations of both kinds of objects had nearly the same properties and event handlers. Starting with IE4, NN6/Moz, and W3C-compatible browsers, all `area` element attributes are accessible as scriptable properties. Moreover, you can change the makeup of client-side image map areas by way of the `map` element object. The `map` element object contains an array of `area` element objects nested inside. You can remove, modify, or add to the `area` elements inside the `map` element.

Client-side image maps are fun to work with, and they have been well documented in HTML references since Netscape Navigator 2 introduced the feature. Essentially, you define any number of areas within the image, based on shape and coordinates. Many graphics tools can help you capture the coordinates of images that you need to enter into the `coords` attribute of the `<area>` tag.

Tip

If one gotcha exists that trips up most HTML authors, it's the tricky link between the `<img>` and `<map>` tags. You must assign a name to the `<map>`; in the `<img>` tag, the `usemap` attribute requires a hash symbol (#) and the map name. If you forget the hash symbol, you can't create a connection between the image and its map. ■

Listing 31-5 contains an example of a client-side image map that allows you to navigate through different geographical features of the Middle East. As you drag the mouse around an aerial image, certain regions cause the mouse pointer to change, indicating that there is a link associated with the region. Clicking a region results in an alert box indicating which region you clicked.

            onmouseout="return clearIt()" />
    </map>
  </body>
</html>
```

Properties

`alt`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `alt` property represents the `alt` attribute of an `area`. Internet Explorer displays the `alt` text in a tiny pop-up window (tool tip) above an area when you pause (hover) the mouse pointer over it. There is debate among web developers about Microsoft's usage of tool tips for `alt` text, both in image maps and regular images.

Future browsers may implement this attribute to provide additional information about the link associated with the `area` element. For the time being, Internet Explorer is the only mainstream browser to use the `alt` property in any noticeable way, although all the browsers recognize it.

Related Item: `title` property

`coords`
`shape`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `coords` and `shape` properties control the location, size, and shape of the image hot spot governed by the `area` element. Shape values that you can use for this property control the format of the `coords` property values, as follows:

Shape	Coordinates	Example
`circ`	center-x, center-y, radius	`"30, 30, 20"`
`circle`	center-x, center-y, radius	`"30, 30, 20"`
`poly`	x1, y1, x2, y2, . . .	`"0, 0, 0, 30, 15, 30, 0, 0"`
`polygon`	x1, y1, x2, y2, . . .	`"0, 0, 0, 30, 15, 30, 0, 0"`
`rect`	left, top, right, bottom	`"10, 20, 60, 40"`
`rectangle`	left, top, right, bottom	`"10, 20, 60, 40"`

The default shape for an `area` is a `rectangle`.

protocol
search
target

(See corresponding properties of the `link` object in Chapter 30, "Link and Anchor Objects.")

noHref

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `noHref` property is used to enable or disable a particular area within a map. The values of the property may be `true`, which means an area is enabled, or `false` to prevent the area from serving as a link within the map. The actual behavior in any of the browsers may be unpredictable, so test carefully.

shape

(See `coords`)

map Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
areas[]		onscroll†
name		

†See Chapter 29

Syntax

Accessing `map` element object properties:

```
(IE4+)        [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)    [window.]document.getElementById("elemID").property |
              method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

The map element object is an invisible HTML container for all area elements, each of which defines a “hot” region for an image. Client-side image maps associate links (and targets) to rectangular, circular, or polygonal regions of the image.

By far, the most important properties of a map element object are the areas array and, to a lesser extent, the name. It is unlikely that you will change the name of a map. (It is better to define multiple map elements with different names, and then assign the desired name to an img element object’s useMap property.) But you can use the areas array to change the makeup of the area objects inside a given client-side map.

Properties

areas[]

Value: Array of area element objects Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Use the areas array to iterate through all area element objects within a map element. Whereas Mozilla-based and WebKit-based browsers adhere closely to the document node structure of the W3C DOM, IE4+ provides more direct access to the area element objects nested inside a map. If you want to rewrite the area elements inside a map, you can clear out the old ones by setting the length property of the areas array to zero. Then assign area element objects to slots in the array to build that array.

Listing 31-6 demonstrates how to use scripting to replace the area element objects inside a map element. The scenario is that the page loads with one image of a computer keyboard. This image is linked to the keyboardMap client-side image map, which specifies details for three hot spots on the image. If you then switch the image displayed in that img element, scripts change the useMap property of the img element object to point to a second map that has specifications more suited to the desk lamp in the second image. Roll the mouse pointer atop the images, and view the URLs associated with each area in the status bar (for this example, the URLs do not lead to other pages).

Another button on the page, however, invokes the makeAreas() function (not supported by MacIE5), which creates four new area element objects and (through DOM-specific pathways) adds those new area specifications to the image. If you roll the mouse atop the image after the function executes, you can see that the URLs now reflect those of the new areas. Also note the addition of a fourth area, whose status bar message appears in Figure 31-2.

Syntax

Accessing `canvas` element object properties:

```
(W3C)     [window.]document.getElementById("canvasID").property |
              method([parameters])
```

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

About this object

A *canvas* is a relatively new construct that enables you to create a rectangular region on a page that can be drawn to programmatically through JavaScript. Relative to a web page, a canvas appears as an image since it occupies a rectangular space. Unlike images, however, canvas content is generated programmatically using a series of methods defined on the `canvas` object. Support for canvases first appeared in the Safari browser in version 1.3, and then spread to Mozilla browsers in Mozilla version 1.8, which corresponds to Firefox 1.5. While the current version of IE does not natively support this object, there are third-party libraries that allow you to use this object in IE.

Canvas objects are created and positioned on the page using the `<canvas>` tag, which supports only two unique attributes: `width` and `height`. After the canvas is created, the remainder of the work associated with creating a canvas graphic falls to JavaScript code. You'll typically want to create a special draw function that takes on the task of drawing to the canvas, upon the page loading. The job of the draw function is to use the methods of the `canvas` object to render the canvas graphic.

Listing 31-7 contains a skeletal page for placing a basic canvas with a border. Notice that there is a `draw()` function that is ready to receive the code for rendering the canvas graphic.

LISTING 31-7

A Skeletal Canvas

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>canvas Object</title>
      <script type="text/javascript">
```

continued

LISTING 31-7 *(continued)*

```
      function draw()
      {
         // Draw some stuff
      }
      </script>
      <style type="text/css">
         canvas { border: 1px solid black; }
      </style>
   </head>
   <body onload="draw();">
      <h1>canvas Object</h1>
      <hr />
      <canvas width="350" height="250"></canvas>
   </body>
</html>
```

Listing 31-8 contains a more interesting canvas example that builds on the skeletal page by adding some actual canvas drawing code. The properties and methods in the `canvas` object provide you with the capability to do some amazing things, so consider this example a rudimentary scratching of the canvas surface.

LISTING 31-8

A Canvas Containing a Simple Chart

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>canvas Object</title>
      <script type="text/javascript">
      function draw()
      {
         var canvas = document.getElementById('chart');
            if (canvas.getContext)
            {
               var context = canvas.getContext('2d');
               context.lineWidth = 20;
               // First bar
               context.strokeStyle = "red";
               context.beginPath();
               context.moveTo(20, 90);
               context.lineTo(20, 10);
               context.stroke();
               // Second bar
               context.strokeStyle = "green";
               context.beginPath();
               context.moveTo(50, 90);
```

```
            context.lineTo(50, 50);
            context.stroke();
            // Third bar
            context.strokeStyle = "yellow";
            context.beginPath();
            context.moveTo(80, 90);
            context.lineTo(80, 25);
            context.stroke();
            // Fourth bar
            context.strokeStyle = "blue";
            context.beginPath();
            context.moveTo(110, 90);
            context.lineTo(110, 75);
            context.stroke();
         }
      }
      </script>
      <style type="text/css">
         canvas { border: 1px solid black; }
      </style>
   </head>
   <body onload="draw();">
      <h1>canvas Object</h1>
      <hr />
      <canvas id="chart" width="130" height="100"></canvas>
   </body>
</html>
```

Figure 31-3 shows this canvas example in action, which involves the display of a simple bar chart. The thing to keep in mind is that this bar chart is being rendered programmatically using vector graphics, which is quite powerful.

This example reveals a few more details about how canvases work. Notice that you must first obtain a context in order to perform operations on the canvas. (In reality, you perform graphics operations on a canvas context, not the canvas element itself.) The job of a context is to provide you with a virtual surface on which to draw. You obtain a canvas context by calling the `getContext()` method on the canvas object and specifying the type of context; currently, only the `2d` (two-dimensional) context is supported in browsers.

When you have a context, canvas drawing operations are carried out relative to the context. You are then free to tinker with stroke and fill colors, create paths and fills, and do most of the familiar graphical things that go along with vector drawing.

You can find a more complete tutorial and examples dedicated to drawing with the canvas element at `http://developer.mozilla.org/en/docs/Canvas_tutorial`.

Properties

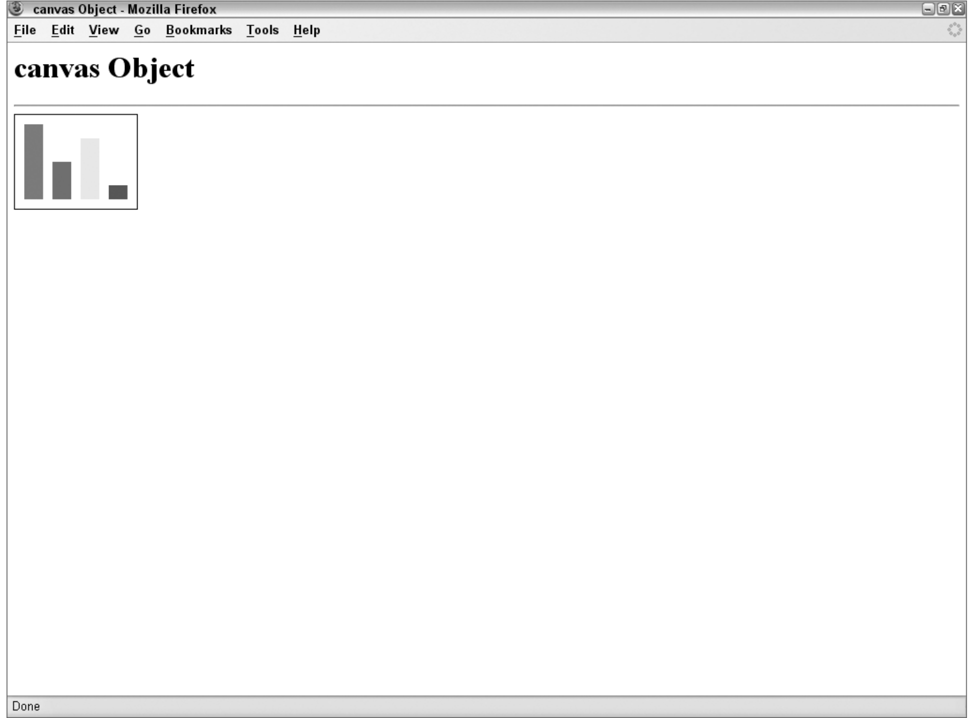
`fillStyle`

Value: String Read/Write

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

FIGURE 31-3

A simple bar chart created using a vector canvas.



The `fillStyle` property sets the fill for the brush used in filling a region of a canvas is with a color or pattern. Although you can create gradients and other interesting patterns for use in filling shapes, the most basic usage of the `fillStyle` property is creating a solid color fill by setting the property to an HTML-style color (`#RRGGBB`). All fill operations that follow the `fillStyle` setting will use the new fill style.

Example

Setting a fill color simply involves assigning an HTML-style color to the `fillStyle` property:

```
context.fillStyle = "#FF00FF";
```

Related Item: `strokeStyle` property

globalAlpha

Value: Float Read/Write

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

The `globalAlpha` property is a floating-point property that establishes the transparency (or opacity, depending on how you think about it) of the content drawn on a canvas. Acceptable

values for this property range from 0.0 (fully transparent) to 1.0 (fully opaque). The default setting is 1.0, which means that all canvases initially have no transparency.

Example

To set the transparency of a canvas to 50 percent transparency, set the `globalAlpha` property to 0.5:

```
context.globalAlpha = 0.5;
```

Related Item: None

globalCompositeOperation

Value: String — Read/Write

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

The `globalCompositeOperation` property determines how the canvas appears in relation to background content on a web page. This is a powerful property because it can dramatically affect the manner in which canvas content appears with respect to any underlying web page content. The default setting is `source-over`, which means opaque areas of the canvas are displayed, but transparent areas are not. Other popular settings include `copy`, `lighter`, and `darker`, among others.

Example

If you want a canvas to always fully cover the background web page, regardless of any transparent areas it may have, you should set the `globalCompositeOperation` property to `copy`:

```
context.globalCompositeOperation = "copy";
```

Related Item: None

lineCap
lineJoin
lineWidth

Value: String, Float (`lineWidth`) — Read/Write

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

These properties all impact the manner in which lines are drawn on a canvas. The `lineCap` property determines the appearance of line end points (`butt`, `round`, or `square`). Similar to `lineCap` is the `lineJoin` property, which determines how lines are joined to each other (`bevel`, `miter`, or `round`). By default, lines terminate with no special end point (`butt`) and are joined cleanly with no special joint graphic (`miter`).

The `lineWidth` property establishes the width of lines and is expressed as an integer value greater than 0 in the canvas coordinate space. When a line is drawn, its width appears centered over the line coordinates.

Example

You'll often want to change the `lineWidth` property to get different effects when assembling a canvas graphic. Here's an example of setting a wider line width (`10` in this case):

```
context.lineWidth = 10;
```

Related Items: `miterLimit`, `strokeStyle` properties

miterLimit

Value: Float Read/Write

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

The `miterLimit` property is a floating-point value that determines more specifically how lines are joined together. The `miterLimit` property works in conjunction with the `lineJoin` property to cleanly and consistently join lines in a path.

Related Item: `lineJoin` property

shadowBlur
shadowColor
shadowOffsetX
shadowOffsetY

Value: Integer, String (`shadowColor`) Read/Write

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

These properties all work in conjunction to establish a shadow around canvas content. The `shadowBlur` property determines the width of the shadow itself, whereas `shadowColor` sets the color of the shadow as an HTML-style RGB value (#RRGGBB). Finally, the `shadowOffsetX` and `shadowOffsetY` properties specify exactly how far the shadow is offset from a graphic. The `shadowBlur`, `shadowOffsetX`, and `shadowOffsetY` properties are all expressed in units of the canvas coordinate space.

Example

The following code creates a shadow that is 5 units wide, light gray in color (#BBBBBB), and offset 3 units in both the X and Y directions:

```
context.shadowBlur = 5;
context.shadowColor = "#BBBBBB";
context.shadowOffsetX = 3;
context.shadowOffsetY = 3;
```

Related Item: None

strokeStyle

Value: String Read/Write

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

The `strokeStyle` property controls the style of strokes used to draw on the canvas. You are free to set the stroke style to a gradient or pattern using more advanced canvas features, but the simpler approach is to just set a solid colored stroke as an HTML-style color value (#RRGGBB). The default stroke style is a solid black stroke.

Example

To change the stroke style to a solid green brush, set the `strokeStyle` property to the color green:

```
context.strokeStyle = "#00FF00";
```

Related Item: `fillStyle` property

Methods

arc(*x, y, radius, startAngle, endAngle, clockwise*)
arcTo(*x1, y1, x2, y2, radius*)
bezierCurveTo(*cp1x, cp1y, cp2x, cp2y, x, y*)
quadraticCurveTo(*cpx, cpy, x, y*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

These methods are all responsible for drawing curves in one way or another. If you have any experience with drawing vector graphics, then you're probably familiar with the difference between arcs, Bezier curves, and quadratic curves.

The `arc()` method draws a curved line based upon a center point, a radius, and start and end angles. You can think of this method as tracing the curve of a circle from one angle to another. The angles are expressed in radians, not degrees, so you'll probably need to convert degrees to radians:

```
var radians = (Math.PI / 180) * degrees;
```

The last argument to `arc()` is a Boolean value that determines whether or not the arc is drawn in the clockwise (`true`) or counterclockwise (`false`) direction.

The `arcTo()` method draws an arc along a curve based upon tangent lines of a circle. This method is not implemented in Mozilla until version 1.8.1.

Finally, the `bezierCurveTo()` and `quadraticCurveTo()` methods draw a curved line based upon arguments relating to Bezier and quadratic curves, respectively, which are a bit beyond this discussion. To learn more about Bezier and quadratic curves, check out `en.wikipedia.org/wiki/Bézier_curve`.

beginPath()
closePath()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

These two methods are used to manage paths. Call the `beginPath()` method to start a new path, into which you can then add shapes. When you're finished, call `closePath()` to close up the path. The only purpose of `closePath()` is to close a subpath that is still open, meaning that you want to finish connecting an open shape back to its start. If you've created a path that is already closed,

there is no need to call the `closePath()` method. Listing 31-8 contains a good example of where the `closePath()` method is unnecessary because the bar shapes don't need to be closed.

`clip()`

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

The `clip()` method recalculates the clipping path based upon the current path and the clipping path that already exists. Subsequent drawing operations rely on the newly calculated clipping path.

`createLinearGradient(`*`x1, y1, x2, y2`*`)`
`createRadialGradient(`*`x1, y1, radius1, x2, y2, radius2`*`)`
`createPattern(`*`image, repetition`*`)`

Returns: Gradient object reference, pattern object reference (`createPattern()`)

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

These methods are used to create special patterns and gradients for fill operations. A linear gradient is specified as a smooth color transition between two coordinates, whereas a radial gradient is specified based upon two circles with similar radii. You set the actual color range of a gradient by calling the `addColorStop()` method on the gradient object returned from the `createLinearGradient()` and `createRadialGradient()` methods. The `addColorStop()` method accepts a floating-point offset and a string color value as its only two arguments.

The `createPattern()` method is used to create a fill pattern based upon an image. You provide an image object and a repetition argument for how the image is tiled when filling a region. Repetition options include `repeat`, `repeat-x`, `repeat-y`, and `no-repeat`.

`drawImage(`*`image, x, y`*`)`
`drawImage(`*`image, x, y, width, height`*`)`
`drawImage(`*`image, srcX, srcY, srcWidth, srcHeight, destX, destY, destWidth, destHeight`*`)`

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

These `drawImage()` methods all draw an image to the context. The difference between them has to do with if and how the image is scaled as it is drawn. The first version draws the image at a coordinate with no scaling, whereas the second version scales the image to the specified target width and height. Finally, the third version enables you to draw a portion of the image to a target location with a scaled width and height.

`fill()`
`fillRect(`*`x, y, width, height`*`)`
`clearRect(`*`x, y, width, height`*`)`

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

These methods are used to fill and clear areas. The `fill()` method fills the area within the current path, whereas the `fillRect()` method fills a specified rectangle independent of the current path. The `clearRect()` method is used to clear (erase) a rectangle.

getContext(*contextID*)

Returns: Context object reference

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

The `getContext()` method operates on a canvas element object, not a context, and is used to obtain a context for further graphical operations. You must call this method to obtain a context before you can draw to a canvas since all of the canvas drawing methods are actually called relative to a context, not a canvas. For the standard two-dimensional canvas context, specify `"2d"` as the sole parameter to the method.

lineTo(*x, y*)
moveTo(*x, y*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

These two methods are used to draw lines and adjust the stroke location. The `moveTo()` method simply moves the current stroke location without adding anything to the path. The `lineTo()` method, on the other hand, draws a line from the current stroke location to the specified point. It's worth pointing out that drawing a line with the `lineTo()` method only adds a line to the current path; the line doesn't actually appear on the canvas until you call the `stroke()` method to carry out the actual drawing of the path.

rect(*x, y, width, height*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

The `rect()` method adds a rectangle to the current path. Similar to other drawing methods, the rectangle is actually just added to the current path, which isn't truly visible until you render it using the `stroke()` method.

restore()
save()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

It's possible to save and restore the state of the graphic context, in which case you can make changes and then return to a desired state. The context state includes information such as the clip region, line width, fill color, and so forth. Call the `save()` and `restore()` methods to save and restore the context state.

rotate(*angle*)
scale(*x*, *y*)
translate(*x*, *y*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

All of the drawing operations that you perform on a canvas are expressed in units relative to the coordinate system of the canvas. These three methods enable you to alter the canvas coordinate system by rotating, scaling, or translating its origin. Rotating the coordinate system affects how angles are expressed in drawing operations that involve angles. Scaling the coordinate system impacts the relative size of units expressed in the system. And finally, translating the coordinate system alters the location of the origin, which affects where positive and negative values intersect on the drawing surface.

stroke()
strokeRect(*x*, *y*, *width*, *height*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN-, Moz1.8+, Safari1.3+, Opera+, Chrome+

Most of the drawing operations on a canvas impact the current path, which you can think of as a drawing you've committed to memory but have yet to put on paper. You render a path to the canvas by calling the `stroke()` method. If you want to draw a rectangle to the canvas without dealing with the current path, call the `strokeRect()` method.

CHAPTER

Event Objects

IN THIS CHAPTER

The "life" of an event object

Event support in different browser generations

Retrieving information from an event

Prior to version 4 browsers, user and system actions — events — were captured predominantly by event handlers defined as attributes inside HTML tags. For instance, when a user clicked a button, the `clickevent` triggered the `onclick` event handler in the tag. That handler may invoke a separate function or perform some inline JavaScript script. Even so, the events themselves were rather dumb: Either an event occurred or it didn't. Where an event occurred (that is, the screen coordinates of the pointer at the moment the mouse button was clicked) and other pertinent event tidbits (for example, whether a keyboard modifier key was pressed at the same time) were not part of the equation — until version 4 browsers, that is.

While remaining fully backward compatible with the event handler mechanism of old, version 4 browsers had the first event model that turn events into first-class objects whose properties automatically carry a lot of relevant information about the event when it occurs. These properties are fully exposed to scripts, allowing pages to respond more intelligently about what the user does with the page and its elements.

Another new aspect of version 4 event models was the notion of "event propagation." It was possible to have an event processed by an object higher up the element containment hierarchy whenever it made sense to have multiple objects share one event handler. That the event being processed carried along with it information about the intended target, plus other golden information nuggets, made it possible for event handler functions to be smart about processing the event without requiring an event handler call to pass all kinds of target-specific information.

Unfortunately, the joy of this newly found power is tempered by the forces of object model incompatibility. Event object models are clearly divided along two fronts:

- The IE4+ model
- The model adopted by the W3C DOM Level 2, as implemented in NN6+/Moz and Gecko-, WebKit-, and Presto-based browsers

Many of these distinctions are addressed in the overviews of the object models in Chapter 26, "Generic HTML Element Objects." In this chapter, you find out more about the actual event objects that contain all the "goodies." Where possible, cross-browser concerns are addressed.

Why "Events"?

Graphical user interfaces are more difficult to program than the "old-fashioned" command-line interface. With a command-line or menu-driven system, users were intentionally restricted in the types of actions they could take at any given moment. The world was very modal, primarily as a convenience to programmers who led users through rigid program structures.

That all changes in a graphical user interface, such as Windows, Mac OS, XWindow System, or any other derived from the pioneering work of the Xerox Star system. The challenge for programmers is that a good user interface in this realm must make it possible for users to perform all kinds of actions at any given moment: roll the mouse, click a button, type a key, select text, choose a pull-down menu item, and so on. To accommodate this, a program (or, better yet, the operating system) must be on the lookout for any possible activity coming from all input ports, whether it be the mouse, keyboard, or network connection.

A common methodology to accomplish this at the operating system level is to look for any kind of event, whether it comes from user action or some machine-generated activity. The operating system or program then looks up how it should process each kind of event. Such events, however, must have some smarts about them so that the program knows what, and where on the screen, the event is.

What an event knows (and when it knows it)

Although the way to reference an event object varies a bit among the three event models, the one concept they all share is that an event object is created the instant the event action occurs. For instance, if you click a button, an event object is created in the browser's memory. As the object is created, the browser assigns values to the object's properties — properties that reflect numerous characteristics of that specific event. For a `click` event, that information includes the coordinates of the click, and which mouse button was used to generate the event. To be even more helpful, the browser does some quick calculations to determine that the coordinates of the `click` event coincide with the rectangular space of a button element on the screen. Therefore, the event object has as one of its properties a reference to the "screen thing" that you clicked on.

Most event object properties are read-only (in some even models, all the properties are), because an event object is like a snapshot of an event action. If the event model were to allow modification of event properties, performing both potentially useful and potentially unfriendly actions would be possible. For example, how frustrating would it be to a user to attempt to type into a text box, only for a keystroke to be modified after the actual key press and a totally different character to appear in the text box? On the other hand, perhaps it may be useful in some situations to make sure that anything typed into a text box is converted to uppercase characters, no matter what is typed. Each event model brings its own philosophy to the table in this regard. For example, the IE4+ event model allows keyboard character events to be modified by script; the W3C DOM event model does not.

Perhaps the most important aspect of an event object to keep in mind is that it exists only as long as scripts process the event. An event can trigger an event handler — usually a function. That function, of course, can invoke other functions. As long as statements are still executing in response to the event handler, the event object and all its properties are still "alive" and available to your scripts. But after the last script statement runs, the event object reverts to an empty object.

The reason an event object has such a brief life is that there can be only one event object at a time. In other words, no matter how complex your event handler functions are, or how rapidly events fire, they are executed serially (for experienced programmers: there is one execution thread). The operating system buffers events that start to bunch up on each other. Except in rare cases in which the buffer gets full and events are not recorded, event handlers are executed in the order in which the events occur.

The static Event object

Up to this point, the discussion has been about the event object (with a lowercase “e”), which is one instance of an event, with all the properties associated with that specific event action. In the W3C DOM event model, there is also a static `Event` object (with an uppercase “E”) that includes additional subcategories within it. These subcategories are all covered later in this chapter, but they are introduced here to illustrate the contrast between the event and `Event` objects. The former, as you’ve seen, is a transient object with details about a specific event action; the latter serves primarily as a holder of event-related constant values that scripts can use. The static `Event` object is always available to scripts inside any window or frame. For a list of all `Event` object properties in NN6+/Moz and Gecko-, WebKit-, and Presto-based browsers, use The Evaluator (see Chapter 4, ‘JavaScript Essentials’): enter **Event** into the bottom text box (also check out the `KeyEvent` object in NN6+/Moz).

The static `Event` object also turns out to be the object from which event objects are cloned. Thus, the static `Event` object has a number of properties and methods that apply to (are inherited by) the event objects created by event actions. These relationships are more important in the W3C DOM event model, which builds upon the DOM’s object-oriented tendencies to implement the event model.

Event Propagation

Prior to version 4 browsers, an event fired on an object. If an event handler was defined for that event and that object, the handler executed; if there was no event handler, the event just disappeared into the ether. Newer browsers, however, send events on a longer ride, causing them to propagate through the document object models. As you know by now, two propagation models exist, one for each of the event models in use today: IE4+ and W3C DOM, as implemented in NN6+/Moz and Gecko-, WebKit-, and Presto-based browsers. It’s also worth mentioning the event model that is unique to NN4, which served as a third model prior to NN4 succumbing to modern browsers. The NN4 event model has historical relevance because it aids in understanding the latter two models. Conceptually, the NN4 and IE4+ propagation models are diametrically opposite each other — any NN4 event propagates inward toward the target, whereas an IE event starts at the target and propagates outward. But the W3C DOM model manages to implement both models simultaneously, albeit with all new syntax so as not to step on the older models.

At the root of all three models is the notion that every event has a target. For user-initiated actions, this is fairly obvious. If you click a button or type in a text box, that button is the target of your mouse-related event; the text box is the target of your keyboard event. System-generated events are not so obvious, such as the `onload` event that fires after a page finishes loading. In all event models, this event fires on the `window` object. What distinguishes the event propagation models is how an event reaches its target, and what, if anything, happens to the event after it finishes executing the event handler associated with the target.

NN4-only event propagation

Although NN4 has given way to newer browsers, its propagation model initiated some concepts that are found in the modern W3C DOM event propagation model. The name for the NN4 model is *event capture*.

In NN4, all events propagate from the top of the document object hierarchy (starting with the `window` object) downward to the target object. For example, if you click a button in a form, the `click` event passes through the `window` and `document` (and, if available, `layer`) objects before reaching the button (the `form` object is not part of the propagation path). This propagation happens instantaneously, so that there is no performance penalty by this extra journey.

The event that passes through the `window`, `document`, and `layer` objects is a fully formed event object, complete with all properties relevant to that event action. Therefore, if the event were processed at the window level, one of the event object's properties is a reference to the target object, so that the event handler scripts at the window level can find out information, such as the name of the button, and even get a reference to its enclosing form.

By default, event capture is turned off. To instruct the `window`, `document`, or `layer` object levels to process that passing click object, requires turning on event capture for the `window`, `document`, and/or `layer` object.

Enabling NN4 event capture

All three objects just mentioned — `window`, `document`, and `layer` — have a `captureEvents()` method. You use this method to enable event capture at any of those object levels. The method requires one or more parameters, which are the event types (as supplied by `Event` object constants) that the object should capture, while letting all others pass untouched. For example, if you want the `window` object to capture all `keypress` events, you include the following statement in a script that executes as the page loads:

```
window.captureEvents(Event.KEYPRESS);
```

Defining event handlers in the intended targets is also a good idea, even if they are empty (for example, `onkeypress=""`) to help NN4 generate the event in the first place. If you want the window to capture multiple event types, string the event type constants together, separated by the pipe character:

```
window.captureEvents(Event.KEYPRESS | Event.CLICK);
```

Now you must assign an action to the event, at the window's level, for each event type. More than likely, you have defined functions to execute for the event. Assign a function reference to the event handler by setting the handler property of the `window` object:

```
window.onkeypress = processKeyEvent;
window.onclick = processClickEvent;
```

Hereafter, if a user clicks a button or types into a field inside that window, the events are processed by their respective window-level event handler functions.

Turning off event capture

As soon as you enable event capture for a particular event type in a document, that capture remains in effect until the page unloads or you specifically disable the capture. You can turn off event capture for each event via the `window`, `document`, or `layer releaseEvents()` method. The `releaseEvents()` method takes the same kind of parameters — `Event` object type constants — as the `captureEvents()` method.

The act of releasing an event type simply means that events go directly to their intended targets without stopping elsewhere for processing, even if an event handler for the higher-level object

is still defined. And because you can release individual event types based on parameters set for the `releaseEvents()` method, other events being captured are not affected by the release of others.

Passing events toward their targets

If you capture a particular event type in NN4, your script may need to perform some limited processing on that event before letting it reach its intended target. For example, perhaps you want to do something special if a user clicks an element with the Shift meta key pressed. In that case, the function that handles the event at the document level inspects the event's `modifiers` property to determine if the Shift key was pressed at the time of the event. If the Shift key was not pressed, you want the event to continue on its way to the element that the user clicked.

To let an event pass through the object hierarchy to its target, you use the `routeEvent()` method, passing as a parameter the event object being handled in the current function. A `routeEvent()` method does not guarantee that the event will reach its intended destination, because another object in between may have event capturing for that event type turned on and will intercept the event. That object, too, can let the event pass through with its own `routeEvent()` method.

In some cases, your scripts need to know if an event that is passed onward by the `routeEvent()` method activated a function that returns a value. This knowledge is especially valuable if your event must return a `true` or `false` value to let an object know if it should proceed with its default behavior (for example, whether a link should activate its `href` attribute URL or cancel after the event handler evaluates to `return true` or `return false`). When a function is invoked by the action of a `routeEvent()` method, the return value of the destination function is passed back to the `routeEvent()` method. That value, in turn, can be returned to the object that originally captured the event.

Event traffic cop

The last scenario is one in which a higher-level object captures an event and directs the event to a particular object elsewhere in the hierarchy. For example, you could have a document-level event handler function direct every `click` event whose `modifiers` property indicates that the Alt key was pressed, to a Help button object whose own `onclick` event handler displays a help panel (perhaps showing an otherwise hidden layer).

You can redirect an event to any object via the `handleEvent()` method. This method works differently from the others described in this chapter, because the object reference of this method is the reference of the object to handle the event (with the event object being passed as a parameter, such as one of the other methods). As long as the target object has an event handler defined for that event, it will process the event as if it had received the event directly from the system (even though the event object's target property may be some other object entirely).

IE4+ event propagation

IE's event propagation model is called *event bubbling*, since events "bubble" upward from the target object through the HTML element containment hierarchy. It's important to distinguish between the old-fashioned document object hierarchy (followed in the NN4 event capture model) and the more modern notion of HTML element containment — a concept that carries over to the W3C DOM as well.

A good way to demonstrate the effect of event bubbling — a behavior that is turned on by default — is to populate a simple document with lots of event handlers to see which ones fire and in

what order. Listing 32-1 has `onclick` event handlers defined for a button inside a form, the form itself, and other elements and objects, all the way up the hierarchy to the window.

LISTING 32-1

Event Bubbling Demonstration

```
<!DOCTYPE html>
<html onclick="alert('Event is now at the HTML element.')">
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Event Bubbles</title>
      <script type="text/javascript">
      function init()
      {
         window.onclick = winEvent
         document.onclick = docEvent;
         document.body.onclick = docBodEvent;
      }
      function winEvent()
      {
         alert("Event is now at the window object level.");
      }
      function docEvent()
      {
         alert("Event is now at the document object level.");
      }
      function docBodEvent()
      {
         alert("Event is now at the BODY element.");
      }
      </script>
   </head>
   <body onload="init()">
      <h1>Event Bubbles</h1>
      <hr />
      <form onclick="alert('Event is now at the FORM element.')">
         <input type="button" value="Button 'main1'" name="main1"
                onclick="alert('Event started at Button: ' + this.name)" />
      </form>
   </body>
</html>
```

You can try this listing in IE4+ and even NN6+/Moz , Safari, Opera, or Chrome because W3C DOM browsers also observe event bubbling. But you will notice differences in the precise propagation among WinIE4+, MacIE4+, and W3C DOM browsers. But notice that after you click the button in Listing 32-1, the event first fires at the target: the button. Then the event bubbles upward through the HTML containment to fire at the enclosing `form` element, next to the enclosing `body` element, and so on. Where the differences occur are after the `body` element. Table 32-1 shows the objects for which event handlers are defined in Listing 32-1, and to which objects the `click` event bubbles in the three classes of browsers.

Despite the discrepancies in Table 32-1, events do bubble through the most likely HTML containers that come to mind. The object level with the most global scope, and that works in all browser categories shown in the table, is the `document` object.

Preventing IE event bubbling

Because bubbling occurs by default, there are times when you may prefer to prevent an event from bubbling up the hierarchy. For example, if you have one handler at the `document` level whose job is to deal with the `click` event from a related series of buttons, any other object that receives `click` events will allow those events to bubble upward to the `document` level unless the bubbling is cancelled. Having the event bubble up could conflict with the document-level event handler.

TABLE 32-1

Event Bubbling Variations for Listing 32-1

Event Handler Location	WinIE4+/Opera	MacIE4+	NN6+/Moz/Safari/Chrome
`button`	Yes	Yes	Yes
`form`	Yes	Yes	Yes
`body`	Yes	Yes	Yes
`HTML`	Yes	No	Yes
`document`	Yes	Yes	Yes
`window`	No	No	Yes

Each `event` object in IE has a property called `cancelBubble`. The default value of this property is `false`, which means that the event bubbles to the next outermost container that has an event handler for that event. But if, in the execution of an event handler, that property is set to `true`, the event does not bubble up any higher when the processing of that handler finishes its job. Therefore, to stop an event from bubbling beyond the current event handler, include the following statement somewhere in the handler function:

```
event.cancelBubble = true;
```

You can prove this to yourself by modifying the page in Listing 32-1 to cancel bubbling at any level. For example, if you change the event handler of the `form` element to include a statement that cancels bubbling, the event goes no further than the `form` in IE (while the WebKit engine and recent versions of the Mozilla/Gecko engine support some of the IE syntax, the syntax is different for NN6+/Moz browsers, as discussed later in this chapter):

```
<form onclick="alert('Event is now at the form element.');
   event.cancelBubble=true">
```

Preventing IE event default action

In the days when events were almost always bound to elements by way of attributes in tags, the technique to block the event's default action was to make sure the event handler evaluated to

`return false`. This is how, for instance, a `form` element's `onsubmit` event handler could prevent the form from carrying out the submission if client-side form validation failed.

To enhance that capability — especially when events are bound by other means, such as object element properties — IE's `event` object includes a `returnValue` property. Assign `false` to this property in the event handler function to block the element's default action to the event:

```
event.returnValue = false;
```

This way of blocking default actions in IE is often more effective than the old `return false` technique.

Redirecting events

Starting with IE5.5, you can redirect an event to another element, but with some limitations. The mechanism that makes this possible is the `fireEvent()` method of all HTML element objects (see Chapter 26). This method isn't so much redirecting an event as causing a brand-new event to be fired. But you can pass most of the properties of the original `event` object with the new event by specifying a reference to the old `event` object as the optional second parameter to the `fireEvent()` method.

The big limitation in this technique, however, is that the reference to the target element gets lost in this hand-off to the new event. The `srcElement` property of the old event gets overwritten with a reference to the object that is the target of the call to `fireEvent()`. For example, consider the following `onclick` event handler function for a button inside a `form` element:

```
function buttonEvent() {
   event.cancelBubble = true;
   document.body.fireEvent("onclick", event);
}
```

By cancelling event bubbling, the event does not propagate upward to the enclosing `form` element. Instead, the event is explicitly redirected to the `body` element, passing the current `event` object as the second parameter. When the event handler function for the `body` element runs, its `event` object has information about the original event, such as the mouse button used for the click and the coordinates. But the `event.srcElement` property points to the `document.body` object. As the event bubbles upward from the `body` element, the `srcElement` property continues to point to the `document.body` object. You can see this at work in Listing 32-2 for IE5.5+.

LISTING 32-2

Cancelling and Redirecting Events in IE5.5+

```
<!DOCTYPE html>
<html onclick="revealEvent('HTML', event)">
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Event Cancelling & Redirecting</title>
      <script type="text/javascript">
         // display alert with event object info
         function revealEvent(elem, evt)
```

```
        {
           var msg = "Event (from " + evt.srcElement.tagName + " at ";
           msg += event.clientX + "," + event.clientY + ") is now at the ";
           msg += elem + " element.";
           alert(msg);
        }
        function init()
        {
           document.onclick = docEvent;
           document.body.onclick = docBodEvent;
        }
        function docEvent()
        {
           revealEvent("document", event);
        }
        function docBodEvent()
        {
           revealEvent("BODY", event);
        }
        function buttonEvent(form)
        {
           revealEvent("BUTTON", event);
           // cancel if checked (IE4+)
           event.cancelBubble = form.bubbleCancelState.checked;
           // redirect if checked (IE5.5+)
              if (form.redirect.checked)
              {
                 document.body.fireEvent("onclick", event);
              }
        }
     </script>
  </head>
  <body onload="init()">
     <h1>Event Cancelling &amp; Redirecting</h1>
     <hr />
     <form onclick="revealEvent('FORM', event)">
        <p><button name="main1" onclick="buttonEvent(this.form)">Button
           'main1'</button>
        </p>
        <p><input type="checkbox" name="bubbleCancelState"
                  onclick="event.cancelBubble=true" />Cancel Bubbling at BUTTON
           <br />
           <input type="checkbox" name="redirect"
                  onclick="event.cancelBubble=true" />Redirect Event to BODY
        </p>
     </form>
  </body>
</html>
```

Listing 32-2 is a modified version of Listing 32-1. Major additions are enhanced event handlers at each level so that you can see the tag name of the event that is regarded as the `srcElement` of the event, as well as the coordinates of the `click` event. With both check boxes unchecked, events bubble upward from the button, and the `button` element is then shown to be the original target all the

way up the bubble hierarchy. If you check the Cancel Bubbling check box, the event goes no further than the button element, because that's where event bubbling is turned off. If you then check the "Redirect Event to Body" check box, the original event is cancelled at the button level, but a new event is fired at the body element. But notice that by passing the old event object as the second parameter, the click location properties of the old event are applied to the new event directed at the body. This event then continues to bubble upward from the body.

As a side note, if you uncheck the Cancel Bubbling check box but leave the Redirect Event box checked, you can see how the redirection is observed at the end of the button's event handler, and that something special goes on. The original event is held aside by the browser while the redirected event bubbles upward. As soon as that event-processing branch finishes, the original bubbling propagation carries on with the form. Notice, though, that the event object still knows that it was targeted at the button element, and the other properties are intact. This means that for a time, two event objects were in the browser's memory, but only one is "active" at a time. While the redirected event is propagating, the window.event object refers to that event object only.

Applying event capture

WinIE 5 and later also provide a kind of event capture, which overrides all other event propagation. Intended primarily for temporary capture of mouse events, it is controlled not through the event object but via the setCapture() and releaseCapture() methods of all HTML element objects (described in Chapter 26).

When you engage capture mode, all mouse events are directed to the element object that invoked the setCapture() method, regardless of the actual target of the event. This action facilitates such activities as element dragging, so that mouse events that might fire outside of the intended target (for example, when dragging the cursor too fast for the animation to track) continue to go to the target. When the drag mode is no longer needed, invoke the releaseCapture() method to allow mouse events to propagate normally.

W3C event propagation

Yielding to arguments in favor of both NN4's event capture and IE's event bubbling, the W3C DOM group managed to assemble an event model that employs both propagation systems. Although forced to use new syntax so as not to conflict with older browsers, the W3C DOM propagation model works like the NN4 model for capture and like IE4+ for bubbling. In other words, an event bubbles by default, but you can also turn on event capture if you want. Thus, an event first trickles down the element containment hierarchy to the target; then it bubbles up through the reverse path.

Event bubbling is on by default, just as in IE4+. To enable capture, you must apply a W3C DOM event listener to an object at some higher container. Use the addEventListener() method (see Chapter 26) for any visible HTML element or node. One of the parameters of the addEventListener() method determines whether the event listener function should be triggered while the event is bubbling or while it is captured.

Listing 32-3 is a simplified example for NN6+/Moz/W3C that demonstrates how a click event aimed at a button can be both captured and allowed to bubble. Most event handling functions are assigned inside the init() function. Borrowing code from Listing 32-1, event handlers are assigned to the window, document, and body objects as property assignments. These are automatically treated as bubble-type event listeners. Next, two objects — document and form — are given capture-type event listeners for the click event. The document object event listener invokes the same function as the bubble-type event handler (the alert text includes some asterisks to remind you

that it is the same alert being displayed in both the capture and bubble phases of the event). For the form object, however, the capture-type event listener is directed to one function, while a bubble-type listener for the same object is directed at a separate function. In other words, the form object invokes one function as the event trickles down to the target, and another function when the event starts bubbling back up. Many of the event handler functions dynamically read the eventPhase property of the event object to reveal which phase of event propagation is in force at the instance the event handler is invoked (although an apparent bug reports the incorrect phase at the document object during event capture).

LISTING 32-3

W3C Event Capture and Bubble

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>W3C DOM Event Propagation</title>
      <script type="text/javascript">
         function init()
         {
            // using old syntax to assign bubble-type event handlers
            window.onclick = winEvent;
            document.onclick = docEvent;
            document.body.onclick = docBodEvent;
            // turn on click event capture for two objects
            document.addEventListener("click", docEvent, true);
            document.forms[0].addEventListener("click", formCaptureEvent, true);
            // set event listener for bubble
            document.forms[0].addEventListener("click", formBubbleEvent, false);
         }
         function winEvent(evt)
         {
            alert("Event is now at the window object level
                 (" + getPhase(evt) + ").");
         }
         function docEvent(evt)
         {
            alert("Event is now at the **document** object level
                 (" + getPhase(evt) + ").");
         }
         function docBodEvent(evt)
         {
            alert("Event is now at the BODY level (" + getPhase(evt) + ").");
         }
         function formCaptureEvent(evt)
         {
            alert("This alert triggered by FORM only on CAPTURE.");
         }
         function formBubbleEvent(evt)
         {
            alert("This alert triggered by FORM only on BUBBLE.");
```

continued

LISTING 32-3 *(continued)*

```
         }
         // reveal event phase of current event object
         function getPhase(evt)
         {
            switch (evt.eventPhase)
            {
               case 1:
                  return "CAPTURING";
                  break;
               case 2:
                  return "AT TARGET";
                  break;
               case 3:
                  return "BUBBLING";
                  break;
               default:
                  return "";
            }
         }
      </script>
   </head>
   <body onload="init()">
      <h1>W3C DOM Event Propagation</h1>
      <hr />
      <form>
         <input type="button" value="Button 'main1'" name="main1"
                onclick="alert('Event is now at the button object level ('
                               + getPhase(event)
                               + ').')" />
      </form>
   </body>
</html>
```

If you want to remove event capture after it has been enabled, use the `removeEventListener()` method on the same object as the event listener that was originally added (see Chapter 26). And, because multiple event listeners can be attached to the same object, specify the exact same three parameters to the `removeEventListener()` method that were applied to the `addEventListener()` method.

Preventing W3C event bubbling or capture

Corresponding to the `cancelBubble` property of the IE4+ `event` object is an event object method in the W3C DOM. The method that prevents propagation in any event phase is the `stopPropagation()` method. Invoke this method anywhere within an event listener function. The current function executes to completion, but the event propagates no further.

Listing 32-4 extends the example of Listing 32-3 to include two check boxes that let you stop propagation at the `form` element in your choice of the capture or bubble phase.

LISTING 32-4

Preventing Bubble and Capture

```

         {
            alert("This alert triggered by FORM only on CAPTURE.");
            if (document.forms[0].stopAllProp.checked)
            {
               evt.stopPropagation();
            }
         }
      }
      function formBubbleEvent(evt)
      {
         if (evt.target.type == "button")
         {
            alert("This alert triggered by FORM only on BUBBLE.");
            if (document.forms[0].stopDuringBubble.checked)
            {
               evt.stopPropagation();
            }
         }
      }
      // reveal event phase of current event object
      function getPhase(evt)
      {
         switch (evt.eventPhase)
         {
            case 1:
               return "CAPTURING";
               break;
            case 2:
               return "AT TARGET";
               break;
            case 3:
               return "BUBBLING";
               break;
            default:
               return "";
         }
      }
   </script>
</head>
<body onload="init()">
   <h1>W3C DOM Event Propagation</h1>
   <hr />
   <form>
      <input type="checkbox" name="stopAllProp" />Stop all propagation at FORM
      <br />
```

```
         <input type="checkbox" name="stopDuringBubble" />Prevent bubbling past FORM
         <hr />
         <input type="button" value="Button 'main1'" name="main1"
                onclick="alert('Event is now at the button object level ('
                        + getPhase(event)
                        + ').')" />
      </form>
   </body>
</html>
```

In addition to the W3C DOM `stopPropagation()` method, NN6+, Moz, Safari, Opera, and Chrome also support IE's `cancelBubble` property for syntactical convenience.

Preventing W3C event default action

The W3C DOM counterpart to IE's `returnValue` property is the event object's `preventDefault()` method. Invoke this method in an event handler function when you wish to block the element's default action to the event:

```
evt.preventDefault();
```

Redirecting W3C DOM events

The mechanism for sending an event to an object outside the normal propagation pattern in W3C is similar to that of IE4+, although with different syntax and an important requirement. In place of the IE4+ `fireEvent()` method, NN6+/Moz and Gecko-, WebKit-, and Presto-based browsers use the W3C DOM `dispatchEvent()` method. The sole parameter of the method is an event object, but it cannot be an event object that is already propagating through the element hierarchy. Instead, you must create a new event object via a W3C DOM event object constructor (described later in this chapter). Listing 32-5 is the same as the IE4+ Listing 32-2, but with just a few modifications to run in the W3C event model. Notice that the `dispatchEvent()` method passes a newly created event object as its sole parameter.

LISTING 32-5

Cancelling and Redirecting Events in the W3C DOM

```
<!DOCTYPE html>
<html onclick="revealEvent('HTML', event)">
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Event Cancelling & Redirecting</title>
      <script type="text/javascript">
         // display alert with event object info
         function revealEvent(elem, evt)
         {
            var msg = "Event (from " + evt.target.tagName + " at ";
            msg += evt.clientX + "," + evt.clientY + ") is now at the ";
            msg += elem + " element.";
            alert(msg);
```

continued

        {
           document.onclick = docEvent;
           document.body.onclick = docBodEvent;
        }
        function docEvent(evt)
        {
           revealEvent("document", evt);
        }
        function docBodEvent(evt)
        {
           revealEvent("BODY", evt);
        }
        function buttonEvent(form, evt)
        {
           revealEvent("BUTTON", evt);
           // redirect if checked
              if (form.redirect.checked)
              {
                 document.body.dispatchEvent(evt);
              }
           // cancel if checked
              if (form.bubbleCancelState.checked)
              {
                 evt.stopPropagation();
              }
        }
     </script>
  </head>
  <body onload="init()">
     <h1>Event Cancelling & Redirecting</h1>
     <hr />
     <form onclick="revealEvent('FORM', event)">
        <p><button name="main1" onclick="buttonEvent(this.form, event)">Button
             'main1'</button>
        </p>
        <p><input type="checkbox" name="bubbleCancelState"
                  onclick="event.stopPropagation()" />Cancel Bubbling at BUTTON
           <br />
           <input type="checkbox" name="redirect"
                  onclick="event.stopPropagation()" /> Redirect Event to BODY
        </p>
     </form>
  </body>
</html>
```

Referencing the event Object

Just as there are two different event object models in today's browsers, the way your scripts access those objects is divided into two camps: the IE way and the W3C way. We start with the simpler, IE way.

In IE4+, the `event` object is accessible as a property of the `window` object:

```
window.event
```

But, as you are well aware, the `window` part of references is optional, so your scripts can treat the `event` object as if it were a global reference:

```
event.propertyName
```

Thus, any statement in an event handler function can access the `event` object without any special preparation or initializations.

The situation is a bit more complicated in the W3C event model. In some cases you must explicitly pass the event object as a parameter to an event handler function, whereas in other cases, the event object is delivered as a parameter automatically. The difference depends on how the event handler function is bound to the object.

Binding Events

Perhaps the most important facet of event handling in any script is binding an event to an element on the page. There are several different ways that you can carry out this event binding, and as you might expect, they aren't all compatible across different browsers. Furthermore, some of the techniques are considered passé in the sense that they have been improved upon by more modern approaches. Following are the four main techniques that can be used to bind events to elements:

- Assignment through tag attributes
- Assignment through object properties
- Attachment in IE
- Event listeners in NN/Moz/W3C

The following sections explore these event binding options in more detail, with an emphasis on showing you how to craft a modern, cross-browser event binding function based upon the last two techniques listed.

Binding events through tag attributes

Dating back to some of the earliest JavaScript-powered browsers, the original way of binding event handlers to objects is through an attribute in the element's tag. To bind an event in this manner, you simply assign inline JavaScript code in the attribute of an element, as in the following:

```
<input type="button" value="Click Me" onclick="handleClick();" />
```

The attribute name is the name of the event being handled, and its value is inline JavaScript code that is executed upon the event firing. You can include multiple statements in the event attribute, as this code reveals:

```
<input type="button" value="Click Me"
onclick="doSomething(this); doSomethingElse(this.form);" />
```

For modern browsers that support the W3C event model (NN6+/Moz and Gecko, WebKit- and Presto-based browsers), if you intend to inspect properties of the event within the event handler function, you must specify the event object as a parameter by passing `event` as a parameter, as in:

```
<input type="button" value="Click Me" onclick="handleClick(event);" />
```

This is the only time in the W3C model that you see an explicit reference to the `event` (lowercase `e`) object as if it were a global reference. This reference does not work in any other context — only as a parameter to an event handler function. If you have multiple parameters, the `event` reference can go in any order, but we tend to put it last:

```
<input type="button" value="Click Me" onclick="doSomething(this, event);" />
```

The function definition that is bound to the element should therefore have a parameter variable in place to catch the event object parameter:

```
function doSomething(widget, evt) {...}
```

You have no restrictions on how you name this parameter variable. In some examples of this book, you may see the variable assigned as `event` or, more commonly, `evt`. When working with cross-browser scripts, avoid using `event` as a parameter variable name so as not to interfere with the Internet Explorer `window.event` property.

The good news is that binding an event through an event tag attribute works well across all browsers. The bad news is that it goes against the prevailing trend in web design, which is to separate HTML content from the code that makes it interactive. In other words, there is a concerted effort among web developers to clearly delineate JavaScript code from HTML code.

This concept is closely related to the notion of separating content from presentation, which is afforded by style sheets. In this way, you could think of a web page as having three distinct components: HTML content, CSS, and JavaScript code. Keeping these three components as compartmentalized as possible results in cleaner, more manageable code.

Note

You see many examples of event tag attribute binding throughout this book during demonstrations of various objects, properties, and methods. The usage is intentional because it is generally easier to understand the concepts under discussion when the events are bound closely to the elements. ■

The trick to maintaining a clean separation between JavaScript event binding and HTML code is to bind the events purely within script code as opposed to within attributes of HTML elements. The latter three event binding approaches mentioned earlier all offer this separation.

Binding events through object properties

Dating back as far as NN3 and IE4, element objects have event properties that can be used to bind events by assignment. For every event that an element is capable of receiving and responding to, there is a suitably named property, in all lowercase. For example, the `button` element object has a property named `onclick` that corresponds to the `onclick` event. You can bind an event handler to a `button` element by assigning a function reference to the `onclick` property:

```
document.forms[0].myButton.onclick = handleClick;
```

Note

Although event properties should be specified in all lowercase (`onclick`), some browsers also recognize mixed case event names (`onClick`). ■

One catch to binding events as object properties is that at first glance it doesn't appear to be possible to pass your own parameters to the invoked handler functions. W3C browsers pass an event object as the only parameter to event handler functions, and this doesn't exactly leave room for you to include your own parameters. Without any further trickery, this means that your functions should receive the passed event object in a parameter variable:

```
function doSomething(evt) {...}
```

Recall that the `event` object contains a reference to the object that was the target of the event. From that, you can access any properties of that object, such as the `form` object that contains a form control object.

It is in fact perfectly possible to pass along your own parameters; it just takes an intermediary anonymous function to do the go-between work. For example, the following code demonstrates how to pass a single custom parameter along with the standard `event` object:

```
document.forms[0].myButton.onclick =
   function(evt) {doSomething("Cornelius", evt);};
```

In this example, a name string is passed along as the first parameter to the event handler, whereas the `event` object (automatically passed to the anonymous function as its sole parameter, and assigned to the parameter variable `evt`) is routed along as the second parameter. The actual handler code would look something like this:

```
function doSomething(firstName, evt) {...}
```

The `evt` parameter variable in the `doSomething()` event handler function acts as a reference to the `event` object for statements within the function. If you need to invoke other functions from there, you can pass the `event` object reference further along as needed. The `event` object retains its properties as long as the chain of execution triggered by the event action continues.

Binding events through IE attachments

In IE5 Microsoft set out to establish a new means of binding events to elements through attachments, which were originally intended for use with IE behaviors (see Chapter 51, "Internet Explorer Behaviors," on the CD-ROM). Eventually, the attachment approach to event binding expanded beyond

behaviors and became the de facto IE standard for event binding. Seeing as how IE (as of version 8) still does not support the W3C approach to binding events, which you see in the next section, you should consider attachments the preferred way of handling events in IE for the foreseeable future.

IE event attachments are managed through the `attachEvent()` and `detachEvent()` methods, which are supported by all element objects that are capable of receiving events. By using both of these methods, you can bind and unbind events throughout the course of an application as needed.

The `attachEvent()` method takes the following form:

```
elementReference.attachEvent("event", functionReference);
```

To put this form in perspective, the following is an example of binding an event using the `attachEvent()` method in IE:

```
document.getElementById("myButton").attachEvent("onclick", doSomething);
```

The first parameter to the `attachEvent()` is the string name of the event, including the `on` prefix, as in `"onclick"`. The second parameter is a reference to the event handler function for the event.

One new power afforded by IE event attachment is the ability to attach the same event to the same element multiple times (presumably pointing to different event handler functions). Just remember that if you choose to bind multiple events of the same type to the same element, they will be processed in the reverse order that they were assigned. This means the first event added is processed last.

Since the IE event model is predicated on the `event` object, which is a property of the `window` object, there is no `event` object passed into the event handler function. To access event properties, you simply access the window's `event` object using either `window.event` or just `event`. The latter approach works because the `window` object is always assumed in client-side scripting. The upcoming section "event Object Compatibility" shows how to reconcile the IE `window.event` property and the W3C `event` event handler parameter.

The IE event binding approach also offers the ability to unbind an event, which means the targeted element will no longer receive event notifications. You unbind an IE event by calling the `detachEvent()` method on the element, like this:

```
document.getElementById("myButton").detachEvent("onclick", doSomething);
```

This example reveals how the `detachEvent()` method relies on the exact same syntax as `attachEvent()`.

Binding events through W3C listeners

The W3C approach to binding events is logically similar to IE event attachment in that it revolves around two methods: `addEventListener()` and `removeEventListener()`. These two methods give elements the ability to listen for events and then respond accordingly. Also similarly to the IE `attachEvent()` and `detachEvent()` methods, `addEventListener()` and `removeEventListener()` work as a pair for adding and removing event listeners, respectively.

The `addEventListener()` method takes the following form:

```
elementReference.addEventListener("eventType", functionReference,
   captureSwitch);
```

The following example should help to reveal the practical usage of the method:

```
document.getElementById("myButton").addEventListener("click", doSomething,
   false);
```

Note how the event name is specified without the `on` prefix, which is different from the name used in IE event attachments. The other notable difference in W3C event listeners as compared to IE event attachments involves the third parameter to `addEventListener()`, `captureSwitch`, which determines whether the element should listen for the event during the capture phase of event propagation. Later in the chapter you learn about event propagation and how this parameter might be used to tweak the propagation of an event. For now, just know that the parameter is typically set to `false`.

Similar to IE event attachments, you can add the same event listener to the same element multiple times. Unlike the IE approach, however, is the fact that W3C events added in this manner are processed in the same order that they were assigned. This means that the first event added is processed first.

Another similarity the W3C event model has to IE event handling is the ability to unbind an event from an element. The W3C version of event unbinding involves the `removeEventListener()` method, which is demonstrated in this example:

```
document.getElementById("myButton").removeEventListener("click", doSomething,
   false);
```

This example shows how the `removeEventListener()` method accepts the same parameters as `addEventListener()`.

A cross-browser event binding solution

Pulling together what you've learned about modern event handling, you know it must be possible to reconcile the IE and W3C approaches to event binding. In fact, it doesn't take all that much extra code to bind events in a manner that cleanly attempts to use the latest event binding techniques while still gracefully falling back on an older technique (object properties) for legacy browsers.

Following is a cross-browser function you can use to add an event binding to an element:

```
function addEvent(elem, evtType, func)
{
   if (elem.addEventListener)
   {
      elem.addEventListener(evtType, func, false);
   }
   else if (elem.attachEvent)
   {
      elem.attachEvent("on" + evtType, func);
   }
   else
   {
      elem["on" + evtType] = func;
   }
}
```

Parameters for the function are a reference to the element, a string of the event type (that is, the version without the `on` prefix), and a reference to the function to be invoked when the event fires

on the element. The addEvent() function first attempts to use the addEventListener() method on the supplied element, which satisfies modern W3C browsers (NN6+/Mozilla/Safari/Opera/Chrome). If that fails, attachEvent() is tried, which accommodates modern IE browsers (IE5+). If that's a bust, the function falls back on simply assigning the event handler function to the event object property, which works on the vast majority of browsers.

Note

You could easily extend the addEvent() **function to allow for the** captureSwitch **parameter of the** addEventListener() **method by adding a fourth parameter and passing it to** addEventListener()**, instead of passing** false**.** ■

Of course, the addEvent() function has to get called in order to bind events for a page. The onload event provides a great opportunity for binding events but, as you know, it's not a good idea to just call the addEvent() function in the onload HTML attribute. That would go against everything you've just learned. The trick is to first add an anonymous event handler for the onload event, and then carry out your other event bindings within that function. Here's an example of how you might do this:

```
addEvent(window, "load", function()
{
   addEvent(document.getElementById("myButton"), "click", handleClick);
   addEvent(document.body, "mouseup",
      function(evt) {handleClick(evt);});
});
```

In case you need to unbind an event, here is a suitable cross-browser function for unbinding events:

```
function removeEvent(elem, evtType, func)
{
   if (elem.removeEventListener)
   {
      elem.removeEventListener(evtType, func, false);
   }
   else if (elem.detachEvent)
   {
      elem.detachEvent("on" + evtType, func);
   }
   else
   {
      elem["on" + evtType] = null;
   }
}
```

event Object Compatibility

Despite the incompatible ways that W3C DOM and IE event objects arrive at an event handler function, you can easily stuff the object into one variable that both browser types can use. For example, the following function fragment receives a W3C DOM event object but also accommodates the IE event object:

```
function doSomething(evt)
```

```
{
   evt = (evt) ? evt : ((window.event) ? window.event : null);
   if (evt)
   {
      // browser has an event to process
      ...
   }
}
```

If an `event` object arrives as a parameter, it continues to be available as `evt`; but if not, the function makes sure that a `window.event` object is available and assigns it to the `evt` variable; finally, if the browser doesn't know about an `event` object, the `evt` variable is made `null`. Processing continues only if `evt` contains an event object.

That's the easy part. The madness comes in the details: reading properties of the event object when the property names can vary widely across the two event object models. Sections later in this chapter provide specifics of each property and method of both event object models, but seeing an overview of the property terminology on a comparative basis is helpful. Table 32-2 lists the common information bits and actions you are likely to want from an event object, and the property or method names used in the event object models.

TABLE 32-2

Common event Object Properties and Methods

Property/Action	IE4+	W3C DOM
Target element	`srcElement`	`target`
Event type	`type`	`type`
X coordinate in element	`offsetX`	n/a†
Y coordinate in element	`offsetY`	n/a†
X coordinate on page	n/a†	`pageX`††
Y coordinate on page	n/a†	`pageY`††
X coordinate in window	`clientX`	`clientX`
Y coordinate in window	`clientY`	`clientY`
X coordinate on screen	`screenX`	`screenX`
Y coordinate on screen	`screenY`	`screenY`
Mouse button	`button`	`button`
Keyboard key	`keyCode`	`keyCode`
Shift key pressed	`shiftKey`	`shiftKey`
Alt key pressed	`altKey`	`altKey`
Ctrl key pressed	`ctrlKey`	`ctrlKey`

TABLE 32-2 *(continued)*

Property/Action	IE4+	W3C DOM
Previous Element	fromElement	relatedTarget
Next Element	toElement	relatedTarget
Cancel bubbling	cancelBubble	stopPropagation()
Prevent default action	returnValue	preventDefault()

†Value can be derived through calculations with other properties.
††Not an official W3C DOM property, but is supported in Mozilla, Safari, Opera, and Chrome.

As you can see in Table 32-2, properties for the IE4+ and W3C event objects have a lot in common. Perhaps the most important incompatibility to overcome is referencing the element that is the intended target of the event. This, too, can be branched in your code to achieve a common variable that references the element. For example, embedded within the previous function fragment can be a statement, such as the following:

```
var elem = (evt.target) ? evt.target : ((evt.srcElement) ?
   evt.srcElement : null);
```

Each event model has additional properties that are not shared by the other. Details about these are covered in the rest of this chapter.

Dueling Event Models

Despite the sometimes widely divergent ways event object models treat their properties, accommodating a wide range of browsers for event manipulation is not difficult. In this section, you see two scripts that examine important event properties. The first script reveals which, if any, modifier keys are held down during an event; the second script extracts the codes for both mouse buttons and keyboard keys. Both scripts work with all modern browsers that have event objects.

Cross-platform modifier key check

Listing 32-6 demonstrates branching techniques for examining the modifier key(s) being held down while an event fires. You can find details of the event object properties, such as `modifiers` and `altKey`, later in this chapter. To see the page in action, click a link, type into a text box, and click a button while holding down any combination of modifier keys. A series of four check boxes representing the four modifier keys is at the bottom. As you click or type, the check box(es) of the pressed modifier key(s) become checked.

LISTING 32-6

Checking Events for Modifier Keys

             if (evt)
             {
                var elem = (evt.target) ? evt.target : evt.srcElement;
                var form = document.output;
                form.modifier[0].checked = evt.altKey;
                form.modifier[1].checked = evt.ctrlKey;
                form.modifier[2].checked = evt.shiftKey;
                form.modifier[3].checked = false;
             }
          return false;
       }

       // bind the event handlers
       function addEvent(elem, evtType, func)
       {
          if (elem.addEventListener)
          {
             elem.addEventListener(evtType, func, false);
          }
          else if (elem.attachEvent)
          {
             elem.attachEvent("on" + evtType, func);
          }
          else
          {
             elem["on" + evtType] = func;
          }
       }

       addEvent(window, "load", function()
       {
          addEvent(document.getElementById("link"), "mousedown",
             function(evt) {return checkMods(evt);});
          addEvent(document.getElementById("text"), "keyup",
             function(evt) {checkMods(evt);});
          addEvent(document.getElementById("button"), "click",
             function(evt) {checkMods(evt);});
       });
    </script>
 </head>
 <body>
    <h1>Event Modifiers</h1>
    <hr />
    <p>Hold one or more modifier keys and click on
       <a id="link" href="javascript:void(0)">this link</a>
       while looking at the checkboxes to see which keys you are holding.
    </p>
    <form name="output">
```

continued

LISTING 32-6 *(continued)*

```
         <p>Enter some text with uppercase and lowercase letters
            (while looking at the checkboxes):
            <input id="text" type="text" size="40" />
         </p>
         <p>
            <input id="button" type="button"
            value="Click Here With Modifier Keys" />
         </p>
         <p>
            <input type="checkbox" name="modifier" />Alt
            <input type="checkbox" name="modifier" />Control
            <input type="checkbox" name="modifier" />Shift
            <input type="checkbox" name="modifier" />Meta
         </p>
      </form>
   </body>
</html>
```

The script checks the event object property for each of three modifiers to determine which, if any, modifier keys are being pressed.

Cross-platform key capture

To demonstrate keyboard events in both event capture models, Listing 32-7 captures the key character being typed into a text box, as well as the mouse button used to click a button.

     <p>Mouse down atop this
        <input id="button" type="button" value="Button" />
        with either mouse button (if you have more than one).
     </p>
     <p>Enter some text with uppercase and lowercase letters:
        <textarea id="text" cols="40" rows="4" wrap="virtual"></textarea>
     </p>
  </form>
</body>
</html>
```

The codes displayed for each keyboard event are equivalent to the ASCII values of character keys. If you need the codes of other keys, the `onkeydown` and `onkeyup` event handlers provide Unicode values for any key that you press on the keyboard. See the `charCode` and `keyCode` property listings for event objects later in this chapter for more details.

Event Types

Although browsers prior to version 4 did not have an accessible event object, this is a good time to summarize the evolution of what in today's browsers is known as the `type` property. The `type` property reveals the kind of event that generates an event object (the event handler name minus the "on"). Object models in IE4+ and NN6+/W3C provide event handlers for virtually every HTML element, so that it's possible, for example, to define an `onclick` event handler for not only a clickable button, but also for a `p` or even an arbitrary `span` element.

Older Browsers

Earlier browsers tended to limit the number of event handlers for any particular element to just those that made sense for the kind of element it was. Even so, many scripters wanted more event handlers on more objects. But until that became a reality in IE4+ and NN6+/W3C, authors had to know the limits of the object models. Table 32-4 shows the event handlers available for objects within three generations of early browsers. Each column represents the version in which the event type was introduced. For example, the `window` object started out with four event types, and gained three more when NN4 was released. In contrast, the `area` object was exposed as an object for the first time in NN3, which is where the first event types for that object are listed.

With the exception of the NN4 `layer` object, all objects shown in Table 32-4 have survived into the newer browsers, so that you can use these event handlers with confidence. Again, keep in mind that of the browsers listed in Table 32-4, only NN4 has an `event` object of any kind exposed to scripts.

TABLE 32-3

Event types in IE4+ and NN6+/W3C

By now you should have at least scanned the list of event handlers defined for elements in common, as shown in Chapter 26. This list of event types is enormous. A sizable number of the event types are unique to IE4, IE5, and IE5.5+, and in some cases, just the Windows version at that.

If you compose pages for both IE4+ and NN6+/W3C, however, you need to know which event types these browser families and generations have in common. Event types for NN6+/Moz and Gecko-, WebKit-, and Presto-based browsers, are based primarily on the W3C DOM Level 2 specification, although they also include keyboard events, whose formal standards are still under development for DOM Level 3. Table 32-4 lists a common denominator of event types for modern browsers and the

TABLE 32-4

objects that support them. Although not as long as the IE event list, the event types in Table 32-4 are the basic set you should get to know for all browsers.

Syntax

Accessing IE4+ `event` object properties:

```
[window.]event.property
```

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

About this object

The IE4+ `event` object is a property of the `window` object. Its basic operation is covered earlier in this chapter.

You can see a little of what the `event` object is about with the help of The Evaluator (see Chapter 4, "JavaScript Essentials"). If you type `event` into the bottom text box, you can examine the properties of the `event` object for the event that triggers the function that displays the `event` object properties. If you press the Enter key in the text box, you see properties of the `keypress` event that caused the internal script to run; click the List Properties button to see the properties of the `click` event fired at the button. Hold down some of the modifier keys while clicking to see how this affects some of the properties.

As you review the properties for the `event` object, make special note of the compatibility rating for each property. The list of properties for this object has grown over the evolution of the IE4+ event object model. Also, most properties are listed here as being read-only, which they were in IE4. But for IE5+, these properties are also Read/Write if the event is created artificially via methods, such as IE5.5+'s `document.createEventObject()` method. Event objects that are created by user or system action have very few properties that can be modified on the fly (to prevent your scripts from altering user actions). Notice, too, that some properties are the same as for the W3C DOM event object, as revealed in the compatibility ratings.

Properties

altKey
ctrlKey
shiftKey

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

When an `event` object is created in response to a user or system action, these three properties are set based on whether their corresponding keys were being held down at the time — a Shift-click, for example. If the key was held down, the property is assigned a value of `true`; otherwise the value is `false`.

Most commonly, you use expressions consisting of this property as `if` construction conditional statements. Because these are Boolean values, you can combine multiple properties in a single condition. For example, if you have a branch of a function that is to execute only if the event occurred with both the Shift and Control keys held down, the condition looks as the following:

```
if (event.shiftKey && event.ctrlKey)
{
   // statements to execute
}
```

Conversely, you can take a more user-friendly approach to provide special processing if the user holds down any one of the three modifier keys:

```
if (event.shiftKey || event.ctrlKey || event.altKey)
{
   // statements to execute
}
```

The rationale behind this approach is to offer perhaps some shortcut operation for users, but not force them to memorize a specific modifier key combination.

Example

See Listing 32-6, where the values of these three properties are used to set the `checked` properties of corresponding check boxes for a variety of event types.

Related Items: `altLeft`, `ctrlLeft`, `shiftLeft` properties

altLeft
ctrlLeft
shiftLeft

Value: Boolean Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Some versions of Windows allow events to be modified by only the left-hand Alt, Ctrl, and Shift keys when using IE5.5+. For these modifiers to be recorded by the `event` object, focus must be on the document (body), and not in any form control. If the left-key version is `false` and the regular version is `true`, then your script knows that the right-hand key had been held down during the event.

Related Items: `altKey`, `ctrlKey`, `shiftKey` properties

behaviorCookie
behaviorPart

Value: Integer Read-Only

Compatibility: WinIE6+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

These two properties are related to a Windows technology that Microsoft calls *rendering behaviors*. Unlike the behaviors discussed under the `addBehavior()` method in Chapter 26, rendering behaviors are written in C++ and provide services for custom drawing on your web page. For more details, consult the document "Implementing Rendering Behaviors" at `http://msdn.microsoft.com/en-us/library/aa753628%28VS.85%29.aspx`.

recordset

Value: See text Read-Only

Compatibility: WinIE6+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

TABLE 32-5

ADO-Related event Object Properties

Property	Value	First Implemented	Description
`bookmarks`	Array	IE4	Array of ADO bookmarks (saved positions) for records within a recordset associated with the object that received the event.
`boundElements`	Array	IE5	Array of element references for all elements bound to the same data set that was touched by the current event.
`dataFld`	String	IE5	Name of the data source column that is bound to a table cell that receives a `cellchange` event.
`qualifier`	String	IE5	Name of the data member associated with a data source that receives a data-related event. Available only if the data source object (DSO) allows multiple-named data members or a qualifier has been explicitly set via the `datasrc` attribute of the bound element. Read-write in IE5+.
`reason`	Integer	IE4	Set only from `onDataSetComplete` event, provides the result code of the data set loading (`0`=successful; `1`=transfer aborted; `2`=other error).
`recordset`	Object	IE4	Reference to the current recordset in a data source object.

This group of `event` object properties is tied to using Data Binding in Windows versions of IE4+. Extensive details of Data Binding lie outside the scope of this book, but Table 32-5 provides a summary of these `event` object properties within that context (much of the terminology is used in Data Binding, but doesn't affect other scripting). For more details, search for ActiveX Data Objects (ADO) at `http://msdn.microsoft.com/en-us/library/default.aspx`.

Note

Although still supported in IE, Microsoft's original ADO technology has given way to ADO.NET, which is designed for tighter integration with Microsoft's .NET architecture. To learn more about the differences between the two technologies, visit `http://msdn.microsoft.com/library/en-us/dndotnet/html/adonetprogmsdn.asp`. ■

button

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `button` property reveals which button or buttons were pressed to activate a mouse event. If no mouse button is pressed to generate an event, this property is zero in IE. But integers 1 through 7 reveal single and multiple button presses, including the actions of three-button mice when they are recognized by the operating system. Integer values in IE correspond to buttons according to the following scheme:

Value	Description
0	No button
1	Left (primary) button
2	Right button
3	Left and right buttons together
4	Middle button
5	Left and middle buttons together
6	Right and middle buttons together
7	Left, middle, and right buttons together

Mouse buttons other than the primary one are easier to look for in `mousedown` or `mouseup` events rather than in `onclick` events. Be aware that as the user works toward pressing multiple buttons, each press fires a `mousedown` event. Therefore, if the user presses the left button first, the `mousedown` event fires, with the `event.button` property bearing the `1` value; as soon as the right button is pressed, the `mousedown` event fires again, but this time with an `event.button` value of `3`. If your script intends to perform special action with both buttons pressed, it should ignore and not perform any action for a single mouse button, because that one-button event will very likely fire in the process, disturbing the intended action.

Exercise caution when scripting the `event.button` property for both IE4+ and NN6+/Moz/W3C. The W3C DOM event model defines different button values for mouse buttons (`0`, `1`, and `2` for left, middle, and right) and no values for multiple buttons.

Example

See Listing 32-7, where the `event.button` property is revealed in the status bar. Try pressing individual mouse buttons on, for example, the screen button. Then try combinations, watching the results very closely in the status bar.

Related Items: None

cancelBubble

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cancelBubble` property (which sounds more as if it should be a method name) determines whether the current `event` object bubbles up any higher in the element containment hierarchy of the document. By default, this property is `false`, meaning that if the event is supposed to bubble, it will do so automatically.

To prevent event bubbling for the current event, set the property to `true` anywhere within the event handler function. As an alternative, you can cancel bubbling directly in an element's event handler attribute, as in the following:

```
onclick="doButtonClick(this); event.cancelBubble = true"
```

Cancelling event bubbling works only for the current event. The very next event to fire will have bubbling enabled (provided the event bubbles).

Example

See Listing 32-2 to see the `cancelBubble` property in action. Even though that listing has some features that apply to IE5.5+, the bubble cancelling demonstration works all the way back to IE4.

Related Item: `returnValue` property

clientX
clientY
offsetX
offsetY
screenX
screenY
x
y

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

An IE `event` object provides coordinates for an event in as many as four coordinate spaces: the element itself, the parent element of the event's target, the viewable area of the browser window, and the entire video screen. Unfortunately, misleading values can be returned by some of the properties that correspond to these coordinate spaces, as discussed in this section. Note that no properties provide the explicit position of an event relative to the entire page, in case the user has scrolled the window.

Starting with the innermost space — that of the element that is the target of the event — the `offsetX` and `offsetY` properties should provide pixel coordinates within the target element. This is how, for example, you could determine the click point on an image, regardless of whether the

image is embedded in the body or floating around in a positioned div. Windows versions through IE8 produce the correct values in most cases. But for some elements that are child elements of the body element, the vertical (y) value may be relative to the viewable window, rather than just the element itself. You can see an example of this when you work with Listing 32-8 and click the h1 or p elements near the top of the page. This problem does not affect MacIE, but there is another problem on Mac versions: If the page is scrolled away from its normal original position, the scrolled values are subtracted from the clientX and clientY values. This is an incompatibility bug, and you must take this error into account if you need click coordinates inside an element for a potentially scrolled page. This error correction must be done only for the Mac, because in Windows it works as is.

Extending scope to the offset parent element of the event's target, the x and y properties in IE5+ for Windows should return the coordinates for the event relative to the target's offset parent element (the element that can be found via the offsetParent property). For most non-positioned elements, these values are the same as the clientX and clientY properties because, as discussed in a moment, the offset parent element has a zero offset with *its* parent, the body. Observe an important caution about the x and y properties: In WinIE4 and through MacIE5, the properties do not take into account any offset parent locations other than the body. Even in WinIE5+, this property can give false readings in some circumstances. By and large, these two properties should not be used.

The next set of coordinates, clientX and clientY, are relative to the visible document area of the browser window. When the document is scrolled all the way to the top (or the document doesn't scroll at all), these coordinates are the same as the coordinates on the entire page. But because the page can scroll "underneath" the viewable window, the coordinates on the page can change if the page scrolls. Also, in the Windows versions of IE, you can actually register mouse events that are up to 2 pixels outside of the body element, which is weird, but true. Therefore, in WinIE, if you click the background of the body, the event fires on the body element, but the clientX/clientY values will be 2 pixels greater than offsetX/offsetY (they're equal in MacIE). Despite this slight discrepancy, you should rely on the clientX and clientY properties if you are trying to get the coordinates of an event that may be in a positioned element, but have those coordinates relative to the entire viewable window, rather than just the positioning context.

Taking the page's scrolling into account for an event coordinate is often important. After all, unless you generate a fixed-size window for a user, you don't know how the browser window will be oriented. If you're looking for a click within a specific region of the page, you must take page scrolling into account. The scrolling factor can be retrieved from the document.body.scrollLeft and document.body.scrollTop properties. When reading the clientX and clientY properties, be sure to add the corresponding scroll properties to get the position on the page:

```
var coordX = event.clientX + document.body.scrollLeft;
var coordY = event.clientY + document.body.scrollTop;
```

Do this in your production work without fail.

Finally, the screenX and screenY properties return the pixel coordinates of the event on the entire video screen. These properties would be more useful if IE provided more window dimension properties. In any case, because mouse events fire only when the cursor is somewhere in the content region of the browser window, don't expect to get the screen values of any place outside this region.

If these descriptions seem confusing to you, you are not alone. Throw in a few bugs, and it may seem like quite a mess. But think how you may use event coordinates in scripts. By and large, you want to know one of two types of mouse event coordinates: within the element itself and within the page. Use the offsetX/offsetY properties for the former; use clientX/clientY (plus the scroll property values) for the latter.

Although the coordinate properties are used primarily for mouse events, there is a little quirk that may let you determine if the user has resized the window via the maximize icon in the title bar

(on the Mac, this is called the zoom box) or the resize handle at the bottom-right corner of the screen. Mouse event coordinates are recorded in the `event` object for a `resize` event. In the case of the maximize icon, the `clientY` coordinate is a negative value (above the client space) and the `clientX` coordinate is within about 45 pixels of the previous width of the window (`document.body.clientWidth`). This, of course, happens after the window has resized, so it is not a way to prevent window resizing.

Example

Listing 32-8 provides readings of all event coordinate properties in an interactive way. An `onmousedown` event handler triggers all event handling, and you can click the mouse anywhere on the page to see what happens. You see the tag of the element targeted by the mouse event to help you visualize how some of the coordinate properties are determined. An image is encased inside a positioned `div` element to help you see what happens to some of the properties when the event is targeted inside a positioned element.

      </div>
   </body>
</html>
```

Here are some tasks to try in IE with the page that loads from Listing 32-8 to help you understand the relationships among the various pairs of coordinate properties:

1. Click the dot above the "i" on the "Click Here" button label. The target element is the button (`input`) element, whose `offsetParent` is a table cell element. The `offsetY` value is very low because you are near the top of the element's own coordinate space. The client coordinates (and `x` and `y`), however, are relative to the viewable area in the window. If your browser window is maximized in Windows, the `screenX` and `clientX` values will be the same; the difference between `screenY` and `clientY` is the height of all the window chrome above the content region. With the window not scrolled at all, the client coordinates are the same with and without scrolling taken into account.
2. Jot down the various coordinate values and then scroll the page down slightly (clicking the scrollbar fires an event), and click the dot on the button again. The `clientY` value shrinks because the page has moved upward relative to the viewable area, making the measure between the top of the area smaller with respect to the button. The Windows version does the right thing with the offset properties, by continuing to return values relative to the element's own coordinate space; the Mac, unfortunately, subtracts the scrolled amount from the offset properties.
3. Click the large image. The client properties perform as expected for both Windows and Mac, as do the screen properties. For Windows, the `x` and `y` properties correctly return the event coordinates relative to the `img` element's `offsetParent`, which is the `div` element that surrounds it. Note, however, that the browser "sees" the `div` as starting 10 pixels to the left of the image. In WinIE5.5+, you can click within those 10 transparent pixels to the left of the image to click the `div` element. This padding is inserted automatically and impacts the coordinates of the `x` and `y` properties. A more reliable measure of the event inside the image is the offset properties. The same is true in the Macintosh version, as long as the page isn't scrolled, in which case the scroll, just as in Step 2, affects the values above.
4. Click the top `hr` element under the heading. It may take a couple of tries to actually hit the element (you've made it when the `hr` element shows up in the `srcElement` box). This is to reinforce the way the client properties provide coordinates within the element itself (again, except on the Mac when the page is scrolled). Clicking at the very left end of the rule, you eventually find the 0,0 coordinate.

Finally, if you are a Windows user, here are two examples to try to see some of the unexpected behavior of coordinate properties.

1. With the page not scrolled, click anywhere along the right side of the page, away from any text, so that the `body` element is `srcElement`. Because the `body` element theoretically fills the entire content region of the browser window, all coordinate pairs except for the screen coordinates should be the same. But offset properties are 2 pixels less than all the others. By and large, this difference won't matter in your scripts, but you should be aware of this potential discrepancy if precise positioning is important. For inexplicable reasons, the offset properties are measured in a space that is inset 2 pixels from the left and top of the window. This is not the case in the Macintosh version, where all value pairs are the same from the `body` perspective.

2. Click the text of the `h1` or `p` elements (just above and below the long horizontal rule at the top of the page). In theory, the offset properties should be relative to the rectangles occupied by these elements (they're block elements, after all). But instead, they're measured in the same space as the client properties (plus the 2 pixels). This unexpected behavior doesn't have anything to do with the cursor being a text cursor, because if you click inside any of the text box elements, their offset properties are properly relative to their own rectangles. This problem does not afflict the Macintosh version.

Many of these properties are also in the W3C DOM and are therefore supported in W3C DOM browsers. Unsupported properties display their values as `undefined` when you run Listing 32-8 in those browsers.

You can see further examples of important event coordinate properties in action in the discussion of dragging elements around the IE page in Chapter 43, "Positioned Objects."

Related Items: `fromElement`, `toElement` properties

contentOverflow

Value: Boolean Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The value indicates whether page content has overflowed the current layout rectangle. This property is primarily used during printing as the basis for overflowing content from one page to another.

dataTransfer

Value: Object Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `dataTransfer` property is a reference to the `dataTransfer` object. Use this object in drag-and-drop operations (that is, with drag-and-drop-related events) to control not only the data that gets transferred from the source to the target, but also to control the look of the cursor along the way.

Table 32-6 lists the properties and methods of the `dataTransfer` object.

The `dataTransfer` object acts as a conduit and controller of the data that your scripts need to transfer from one element to another in response to a user's drag-and-drop action. You need to adhere to a well-defined sequence of actions triggered by a handful of event handlers. This means that the object is invoked on different instances of the `event` object as different events fire in the process of dragging and dropping.

The sequence begins at the source element, where an `ondragstart` event handler typically assigns a value to the `dropEffect` property and uses the `getData()` method to explicitly capture whatever data regarding the source object gets transferred to the eventual target. For example, if you drag an image, the information being transferred may simply be the URL of the image — data that is extractable from the `event.srcElement.src` property of that event (the `src` property of the image, that is).

At the target element(s), three event handlers must be defined: `ondragenter`, `ondragover`, and `ondrop`. Most commonly, the first two event handlers do nothing more than mark the element for a particular `dropEffect` (which must match the `effectAllowed` set at the source during the drag's start) and set `event.returnValue` to false so the desired cursor is displayed. These actions are

also carried out in the `ondrop` event handler, but that is also the handler that does the processing of the destination action at the target element. This is when the `dataTransfer` object's `getData()` method is invoked to pick up the data that has been "stored" away by `getData()` at the start of the drag. If you also want to make sure that the data is not picked up accidentally by another event, invoke the `clearData()` method to remove that data from memory.

TABLE 32-6

dataTransfer object Properties and Methods

Property/Method	Returns	Description
`dropEffect`	String	An element that is a potential recipient of a drop action can use the `ondragenter`, `ondragover`, or `ondrop` event handler to set the cursor style to be displayed when the cursor is atop the element. Before this can work, the source element's `ondragstart` event handler must assign a value to the `event.effectAllowed` property. Possible string values for both properties are `copy`, `link`, `move`, or `none`. These properties correspond to the Windows system cursors for the operations users typically do with files and in other documents. You must also cancel the default action (meaning set `event.returnValue` to `false`) for all of these drop element event handlers: `ondragenter`, `ondragover`, and `ondrop`.
`effectAllowed`	String	Set in response to an `ondragstart` event of the source element, this property determines which kind of drag-and-drop action will be taking place. Possible string values are `copy`, `link`, `move`, or `none`. This property value must match the `dropEffect` property value for the target element's event object. Also, cancel the default action (meaning, set `event.returnValue` to `false`) in the `ondragstart` event handler.
`clearData([format])`	Nothing	Removes data in the clipboard. If no format parameters are supplied, all data are cleared. Data formats can be one or more of the following strings: `Text`, `URL`, `File`, `HTML`, `Image`.
`getData(format)`	String	Retrieves data of the specified format from the clipboard. The format is one of the following strings: `Text`, `URL`, `File`, `HTML`, `Image`. The clipboard is not emptied after you get the data, so it can be retrieved in several sequential operations.
`setData(format, data)`	Boolean	Stores string data in the clipboard. The format is one of the following strings: `Text`, `URL`, `File`, `HTML`, `Image`. For non-text data formats, the data must be a string that specifies the path or URL to the content. Returns `true` if the transfer to the clipboard is successful.

Note that the style of dragging being discussed here is not the kind in which you see the source element actually moving on the screen (although you could script it that way). The intention is to treat drag-and-drop operations just as Windows does in, say, the Windows Explorer window or on the Desktop. To the user, the draggable component becomes encapsulated in the cursor. That's why the properties of the `dataTransfer` object control the appearance of the cursor at the drop point as a way of conveying to the user the type of action that will occur with the impending drop. Apple implements the same behavior in Safari 2.

Example

An extensive example of the `dataTransfer` property in action can be found in Listing 26-37 in the section for the `ondrag` event handler.

Related Items: `ondragend`, `ondragenter`, `ondragleave`, `ondragover`, `ondragstart`, `ondrop` event handlers

fromElement
toElement

Value: Element object — Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera+, Chrome+

The `fromElement` and `toElement` properties allow an element to uncover where the cursor rolled in from or has rolled out to. These properties extend the power of the `onmouseover` and `onmouseout` event handlers by expanding their scope to outside the current element (usually to an adjacent element).

When the `onmouseover` event fires on an element, the cursor had to be over some other element just beforehand. The `fromElement` property holds a reference to that element. Conversely, when the `onmouseout` event fires, the cursor is already over some other element. The `toElement` property holds a reference to that element.

Example

Listing 32-9 provides an example of how the `fromElement` and `toElement` properties can reveal the life of the cursor action before and after it rolls into an element. When you roll the cursor to the center box (a table cell), its `onmouseover` event handler displays the text from the table cell from which the cursor arrived.

LISTING 32-9

Using the toElement and fromElement Properties

```
<!DOCTYPE html>

      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>fromElement and toElement Properties</title>
      <style type="text/css">
         .direction {background-color:#00FFFF; width:100; height:50;
                    text-align:center;}
```

```
      #main {background-color:#FF6666; text-align:center;}
   </style>
   <script type="text/javascript">
      function showArrival(evt)
      {
         evt = (evt) ? evt : ((event) ? event : null);
         var direction = (event.fromElement.innerText) ?
            event.fromElement.innerText :
            "parts unknown";
         status = "Arrived from: " + direction;
      }
      function showDeparture(evt)
      {
         evt = (evt) ? evt : ((event) ? event : null);
         var direction = (event.toElement.innerText) ?
            event.toElement.innerText :
            "parts unknown";
         status = "Departed to: " + direction;
      }

      // bind the event handlers
      function addEvent(elem, evtType, func)
      {
         if (elem.addEventListener)
         {
            elem.addEventListener(evtType, func, false);
         }
         else if (elem.attachEvent)
         {
            elem.attachEvent("on" + evtType, func);
         }
         else
         {
            elem["on" + evtType] = func;
         }
      }
      addEvent(window, "load", function()
      {
         addEvent(document.getElementById("main"), "mouseover",
                  function(evt) {showArrival(evt);});
         addEvent(document.getElementById("main"), "mouseout",
                  function(evt) {showDeparture(evt);});
      });
   </script>
</head>
<body>
   <h1>fromElement and toElement Properties</h1>
   <hr />
   <p>Roll the mouse to the center box and look for arrival information in
      the status bar. Roll the mouse away from the center box and look for
      departure information in the status bar.</p>
   <table cellspacing="0" cellpadding="5">
      <tr>
```

continued

LISTING 32-9 *(continued)*

```
            <td></td>
            <td class="direction">North</td>
            <td></td>
         </tr>
         <tr>
            <td class="direction">West</td>
            <td id="main" onmouseover="showArrival()"
                onmouseout="showDeparture()">Roll</td>
            <td class="direction">East</td>
         </tr>
         <tr>
            <td></td>
            <td class="direction">South</td>
            <td></td>
         </tr>
      </table>
   </body>
</html>
```

This is a good example to experiment with in the browser, because it also reveals a potential limitation. The element registered as the `toElement` or `fromElement` must fire a mouse event to register itself with the browser. If not, the next element in the sequence that registers itself is the one acknowledged by these properties. For example, if you roll the mouse into the center box, and then extremely quickly roll the cursor to the bottom of the page, you may bypass the South box entirely. The text that appears in the status bar is actually the inner text of the `body` element, which is the element that caught the first mouse event to register itself as the `toElement` for the center table cell.

Related Item: `srcElement` property

keyCode

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

For keyboard events, the `keyCode` property returns an integer corresponding to the Unicode value of the character (for `onkeypress` events) or the keyboard character key (for `onkeydown` and `onkeyup` events). There is a significant distinction between these numbering code systems.

If you want the Unicode values (the same as ASCII values for the Latin character set) for the key that a user pressed, get the `keyCode` property from the `onkeypress` event handler. For example, a lowercase “a” returns 97, whereas an uppercase “A” returns 65. Non-character keys, such as arrows, page navigation, and function keys, return a `null` value for the `keyCode` property during `onkeypress` events. In other words, the `keyCode` property for `onkeypress` events is more like a character code than a key code.

To capture the exact keyboard key that the user presses, use either the `onkeydown` or `onkeyup` event handler. For these events, the `event` object captures a numeric code associated with a particular key on the keyboard. For the character keys, this varies with the language assigned as the

system language. Importantly, there is no distinction between uppercase or lowercase: The "A" key on the Latin keyboard returns a value of 65, regardless of the state of the Shift key. At the same time, however, the press of the Shift key fired its own `onkeydown` and `onkeyup` events, setting the `keyCode` value to 16. Other non-character keys — arrows, page navigation, function, and similar — have their own codes as well. This gets very detailed, and involves special key codes for the numeric keyboard keys that are different from their corresponding numbers along the top row of the alphanumeric keyboard.

Cross-Reference

Be sure to see the extensive section on keyboard events in Chapter 26 for examples of how to apply the `keyCode` **property in applications.** ■

Example

Listing 32-10 provides an additional play area to view the `keyCode` property for all three keyboard events while you type into a `textarea`. You can use this page later as an authoring tool to grab the precise codes for keyboard keys you may not be familiar with.

      {
         if (elem.addEventListener)
         {
            elem.addEventListener(evtType, func, false);
         }
         else if (elem.attachEvent)
         {
            elem.attachEvent("on" + evtType, func);
         }
         else
         {
            elem["on" + evtType] = func;
         }
      }
      addEvent(window, "load", function()
      {
         addEvent(document.getElementById("scratchpad"), "keydown",
                  function(evt) {clearEm(); showCode("down", evt);});
         addEvent(document.getElementById("scratchpad"), "keypress",
                  function(evt) {showCode("press", evt);});
         addEvent(document.getElementById("scratchpad"), "keyup",
                  function(evt) {showCode("up", evt);});
      });
   </script>
</head>
<body>
   <h1>keyCode Property</h1>
   <hr />
   <form>
      <p>
         <textarea id="scratchpad" name="scratchpad"
          cols="40" rows="5" wrap="hard"></textarea>
      </p>
      <table cellpadding="5">
         <tr>
            <th>Event</th>
            <th>event.keyCode</th>
         </tr>
         <tr>
            <td>onKeyDown:</td>
            <td><input type="text" name="down" size="3" /></td>
         </tr>
         <tr>
            <td>onKeyPress:</td>
            <td><input type="text" name="press" size="3" /></td>
         </tr>
         <tr>
            <td>onKeyUp:</td>
```

```
            <td><input type="text" name="up" size="3" /></td>
         </tr>
      </table>
   </form>
</body>
</html>
```

The following are some specific tasks to try with the page to examine key codes (if you are not using a browser set for English, and a Latin-based keyboard, your results may vary):

1. Enter a lowercase **a**. Notice how the `onkeypress` event handler shows the code to be 97, which is the Unicode (and ASCII) value for the first of the lowercase letters of the Latin alphabet. But the other two events record just the key's code: 65.
2. Type an uppercase **A** via the Shift key. If you watch closely, you see that the Shift key itself generates the code 16 for the `onkeydown` and `onkeyup` events. But the character key then shows the value 65 for all three events, because the ASCII value of the uppercase letter happens to match the keyboard key code for that letter.
3. Press and release the Down Arrow key (be sure the cursor still flashes in the `textarea`, because that's where the keyboard events are being monitored). As a non-character key, it does not fire an `onkeypress` event. But it does fire the other events, and assigns 40 as the code for this key.
4. Poke around with other non-character keys. Some may produce dialog boxes or menus, but their key codes are recorded nonetheless. Note that not all keys on a Macintosh keyboard register with MacIE.

Notice also that the `keyCode` property doesn't work properly for the `onkeypress` event in Mozilla-based browsers. This is because Mozilla uses the `charCode` property for the `onkeypress` event instead of `keyCode`. You could make the code in the listing work for all modern browsers with the following modification in the `showCode()` function:

```
if (evt)
{
   var charCode = (evt.charCode) ? evt.charCode : evt.keyCode;
   document.forms[0].elements[which].value = charCode;
}
```

Related Items: `onkeydown`, `onkeypress`, `onkeyup` event handlers

nextPage

Value: String — Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `nextPage` property is applicable only if your WinIE5.5+ page uses a TemplatePrinter behavior. Values of this property are one of the following strings: `left`, `right`, or an empty string.

propertyName

Value: String — Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `propertyName` property is filled only after an `onpropertychange` event fires.

If a script modifies a property, the `onpropertychange` event handler fires, and the string name of the property is stuffed into the `event.propertyName` property. If the property happens to be a property of the `style` object associated with the element, the `propertyName` is the full property reference, as in `style.backgroundColor`.

Example

See Listing 26-45 in the section about the `onpropertychange` event handler for an example of the values returned by this property.

Related Item: `onpropertychange` event handler (Chapter 26, "Generic HTML Element Objects")

repeat

Value: Boolean — Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `repeat` property reveals for `onkeydown` events only whether the key is in repeat mode (as determined by the keyboard control panel settings in the system). With this information, you can prevent the automatic triggering of repeat mode from causing multiple characters from being recognized by the browser. This property can come in handy if users accidentally hold down a key too long. The following script fragment in an `onkeydown` event handler for a text box or `textarea` prevents multiple characters from appearing even if the system goes into repeat mode:

```
if (event.repeat)
{
   event.returnValue = false;
}
```

By disabling the default action while in repeat mode, no further characters reach the text box until repeat mode goes away (with the press of another key).

Related Item: `onkeydown` event handler

returnValue

Value: Boolean — Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari1.2+, Opera+, Chrome+

While IE4+ continues to honor the original way of preventing default action for an event handler (that is, having the last statement of the event handler evaluate to `return false`), the IE4+ event model provides a property that lets the cancellation of default action take place entirely within a function invoked by an event handler. By default, the `returnValue` property of the `event` object is `true`, meaning that the element processes the event after the scripted handler completes its job, just as if the script weren't there. Normal processing, for example, is displaying a typed character, navigating to a link's `href` URL upon being clicked, or submitting a form after the Submit button is clicked.

But you don't always want the default action to occur. For example, consider a text box that is supposed to allow only numbers to be typed in it. The `onkeypress` event handler can invoke a function that inspects each typed character. If the character is not a numeric character, it should not reach the

text box for display. The following validation function may be invoked from the `onkeypress` event handler of just such a text box:

```
function checkIt()
{
   var charCode = event.keyCode;
      if (charCode < 48 || charCode > 57)
      {
         alert("Please make sure entries are numerals only.");
         event.returnValue = false;
      }
}
```

By using this event handler, the errant character won't appear in the text box.

Note that this property is not a substitute for the `return` statement of a function. If you need a value to be returned to the invoking statement, you can use a `return` statement in addition to setting the `event.returnValue` property.

Example

You can find several examples of the `returnValue` property at work in Chapters 1 and 26. Specifically, refer to Listings 26-30, 26-33, 26-36, 26-37, 26-38, and 26-44. Moreover, many of the other examples in Chapter 26 can substitute the `returnValue` property way of cancelling the default action if the scripts were to be run exclusively on IE4+.

Related Item: `return` statement (Chapter 23, "Function Objects and Custom Objects")

saveType

Value: String Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `saveType` property is assigned a value only when an `oncontentsave` event is bound to a WinIE DHTML behavior file. For more information about behaviors, see `http://msdn.microsoft.com/en-us/library/ms531079%28VS.85%29.aspx`.

Related Item: `addBehavior()` method

srcElement

Value: Element object reference Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari1.2+, Opera+, Chrome+

The `srcElement` property is a reference to the HTML element object that is the original target of the event. Because an event may bubble up through the element containment hierarchy and be processed at any level along the way, having a property that points back to the element from which the event originated is comforting. After you have a reference to that element, you can read or write any properties that belong to that element or invoke any of its methods.

Example

As a simplified demonstration of the power of the `srcElement` property, Listing 32-11 has but two event handlers defined for the `body` element, each invoking a single function. The idea is that the `onmousedown` and `onmouseup` events will bubble up from whatever their targets are, and the event handler functions will find out which element is the target and modify the color style of that element.

An extra flair is added to the script in that each function also checks the `className` property of the target element. If the `className` is `bold` — a class name shared by three `span` elements in the paragraph — the stylesheet rule for that class is modified so that all items share the same color. Your scripts can do even more in the way of filtering objects that arrive at the functions to perform special operations on certain objects or groups of objects.

Notice that the scripts don't have to know anything about the objects on the page to address each clicked one individually. That's because the `srcElement` property provides all of the specificity needed for acting on the target element.

LISTING 32-11

Using the srcElement Property

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>srcElement Property</title>
      <style type="text/css">
         .bold {font-weight:bold}
         .ital {font-style:italic}
      </style>
      <script type="text/javascript">
         function highlight()
         {
            var elem = event.srcElement;
               if (elem.className == "bold")
               {
                  document.styleSheets[0].rules[0].style.color = "red";
               }
               else
               {
                  elem.style.color = "#FFCC00";
               }
         }
         function restore()
         {
            var elem = event.srcElement;
               if (elem.className == "bold")
               {
                  document.styleSheets[0].rules[0].style.color = "";
               }
               else
               {
```

```
                elem.style.color = "";
             }
         }

         // bind the event handlers
         function addEvent(elem, evtType, func)
         {
            if (elem.addEventListener)
            {
               elem.addEventListener(evtType, func, false);
            }
            else if (elem.attachEvent)
            {
               elem.attachEvent("on" + evtType, func);
            }
            else
            {
               elem["on" + evtType] = func;
            }
         }
         addEvent(window, "load", function()
         {
            addEvent(document.body, "mousedown", highlight);
            addEvent(document.body, "mouseup", restore);
         });
      </script>
   </head>
   <body>

   </body>
</html>
```

Related Items: `fromElement`, `toElement` properties

srcFilter

Value: String Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

According to Microsoft, the `srcFilter` property should return a string of the name of the filter that was applied to trigger an `onfilterchange` event handler. While the property exists in the `event` object, its value is always `null`, at least through WinIE8.

Related Items: `onfilterchange` event handler; `style.filter` object

srcUrn

Value: String Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

If an event is fired in a WinIE behavior attached to an element, and the behavior has a URN identifier defined for it, the `srcUrn` property returns the string from the URN identifier. For more information about behaviors, see `http://msdn.microsoft.com/en-us/library/ms531079%28VS.85%29.aspx`.

Related Item: `addBehavior()` method

toElement

(See `fromElement`)

type

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

You can find out what kind of event fired to create the current `event` object by way of the `type` property. The value is a string version of the event name — just the name of the event without the "on" prefix that is normally associated with event names in IE. This property can be helpful when you designate one event handler function to process different kinds of events. For example, both the `onmousedown` and `onclick` event handlers for an object can invoke one function. Inside the function, a branch is written for whether the type comes in as `mousedown` or `click`, with different processing for each event type. That is not to endorse such event handler function sharing, but for you to be aware of this power should your script constructions find the property helpful.

This property and its values are fully compatible with the NN6+/Moz/W3C event models.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see values returned by the `type` property. Enter the following object name into the bottom text box and press Enter/Return:

```
event
```

If necessary, scroll the Results box to view the `type` property, which should read `keypress`. Now click the List Properties button. The type changes to `click`. The reason for these types is that the

`event` object whose properties are being shown here is the event that triggers the function to show the properties. From the text box, an `onkeypress` event handler triggers that process; from the button, an `onclick` event handler does the job.

Related Items: All event handlers (Chapter 26, "Generic HTML Element Objects")

wheelData

Value: Integer Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `wheelData` property returns an integer indicating which direction the mouse wheel was rolled for an `onmousewheel` event. The values returned are typically either 120 or −120, with a positive value indicating that the mouse wheel was rolled toward the screen and a negative value indicating that the wheel was rolled the opposite direction.

Syntax

Accessing NN6+/Moz event object properties and methods:

```
eventObject.property | method([parameters])
```

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

Although it is based largely on the event object as defined by the W3C DOM Level 2, the NN6+/Moz event object also carries forward several characteristics from the NN4 event object. A few properties are continued primarily for backward compatibility. But because future Mozilla development will likely forego the peculiarities of the NN4 DOM and event models, you should ignore these items (as highlighted below). Wherever possible, look forward and embrace the W3C DOM aspects of the event model. Safari, Opera, and Chrome, for example, implement a lot of the W3C DOM event model, but exclude all old NN4 properties.

Although the NN6+/Moz event model provides a bubbling event propagation model just as IE4+ does the incompatibility of referencing event objects between the event models is still there. In the W3C DOM (as in NN4), an event object is explicitly passed as a parameter to event handler (or, rather, event listener) functions. But after you have a browser-specific event object assigned to a variable inside a function, a few important properties have the same names between the IE4+ and W3C DOM event models. If Microsoft adopts more of the W3C DOM event model in future versions of IE, the compatibility situation should improve.

The event object discussed in this section is the instance of an event that is created as the result of a user or system event action. The W3C DOM includes an additional static `Event` object. Many of the properties of the static `Event` object are inherited by the event instances, so the detailed coverage of

those shared properties is in this section because it is the event object you'll be scripting for the most part.

In many code fragments in the following detail sections, you will see references that begin with the `evt` reference. This assumes that the statement(s) resides inside a function that has assigned the incoming event object to the `evt` parameter variable:

```
function myFunction(evt) {...}
```

As shown earlier in this chapter, you can equalize W3C DOM and IE4+ event object references when it is practical to do so because the scripts work on identical (or similar) event object properties. The results of this equalization are typically stored in the `evt` variable.

Properties

altKey
ctrlKey
metaKey
shiftKey

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

When an event object is created in response to a user or system action, these four properties are set based on whether their corresponding keys were being held down at the time — a Shift-click, for example. If the key was held down, the property is assigned a value of `true`; otherwise the value is `false`. The `metaKey` property corresponds to the Command key on the Macintosh keyboard but does not register for the Windows key on Wintel computers.

Most commonly, you use expressions consisting of this property as `if` construction conditional statements. Because these are Boolean values, you can combine multiple properties in a single condition. For example, if you have a branch of a function that is to execute only if the event occurred with both the Shift and Control keys held down, the condition looks like the following:

```
if (evt.shiftKey && evt.ctrlKey)
{
   // statements to execute
}
```

Conversely, you can take a more user-friendly approach to provide special processing if the user holds down any one of the four modifier keys:

```
if (evt.shiftKey || evt.ctrlKey || evt.metaKey || evt.altKey)
{
   // statements to execute
}
```

The rationale behind this approach is to offer perhaps some shortcut operation for users, but not force them to memorize a specific modifier key combination.

Example

See Listing 32-6, where the values of these properties are used to set the `checked` properties of corresponding check boxes for a variety of event types.

Related Items: None

`bubbles`

Value: Boolean Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

Not every event bubbles. For example, an `onsubmit` event propagates no further than the form object with which the event is associated. Events that do not bubble have their event object's `bubbles` property set to `false`; all others have the property set to `true`. You use this property in the rare circumstance of a single event handler function processing a wide variety of events. You may want to perform special operations only on events that can bubble, and handle the others without special treatment. For this branch, you can use the property in an `if` conditional statement:

```
if (evt.bubbles)
{
   // special processing for bubble-able events
}
```

You do not have to branch, however, just to cancel bubbling. A non-propagating event doesn't mind if you tell it not to propagate.

Related Item: `cancelBubble` property

`button`

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera8+, Chrome+

The `button` property reveals the button that was pressed to activate the mouse event. In the W3C DOM, the left (primary) button returns a value of `0`. If the mouse is a three-button mouse, the middle button returns `1`. The right button (on any multi-button mouse) returns a value of `2`.

Mouse buttons other than the primary one are easier to look for in `mousedown` or `mouseup` events, rather than `onclick` events. In the case of a user pressing multiple buttons, only the most recent button is registered.

Exercise caution when scripting the `button` property across browsers. The respective event models define different button values for mouse buttons.

Example

See Listing 32-7, where the `button` property is revealed in the status bar. Try pressing individual mouse buttons on, say, the screen button.

Related Items: None

`cancelable`

Value: Boolean Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

If an event is cancelable, then its default action can be prevented from occurring with the help of a script. Although most events are cancelable, some are not. The cancelable property lets you inquire about a particular event object to see if its event type is `cancelable`. Values for the property are Booleans. You may want to perform special operations only on events that are cancelable and handle the others without special treatment. For this branch, you can use the property in an `if` conditional statement:

```
if (evt.cancelable)
{
   // special processing for cancelable events
}
```

You do not have to branch, however, just to prevent an event's default action. A non-cancelable event doesn't mind if you tell it to prevent the default action.

Related Item: `preventDefault()` method

cancelBubble

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cancelBubble` property is a rare instance of an IE4+ event property being implemented in NN6+/Moz and Gecko-, WebKit-, and Presto-based browsers, even though the property is not defined in the W3C DOM. The property operates the same as in IE4+ in that it determines whether the current event object bubbles up any higher in the element containment hierarchy of the document. By default, this property is `false`, meaning that if the event is supposed to bubble, it will do so automatically.

To prevent event bubbling for the current event, set the property to `true` anywhere within the event handler function. Cancelling event bubbling works only for the current event. The very next event to fire will have bubbling enabled (provided the event bubbles).

If you are trying to migrate your code as much as possible to the W3C DOM, use the `stopPropagation()` method instead of `cancelBubble`. For cross-browser compatibility, however, `cancelBubble` is a safe bet.

Example

See Listing 32-2 to see the `cancelBubble` property in action in an IE environment. Even though that listing has some features that apply to WinIE5.5+, the bubble cancelling demonstration works all the way back to IE4.

Related Item: `stopPropagation()` method

charCode
keyCode

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera-, Chrome+

eventObject.keyCode

The W3C DOM event object model clearly distinguishes between the Unicode character attached to the alphanumeric keys of the keyboard and the code attached to each of the keyboard keys (regardless of character). To inspect the character of a key, use the `onkeypress` event to create the `event` object, and then look at the `event` object's `charCode` property. This is the property that returns 97 for "a" and 65 for "A" because it's concerned with the character associated with the key action. This property's value is zero for `onkeydown` and `onkeyup` events.

In contrast, the `keyCode` property is filled with a non-zero value only from `onkeydown` and `onkeyup` events (`onkeypress` sets the property to zero) when alphanumeric keys are pressed; for most other non-character keys, all three events fill the `keyCode` property. Through this property you can look for non-character keys, such as arrows, page navigation, and function keys. For the character keys, there is no distinction between uppercase and lowercase: The "A" key on the Latin keyboard returns a value of 65, regardless of the state of the Shift key. At the same time, however, the press of the Shift key fires its own `onkeydown` and `onkeyup` events, setting the `keyCode` value to 16 (except in Safari, which does not register modifier keys in this way). Other non-character keys — arrows, page navigation, function, and similar — have their own codes as well. This gets very detailed, and involves special key codes for the numeric keyboard keys that are different from their corresponding numbers along the top row of the alphanumeric keyboard.

Cross-Reference

Be sure to see the extensive section on keyboard events in Chapter 26, "Generic HTML Element Objects," for examples of how to apply the `keyCode` property in applications. ■

Example

Listing 32-12 provides a play area to view the `charCode` and `keyCode` properties for all three keyboard events while you type into a `textarea`. You can use this later as an authoring tool to grab the precise codes for keyboard keys you may not be familiar with.

LISTING 32-12

Displaying charCode and keyCode Property Values

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>charCode and keyCode Properties</title>
      <style type="text/css">
         td {text-align:center}
      </style>
      <script type="text/javascript">
         function showCode(which, evt)
         {
            document.forms[0].elements[which + "Char"].value = evt.charCode;
            document.forms[0].elements[which + "Key"].value = evt.keyCode;
         }
         function clearEm()
         {
            for (var i = 1; i < document.forms[0].elements.length; i++)
```

```
            {
               document.forms[0].elements[i].value = "";
            }
         }

         // bind the event handlers
         function addEvent(elem, evtType, func)
         {
            if (elem.addEventListener)
            {
               elem.addEventListener(evtType, func, false);
            }
            else if (elem.attachEvent)
            {
               elem.attachEvent("on" + evtType, func);
            }
            else
            {
               elem["on" + evtType] = func;

Here are some specific tasks to try with the page in NN6+/Moz to examine key codes (if you are not using a browser set for English and a Latin-based keyboard, your results may vary):

1. Enter a lowercase **a**. Notice how the `onkeypress` event handler shows the `charCode` to be 97, which is the Unicode (and ASCII) value for the first of the lowercase letters of the Latin alphabet. But the other two event types record just the key's code: 65.
2. Type an uppercase **A** via the Shift key. If you watch closely, you see that the Shift key, itself, generates the key code 16 for the `onkeydown` and `onkeyup` events. But the character key then shows the value 65 for all three events (until you release the Shift key), because the ASCII value of the uppercase letter happens to match the keyboard key code for that letter.
3. Press and release the Down Arrow key (be sure the cursor still flashes in the `textarea`, because that's where the keyboard events are being monitored). As a non-character key, all three events stuff a value into the `keyCode` property, but zero into `charCode`. The `keyCode` value for this key is 40.
4. Poke around with other non-character keys. Some may produce dialog boxes or menus, but their key codes are recorded nonetheless.

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The W3C DOM `event` object borrows mouse coordinate properties from both the NN4 and the IE4+ event models. If you have worked with event coordinates in these other browsers, you have nothing new to learn for W3C DOM-compatible browsers.

Like the IE4+ `event` object, the W3C DOM `event` object's `clientX` and `clientY` properties are the coordinates within the viewable content region of the window. These values are relative to the window space, not the document. But unlike IE4+, you don't have to calculate the position of the coordinates within the document because another pair of NN/Moz properties, `pageX` and `pageY`, provide that information automatically. If the page has not scrolled, the values of the client and page coordinates are the same. Because it is usually more important to know an event's coordinates with respect to the document than the window, the `pageX` and `pageY` properties are used most often.

Another NN/Moz property pair, `layerX` and `layerY`, borrow terminology from the now defunct layer schemes of NN4, but the properties can still be quite valuable nonetheless. These coordinates are measured relative to the positioning context of the element that received the event. For regular, unpositioned elements in the `body` part of a document, that positioning context is the `body` element. Thus, for those elements, the values of the page and layer coordinates will be the same. But if you create a positioned element, the coordinate space is measured from the top-left corner of that space. Thus, if you are using the coordinates to assist in scripted dragging of positioned elements, you can confine your scope to just the positioned element.

One coordinate system missing from the NN6+/Moz repertoire, but present in Safari, is that of the target element itself (comparable to the `offsetX` and `offsetY` properties of IE4+). These values, however, can be calculated in NN/Moz by subtracting from the page coordinate properties the `offsetLeft` and `offsetTop` properties of both the target element and its positioning context. For example, if you want to get the coordinates of a mouse event inside an image, the event handler can calculate those values as follows:

```
var clickOffsetX = evt.pageX - evt.target.offsetLeft -
   document.body.offsetLeft;
var clickOffsetY = evt.pageY - evt.target.offsetTop -
   document.body.offsetTop;
```

The last set of coordinate properties, `screenX` and `screenY`, provide values relative to the entire video display. Of all these properties, only the client and screen coordinates are defined in the W3C DOM Level 2 standard.

Keep in mind that in most W3C DOM–compatible browsers, event targets include text nodes inside elements. Because nodes do not have all the properties of elements (for example, they have no offset properties signifying their location in the document), you may sometimes have to go to the target node's parent node to get an element object whose offset properties provide the necessary page geography. This matters, of course, only if your scripts need to concern themselves with mouse events on text.

Example

You can see the effects of the coordinate systems and associated NN6+/Moz properties with the page in Listing 32-13. You can view coordinate values for all four measuring systems, as well as some calculated value. Two clickable objects are provided so that you can see the differences between an object not in any layer and an object residing within a layer (although anything you see is clickable, including text nodes). Figure 32-1 shows the results of a click inside the positioned layer.

One of the calculated fields applies window scrolling values to the client coordinates. But, as you will see, these calculated values are the same as the more convenient page coordinates. The other calculated field shows the coordinates relative to the rectangular space of the target element. Notice in the

code that if the `nodeType` of the target indicates a text node, that node's parent node (an element) is used for the calculation.

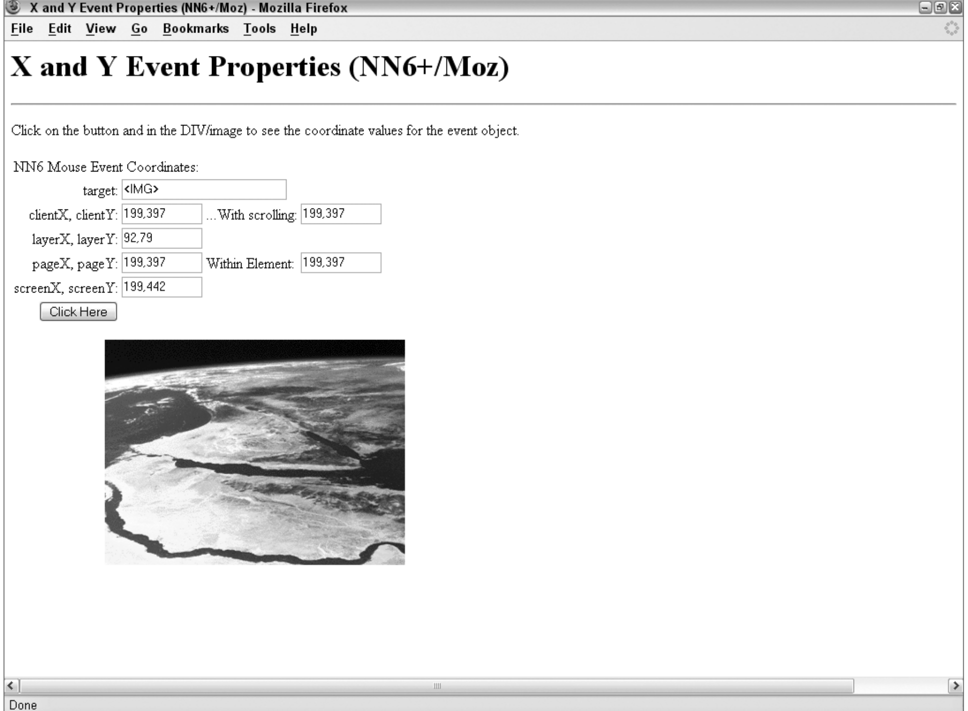
FIGURE 32-1

NN6+/Moz event coordinates for a click inside a positioned element.



Related Item: `target` property

`currentTarget`

Value: Element object reference — Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

As an event courses its way through its propagation paths, an event listener may process that event along the way. Though the event knows what the target is, it can also be helpful for the event listener function to know which element's event listener is now processing the event. The `currentTarget` property provides a reference to the element object whose event listener is processing the event. This allows one listener function to potentially process the event from different levels, branching the code to accommodate different element levels that process the event.

A valuable companion piece of information about the event is the `eventPhase` property, which helps your event listener function determine if the event is in capture mode, bubble mode, or is at the target. This property is demonstrated in the next section.

Example

Listing 32-14 shows the power of the `currentTarget` property in revealing the element that is processing an event during event propagation. Similar to the code in Listing 32-3, this example is made simpler because it lets the event object's properties do more of the work to reveal the identity of each element that processes the event. Event listeners assigned for various propagation modes are assigned to a variety of nodes in the document. After you click the button, each listener in the propagation chain fires in sequence. The alert dialog box shows which node is processing the event. And, as in Listing 32-3, the `eventPhase` property is used to help display the propagation mode in force at the time the event is processed by each node.

      <script type="text/javascript">
         function processEvent(evt)
         {
            var currTargTag, msg;
               if (evt.currentTarget.nodeType == 1)
               {
                  currTargTag = "<" + evt.currentTarget.tagName + ">";
               }
               else
               {
                  currTargTag = evt.currentTarget.nodeName;
               }
            msg = "Event is now at the " + currTargTag + " level ";
            msg += "(" + getPhase(evt) + ").";
            alert(msg);
         }
         // reveal event phase of current event object
         function getPhase(evt)
         {
```

continued

***eventObject*.currentTarget**

LISTING 32-14 *(continued)*

```
            switch (evt.eventPhase)
            {
               case 1:
                  return "CAPTURING";
                  break;
               case 2:
                  return "AT TARGET";
                  break;
               case 3:
                  return "BUBBLING";
                  break;
               default:
                  return "";
            }
         }

         // bind the event handlers
         function addEvent(elem, evtType, func)
         {
            if (elem.addEventListener)
            {
               elem.addEventListener(evtType, func, false);
            }
            else if (elem.attachEvent)
            {
               elem.attachEvent("on" + evtType, func);
            }
            else
            {
               elem["on" + evtType] = func;
            }
         }
         addEvent(window, "load", function()
         {
            // using old syntax to assign bubble-type event handlers
            document.onclick = processEvent;
            document.body.onclick = processEvent;
            // turn on click event capture for document and form
            document.addEventListener("click", processEvent, true);
            document.forms[0].addEventListener("click", processEvent, true);
            // set bubble event listener for form
            document.forms[0].addEventListener("click", processEvent, false);
            // turn on event capture for the button
            document.getElementById("main1").addEventListener("click",
            processEvent, true);
         });
      </script>
   </head>
   <body>
```

```
      <h1>currentTarget and eventPhase Properties</h1>
      <hr />
      <form>
         <input type="button" value="A Button" id="main1" name="main1" />
      </form>
   </body>
</html>
```

You can also click other places on the page. For example, if you click to the right of the button, you will be clicking the `form` element. Event propagation and processing adjusts accordingly. Similarly, if you click the header text, the only event listeners that see the event are in the document and `body` levels.

Related Item: `eventPhase` property

detail

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari2+, Opera8+, Chrome+

The `detail` property is included in the W3C DOM specification as an extra property whose purpose can be determined by the browser maker. Mozilla-, WebKit-, and Presto-based browsers increment a numeric value for rapid instances of `click` events on an object.

Related Items: None

eventPhase

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

An event fires in one of three possible event phases: at event capture, at the target, or during bubbling. Because the same event listener function may be processing an event in multiple phases, it can inspect the value of the `eventPhase` property of the event object to see in which phase the event was when the function was invoked. Values for this property are integers 1 (capture), 2 (at target), or 3 (bubbling).

Example

Refer to Listing 32-14, earlier in this chapter, for an example of how you can use a `switch` construction to branch function processing based on the event phase of the current event object.

Related Item: `currentTarget` property

isChar

Value: Boolean Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera-, Chrome-

You can find out from each keyboard event whether the key being pressed is a character key by examining the `isChar` property. Most typically, however, you are already filtering for character

or non-character keys by virtue of the event handlers used to capture keyboard actions: `onkeypress` for character keys; `onkeydown` or `onkeyup` for non-character keys. Be aware that the `isChar` property returns inconsistent values (even for the same key) in the first release of NN6.

Related Items: `charCode`, `keyCode` properties

isTrusted

Value: Boolean Read-Only

Compatibility: WinIE-, MacIE-, NN8+, Moz1.7.5+, Safari-, Opera-, Chrome-

Because an event can be generated by user action or script, the `isTrusted` property enables you to determine how the event was created. Any event triggered by user action is considered to be trusted from a security point of view. Therefore, when this property returns `true`, it means that the event came to life as the result of user activity (clicking, keyboarding, and so on).

originalTarget

Value: Node object reference Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera-, Chrome-

The `originalTarget` property provides a reference to the node object that serves as the genuine first target of the event. This information is typically associated with the internal construction of certain elements, which makes it less useful for scripting purposes. Additionally, in many cases the `originalTarget` property holds the same value as the `target` property.

relatedTarget

Value: Element object Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `relatedTarget` property allows an element to uncover where the cursor rolled in from or has rolled out to. This property extends the power of the `onmouseover` and `onmouseout` event handlers by expanding their scope to outside the current element (usually to an adjacent element). This one W3C DOM property does the same duty as the `fromElement` and `toElement` properties of the IE4+ `event` object.

When the `onmouseover` event fires on an element, the cursor had to be over some other element just beforehand. The `relatedTarget` property holds a reference to that element. Conversely, when the `onmouseout` event fires, the cursor is already over some other element. The `relatedTarget` property holds a reference to that element.

Example

Listing 32-15 provides an example of how the `relatedTarget` property can reveal the life of the cursor action before and after it rolls into an element. When you roll the cursor to the center box (a table cell), its `onmouseover` event handler displays the text from the table cell from which the cursor arrived (the `nodeValue` of the text node inside the table cell). If the cursor comes in from one of the corners (not easy to do), a different message is displayed.

The two functions that report the results employ a bit of filtering to make sure that they process the event object only if the event occurs on an element and if the `relatedTarget` element is anything

other than a nested text node of the central table cell element. Because nodes respond to events in W3C DOM browsers, this extra filtering prevents processing whenever the cursor makes the transition from the central `td` element to its nested text node.

LISTING 32-15

Using the relatedTarget Property

Related Item: `target` property

`target`

Value: Element object reference Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `target` property is a reference to the HTML element object that is the original target of the event. Because an event may trickle down and bubble up through the element containment hierarchy and be processed at any level along the way, having a property that points back to the element from which the event originated is comforting. As soon as you have a reference to that element, you can read or write any properties that belong to that element, or invoke any of its methods.

Example

As a simplified demonstration of the power of the `target` property, Listing 32-16 has but two event handlers defined for the `body` element, each invoking a single function. The idea is that the `onmousedown` and `onmouseup` events will bubble up from whatever their targets are, and the event handler functions will find out which element is the target and modify the color style of that element.

An extra flair is added to the script in that each function also checks the `className` property of the target element. If the `className` is `bold` — a class name shared by three `span` elements in the paragraph — the stylesheet rule for that class is modified so that all items share the same color. Your scripts can do even more in terms of filtering objects that arrive at the functions by performing special operations on certain objects or groups of objects.

Notice that the scripts don't have to know anything about the objects on the page to address each clicked one individually. That's because the `target` property provides all of the specificity needed for acting on the target element.

LISTING 32-16

Using the target Property

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>target Property</title>
      <style type="text/css">
         .bold {font-weight:bold;}
         .ital {font-style:italic;}
      </style>
      <script type="text/javascript">
         function highlight(evt)
         {
            var elem = (evt.target.nodeType == 3) ?
                       evt.target.parentNode : evt.target;
               if (elem.className == "bold")
               {
                  document.styleSheets[0].cssRules[0].style.color = "red";
               }
               else
               {
                  elem.style.color = "#FFCC00";
               }
```

continued

LISTING 32-16 *(continued)*

```
      }
      function restore(evt)
      {
         var elem = (evt.target.nodeType == 3) ?
                    evt.target.parentNode : evt.target;
            if (elem.className == "bold")
            {
               document.styleSheets[0].cssRules[0].style.color = "black";
            }
            else
            {
               elem.style.color = "black";
            }
      }

      // bind the event handlers
      function addEvent(elem, evtType, func)
      {
         if (elem.addEventListener)
         {
            elem.addEventListener(evtType, func, false);
         }
         else if (elem.attachEvent)
         {
            elem.attachEvent("on" + evtType, func);
         }
         else
         {
            elem["on" + evtType] = func;
         }
      }
      addEvent(window, "load", function()
      {
         addEvent(document.body, "mousedown",
                  function(evt) {highlight(evt);});
         addEvent(document.body, "mouseup",
                  function(evt) {restore(evt);});
      });
   </script>

Related Item: `relatedTarget` property

timeStamp

Value: Integer — Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera-, Chrome+

Each event receives a time stamp in milliseconds, based on the same date epoch as the `Date` object (1 January 1970). Just as with the `Date` object, accuracy is wholly dependent on the accuracy of the system clock of the client computer.

Although the precise time of an event may be of value in only some situations, the time between events can be useful for applications, such as timed exercises or action games. You can preserve the time of the most recent event in a global variable, and compare the time of the current time stamp against the stored value to determine the elapsed time between events.

Example

Listing 32-17 uses the `timeStamp` property to calculate the instantaneous typing speed when you type into a `textarea`. The calculations are pretty raw, and work only on intra-keystroke times without any of the averaging or smoothing that a more sophisticated typing tutor might perform. Calculated values are rounded to the nearest integer.

LISTING 32-17

Using the timeStamp Property

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>timeStamp Property</title>
      <script type="text/javascript">
         var stamp;
         function calcSpeed(evt)
         {
```

continued

eventObject.type

LISTING 32-17 *(continued)*

```
            if (stamp)
            {
               var gross = evt.timeStamp - stamp;
               var wpm = Math.round(6000/gross);
               document.getElementById("wpm").firstChild.nodeValue = wpm + " wpm.";
            }
            stamp = evt.timeStamp;
         }

         // bind the event handlers
         function addEvent(elem, evtType, func)
         {
            if (elem.addEventListener)
            {
               elem.addEventListener(evtType, func, false);
            }
            else if (elem.attachEvent)
            {
               elem.attachEvent("on" + evtType, func);
            }
            else
            {
               elem["on" + evtType] = func;
            }
         }
         addEvent(window, "load", function()
         {
            addEvent(document.getElementById("scratchpad"), "keypress",
                     function(evt) {calcSpeed(evt);});
         });
      </script>
   </head>
   <body>
      <h1>timeStamp Property</h1>
      <hr />
      <p>Start typing, and watch your instantaneous typing speed below:</p>
      <p><textarea id="scratchpad" cols="60" rows="10" wrap="hard"></textarea></p>
      <p>Typing Speed: <span id="wpm"> </span></p>
   </body>
</html>
```

Related Item: `Date` object

`type`

Value: String — Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

You can find out what kind of event fired to create the current event object by way of the `type` property. The value is a string version of the event name — just the name of the event without the "on" prefix that is normally associated with event listener names in NN6+/Moz/W3C. This property can be helpful when you designate one event handler function to process different kinds of events. For example, both the `onmousedown` and `onclick` event listeners for an object can invoke one function. Inside the function, a branch is written for whether the type comes in as `mousedown` or `click`, with different processing for each event type. That is not to endorse such event handler function sharing, but to be aware of this power should your script constructions find the property helpful.

This property and its values are fully compatible with the NN4 and IE4+ event models.

Caution

Keyboard events in earlier versions of Safari reported their types as `khtml_keydown`, `khtml_keypress`, and `khtml_keyup`. This was probably to avoid committing to an unfinished W3C DOM Level 3 keyboard event specification. The current version of Safari reports the keyboard events without the `khtml` prefix. ■

Related Items: All event handlers (Chapter 26, "Generic HTML Element Objects")

view

Value: Window object reference Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The closest that the W3C DOM Level 2 specification comes to acknowledging the browser window is an abstract object called an *abstract view* (AbstractView class). The object's only property is a reference to the document that it contains — the root document node that you've come to know and love. User events always occur within the confines of one of these views, and this is reflected in the `event` object's `view` property. This property holds a reference to the `window` object (which can be a frame) in which the event occurs. This reference allows an event object to be passed to scripts in other frames, and those scripts can then gain access to the `document` object of the target element's window.

Related Item: `window` object

Methods

initEvent("*eventType*", *bubblesFlag*, *cancelableFlag*)

initKeyEvent("*eventType*", *bubblesFlag*, *cancelableFlag*, *view*, *ctrlKeyFlag*, *altKeyFlag*, *shiftKeyFlag*, *metaKeyFlag*, *keyCode*, *charCode*)

initMouseEvent("*eventType*", *bubblesFlag*, *cancelableFlag*, *view*, *detailVal*, *screenX*, *screenY*, *clientX*, *clientY*, *ctrlKeyFlag*, *altKeyFlag*, *shiftKeyFlag*, *metaKeyFlag*, *buttonCode*, *relatedTargetNodeRef*)

initMutationEvent("*eventType*", *bubblesFlag*, *cancelableFlag*, *relatedNodeRef*, *prevValue*, *newValue*, *attrName*, *attrChangeCode*)

initUIEvent("*eventType*", *bubblesFlag*, *cancelableFlag*, *view*, *detailVal*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The W3C DOM `event` object initialization methods provide a means of initializing a newly-created event with a complete set of property values associated with that particular event. The parameters to each of the initialization methods vary according to the type of event being initialized. However, all of the initialization methods share the first three parameters: `eventType`, `bubblesFlag`, and `cancelableFlag`. The `eventType` parameter is a string identifier for the event's type, such as `mousedown` or `keypress`. The `bubblesFlag` parameter is a Boolean value that specifies whether the event's default propagation behavior is to bubble (`true`) or not (`false`). The `cancelableFlag` parameter is also a Boolean value, and its job is to specify if the event's default action may be prevented with a call to the `preventDefault()` method (`true`) or not (`false`).

A few of the methods also include `view` and `detailVal` parameters, which correspond to the window or frame in which the event occurred, and the integer code of detail data associated with the event, respectively. Additional parameters are specified for some of the methods, and are unique to the event being initialized.

You don't have to use the more detailed methods if you need a simple event. For example, if you want a simple `mouseup` event, you can initialize a generic event with `initEvent()`, and dispatch the event to the desired element, without having to fill in all of the coordinate, button, and other parameters of the `initMouseEvent()` method:

```
var evt = document.createEvent("MouseEvents");
evt.initEvent("mouseup", true, true);
document.getElementById("myButton").dispatchEvent(evt);
```

For more details about W3C DOM event types and the values expected for each of the more complex initialization methods, visit `http://www.w3.org/TR/DOM-Level-2-Events/events.html#Events-eventgroupings`.

Related Item: `document.createEvent()` method

preventDefault()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

While NN6+ continues to honor the original way of preventing default action for an event handler (that is, having the last statement of the event handler evaluate to `return false`), the W3C DOM event model provides a method that lets the cancellation of default action take place entirely within a function invoked by an event handler. For example, consider a text box that is supposed to allow only numbers to be typed in it. The `onkeypress` event handler can invoke a function that inspects each typed character. If the character is not a numeric character, it does not reach the text box for display. The following validation function may be invoked from the `onkeypress` event handler of just such a text box:

```
function checkIt(evt)
{
   var charCode = evt.charCode;
      if (charCode < 48 || charCode > 57)
      {
```

```
            alert("Please make sure entries are numbers only.");
            evt.preventDefault();
        }
}
```

This way, the errant character won't appear in the text box.

Invoking the `preventDefault()` method in NN6+/Moz and Gecko-, WebKit-, and Presto-based browsers, is the equivalent of assigning `true` to `event.returnValue` in IE5+.

Related Item: `cancelable` property

stopPropagation()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

Use the `stopPropagation()` method to stop events from trickling down or bubbling up further through the element containment hierarchy. A statement in the event listener function that invokes the following is all that is needed:

```
evt.stopPropagation();
```

As an alternative, you can cancel bubbling directly in an element's event handler attribute, as in the following:

```
onclick="doButtonClick(this); event.stopPropagation()"
```

If you are writing cross-browser scripts, you also have the option of using the `cancelBubble` property, which is compatible with IE4+.

CHAPTER 33

Body Text Objects

A large number of HTML elements fall into a catchall category of elements whose purposes are slightly more targeted than contextual elements covered in Chapter 26, “Generic HTML Element Objects.” In this group are some very widely used elements, such as the `h1` through `h6` header elements, plus several elements that are not yet widely used because their full support may be lacking, even in some of the most modern browsers. In this chapter, you find all sorts of text-related objects, excluding those objects that act as form controls (text boxes and such, which are covered in Chapter 35, “Text-Related Form Objects”). For the most part, properties, methods, and event handlers of this chapter’s objects are the generic ones covered in Chapter 26. Only those items that are unique to each object are covered in this chapter (as will be the case in all succeeding chapters).

IN THIS CHAPTER

Objects that display running body text in documents

Using the NN/Mozilla Range and IE TextRange objects

Scripting search-and-replace actions

Beyond the HTML element objects covered in this chapter, you also meet the `TextRange` object, first introduced in IE4, and the corresponding `Range` object from the W3C DOM. This object is a very powerful one for scripters because it allows scripts to work very closely with body content — not in terms of, for example, the `innerText` or `nodeValue` properties of elements, but rather in terms of the text as it appears on the page in what users see as paragraphs, lists, and the like. The `TextRange` and `Range` objects essentially give your scripts cursor control over running body text for functions, such as cutting, copying, pasting, and applications that extend those basic operations — search and replace, for instance. Bear in mind that everything you read in this chapter requires, at minimum, the dynamic object models of IE4+ and NN6+/Moz/W3C; some items require IE5+. Unfortunately, the IE `TextRange` object is not implemented in MacIE5. In short, consider this chapter to be focused exclusively on modern browsers.

blockquote and q Element Objects

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
`cite`		

Syntax

Accessing `blockquote` or `q` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
           method([parameters])
```

About these objects

The `blockquote` element is a special-purpose text container. Browsers typically start the content on a new line in the body, and indent on both the left and right margins by approximately 40 pixels. An inline quotation can be encased inside a `q` element, which does not force the quoted material to start on the next line.

From an object point of view, the only property that distinguishes these two objects from any other kind of contextual container is the `cite` property, which comes from the HTML 4.0 `cite` attribute. This attribute simply provides a URL reference for the citation and does not act as an `src` or `href` attribute to load an external document.

Property

`cite`

Value: String — Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cite` property can contain a URL (as a string) that points to the source of the quotation in the `blockquote` or `q` element. Future browsers may provide some automatic user interface link to the source document, but none of the current browsers that support the `cite` property do anything special with this information.

br Element Object

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
`clear`		

Syntax

Accessing `br` element object properties or methods:

```
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
            method([parameters])
```

About this object

The `br` element forces a carriage return and line feed for rendered content on the page. This element does not provide the same kind of vertical spacing that goes between paragraphs in a series of `p` elements. Only one attribute (`clear`) distinguishes this element from generic HTML elements and objects.

Property

`clear`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `clear` property defines how any text in an element following the `br` element wraps around a floating element (for example, an image set to float along the right margin). Although modern browsers expose this property, the attribute on which it is based is deprecated in the HTML 4.0 specification in an effort to encourage the use of the `clear` style sheet attribute for a `br` element.

Values for the `clear` property can be one of the following strings: `all`, `left`, or `right`.

Related Items: `clear` style sheet property

font Element Object

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+ Opera+, Chrome+

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
`color`		
`face`		
`size`		

Syntax

Accessing `font` element object properties or methods:

```
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
            method([parameters])
```

About this object

In a juxtaposition of standards implementations, the `font` element is exposed as an object only in browsers that also support Cascading Style Sheets as the preferred way to control font faces, colors, and sizes. This doesn't mean that you shouldn't use `font` elements in your page with modern browsers — using this element may be necessary for a single page that needs to be backward compatible with older browsers. But it does present a quandary for scripters who want to use scripts to modify font characteristics of body text after the page has loaded. Keep in mind that the HTML element has been deprecated. A good rule of thumb to follow these days is to use the standards-compliant style sheets (and their scriptable properties). Use the `font` element (and script the `font`-HTML element object's properties) in those rare cases when the page must work in legacy browsers.

Properties

`color`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

A `font` object's text color can be controlled via the `color` property. Values can be either hexadecimal triplets (for example, `#FFCCFF`) or the plain-language color names recognized by most browsers. In either case, the values are case-insensitive strings.

***fontObject*.color**

Example

Listing 33-1 contains a page that demonstrates changes to the three font element object properties: color, face, and size. Along the way, you can see an economical use of the setAttribute() method to do the work for all of the property changes. This page loads successfully in all browsers, but the select lists make changes to the text only in modern browsers.

A p element contains a nested font element that encompasses three words whose appearance is controlled by three select lists. Each list controls one of the three font object properties, and their name attributes are strategically assigned the names of the properties (as you see in a moment). value attributes for option elements contain strings that are to be assigned to the various properties. Each select element invokes the same setFontAttr() function, passing a reference to itself so that the function can inspect details of the element.

The first task of the setFontAttr() function is to make sure that only browsers capable of treating the font element as an object get to the meat of the function. The test for the existence of document.all and the myFONT element blocks all older browsers from changing the font characteristics.

For suitably equipped browsers, the function next extracts the string from the value property of the select object that was passed to the function. If a selection is made (other than the first, empty one), the single nested statement uses the setAttribute() method to assign the value to the attribute whose name matches the name of the select element.

Note

An odd bug in MacIE5 doesn't let the rendered color change when changing the color property. But the setting is valid, as proven by selecting any of the other two property choices. ■

            <option value="3">3 (Default)</option>
            <option value="+1">Increase Default by 1</option>
            <option value="-1">Decrease Default by 1</option>
            <option value="1">Smallest</option>
            <option value="7">Biggest</option>
         </select>
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique used in this example and throughout the chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects."** ■

Related Items: `color` style sheet attribute

`face`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

A `font` object's font face is controllable via the `face` property. Just as with the `face` attribute (and the corresponding `font-family` style sheet attribute), you can specify one or more font names in a comma-delimited string. Browsers start with the leftmost font face and look for a match in the client computer's system. The first matching font face that is found in the client system is applied to the text surrounded by the `font` element. You should list the most specific fonts first, and generally allow the generic font faces (`sans-serif`, `serif`, and `monospace`) to come last; that way you exert at least some control over the look of the font on systems that don't have your pretty fonts. If you know that Windows displays a certain font you like and the Macintosh has something that corresponds to that font but with a different name, you can specify both names in the same property value. The browser skips over font face names not currently installed on the client.

Example

See Listing 33-1 for an example of values that can be used to set the `face` property of a `font` element object. Although you will notice visible changes to most choices on the page, the font face selections may not change from one choice to another, since that all depends on the fonts that are installed on your PC.

Related Items: `font-family` style sheet attribute

`size`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The size of text contained by a `font` element can be controlled via the `size` property. Unlike the more highly recommended `font-size` style sheet attribute, the `size` property of the `font` element object and its corresponding `SIZE` attribute are restricted to the relative font size scale imposed by early HTML implementations: a numbering scale from 1 to 7.

Values for the `size` property are strings, even though most of the time they are single numeral values. You can also specify a size relative to the default value by including a plus or minus sign before the number. For example, if the default font size (as set by the browser's user preferences) is 3, you can bump up the size of a text segment by encasing it inside a `font` element and then setting its `size` property to `"+2"`.

For more accurate font sizing using units, such as pixels or points, use the `font-size` style sheet attribute.

Example

See Listing 33-1 for an example of values that can be used to set the `size` property of a `font` element object. Notice that incrementing or decrementing the `size` property is applied only to the size assigned to the `size` attribute of the element (or the default, if none is specified) and not the current setting adjusted by script.

Related Items: `font-size` style sheet attribute

h1 . . . h6 Element Objects

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
`align`		

Syntax

Accessing `h1` through `h6` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
           method([parameters])
```

About these objects

The so-called "heading" elements (denoted by `h1`, `h2`, `h3`, `h4`, `h5`, and `h6`) provide shortcuts for formatting up to six different levels of headings and subheadings. Although you can simulate the appearance of these headings with `p` elements and style sheets, the heading elements very often contain important contextual information about the structure of the document. With the power to inspect the node hierarchy of a document afforded by modern browsers, a script can generate its own table of contents or outline of a very long document by looking for elements whose `nodeName` properties are in the `hn` family. Therefore, it is a good idea to continue using these elements for contextual purposes, even if you intend to override the default appearance by way of style sheet templates.

As for the scriptable aspects of these six objects, they are essentially the same as the generic contextual objects with the addition of the `align` property. Because each `hn` element is a block-level element, you can use style sheets, rather than the corresponding attribute or property, to set their alignment. The choice is up to you.

Property

align

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

String values of the `align` property control whether the heading element is aligned with the left margin (`left`), center of the page (`center`), or right margin (`right`). The corresponding `align` attribute is deprecated in HTML 4.0 in favor of the `text-align` style sheet attribute.

Related Items: `text-align` style sheet attribute

hr Element Object

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
`align`		
`color`		
`noShade`		
`size`		
`width`		

Syntax

Accessing `hr` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
           method([parameters])
```

About this object

The `hr` element draws a horizontal rule according to size, dimension, and alignment characteristics normally set by the attributes of this element. Style sheets can also specify many of those settings, the latter route being recommended for pages that will be loaded exclusively in pages that support CSS. In modern browsers, your scripts can modify the appearance of an `hr` element either directly through element object properties or through style sheet properties. To reference a specific `hr` element by script, you must assign an `id` attribute to the element and use the `getElementById()` function — the preferred practice used to access HTML elements in modern browsers.

Properties

align

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

An hr object's horizontal alignment can be controlled via the align property. String values enable you to set it to align with the left margin (left), the center of the page (center), or right margin (right). By default, the element is centered.

Example

Listing 33-2 contains a page that demonstrates the changes to the five hr element object properties: align, color, noShade, size, and width. Along the way, you can see an economical use of the setAttribute() method to do the work for all of the property changes. This page loads successfully in all browsers, including legacy browsers, but the select lists make changes to the text only in modern browsers (because they treat the element as an object).

An hr element (whose id is myHR) is displayed with the browser default settings (100% width, centered, and its "magic" color). Each list controls one of the five hr object properties, and their name attributes are strategically assigned the names of the properties (as you see in a moment). value attributes for option elements contain strings that are to be assigned to the various properties. Each select element invokes the same setHRAttr() function, passing a reference to itself so that the function can inspect details of the element.

The setHRAttr() function reads the string from the value property of the select object that is passed to the function. If a selection is made (that is, other than the first, empty one), the single nested statement uses the setAttribute() method to assign the value to the attribute whose name matches the name of the select element.

LISTING 33-2

Controlling hr Object Properties

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>hr Object Properties</title>
      <script type="text/javascript">
         // one function does all!
         function setHRAttr(select)
         {
            var choice = select.options[select.selectedIndex].value;
            if (choice)
            {
               document.getElementById("myHR").setAttribute(select.name, choice);
```

continued

LISTING 33-2 *(continued)*

```
            }
         }
      </script>
   </head>
   <body>
      <h1>hr Object Properties</h1>
      <br />
      <p>Here is the hr element you will be controlling:</p>
      <hr id="myHR" />
      <form>
         Select an alignment:
         <select name="align" onchange="setHRAttr(this)">
            <option></option>
            <option value="left">Left</option>
            <option value="center">Center</option>
            <option value="right">Right</option>
         </select><br />
         Select a rule color:
         <select name="color" onchange="setHRAttr(this)">
            <option></option>
            <option value="red">Red</option>
            <option value="green">Green</option>
            <option value="blue">Blue</option>
            <option value="#FA8072">Some Hex Triplet Value</option>
         </select><br />
         Select a rule shading (most browsers maintain color when this is set):
         <select name="noShade" onchange="setHRAttr(this)">
            <option></option>
            <option value="true">No Shading</option>
            <option value="false">Shading</option>
         </select><br />
         Select a rule height:
         <select name="size" onchange="setHRAttr(this)">
            <option></option>
            <option value="2">2 (Default)</option>
            <option value="4">4 Pixels</option>
            <option value="10">10 Pixels</option>
         </select><br />
         Select a rule width:
         <select name="width" onchange="setHRAttr(this)">
            <option></option>
            <option value="100%">100% (Default)</option>
            <option value="80%">80%</option>
            <option value="300">300 Pixels</option>
         </select>
      </form>
   </body>
</html>
```

Related Items: `text-align` style sheet attribute

`color`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera+, Chrome+

An `hr` object's color can be controlled via the `color` property. Values can be either hexadecimal triplets (for example, `#FFCCFF`) or the plain-language color names recognized by most browsers. In either case, the values are case-insensitive strings. If you change the color from the default, the default shading (3-D effect) of the rule disappears. We have yet to find the magic value that lets you return the color to the browser default after it has been set to another color. Also, in WebKit-based browsers, if you change the shading after you have changed the color, the color reverts to gray.

Example

See Listing 33-2, earlier in this chapter, for an example of values that can be used to set the `color` property of an `hr` element object.

Related Items: `color` style sheet attribute

`noShade`

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

A default `hr` element is displayed with a kind of three-dimensional effect, called *shading*. You can turn shading off under script control by setting the `noShade` property to `true`. But be aware that in the browsers we tested, the `noShade` property is a one-way journey: You cannot restore shading after it is removed. Moreover, in most browsers, default shading is lost if you assign a different color to the rule. As mentioned above, in WebKit-based browsers, if you change the shading after you have changed the color, the color reverts to gray.

Example

See Listing 33-2, earlier in this chapter, for an example of values that can be used to set the `noShade` property of an `hr` element object. Because of the buggy behavior associated with setting this property, adjusting the property in the example has unexpected (and usually undesirable) consequences, even in some of the latest web browsers.

Related Items: `color` style sheet attribute

`size`

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The size of an `hr` element is its vertical thickness, as controlled via the `size` property. Values are integers, representing the number of pixels occupied by the rule.

Example

See Listing 33-2, earlier in this chapter, for an example of values that can be used to set the `size` property of an `hr` element object.

width

Value: Integer or string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The width of an `hr` element is controlled via the `width` property. By default, the element occupies the entire width of its parent container (usually the Body).

You can specify width as either an absolute number of pixels (as an integer) or as a percentage of the width of the parent container. Percentage values are strings that include a trailing percent character (`%`).

Example

See Listing 33-2, earlier in this chapter, for an example of values that can be used to set the `width` property of an `hr` element object.

Related Items: `width` style sheet attribute

label Element Object

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
accessKey		
form		
htmlFor		

Syntax

Accessing `label` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
           method([parameters])
```

About this object

The `label` element lets you assign a contextual relationship between a form control (text field, radio button, select list, and so on) and the otherwise freestanding text that is used to label the control on the page. This element does not control the rendering or physical relationship between the control and the label — the HTML source code order does that. Wrapping a form control label inside a `label` element is important if scripts will be navigating the element hierarchy of a page's content, and the relationship between a form control and its label effects the results of the document parsing. It is also used by the newer rendering engines for the disabled, so this has become a pretty important element to add to your web pages.

Properties

accessKey

Value: String Read/Write

Compatibility: WinIE4+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

For most other HTML element objects, the `accessKey` property description is covered in the generic element property descriptions of Chapter 26. The function of the property for the `label` object is the same as the IE implementation for all other elements. The single-character string value is the character key to be used in concert with the OS- and browser-specific modifier key (for example, Ctrl in IE for Windows) to bring focus to the form control associated with the label. This value is best set initially, via the `accesskey` attribute for the `label` element.

Related Items: `accessKey` property of generic elements

form

Value: Form object reference Read-Only

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `form` property of a `label` element object returns a reference to the form object that contains the form control with which the label is associated. This property can be useful in a node-parsing script that wants to retrieve the form container from the perspective of the label rather than from the form control. The form object reference returned from the `label` element object is the same form object reference returned by the `form` property of any form control object.

Example

If you want to obtain the form for a label whose ID is `myLabel`, you would use the following code:

```
document.getElementById("myLabel").form
```

Related Items: `form` property of `input` element objects

htmlFor

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The htmlFor property is a string that contains the id of the form control element with which the label is associated. This value is normally set via the for attribute in the label element's tag. Modifying this property does not alter the position or rendering of the label, but it does change the relationships between label and control.

marquee Element Object

Compatibility: WinIE4+, MacIE4+, NN7+, Moz+, Safari+, Opera+, Chrome+

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
behavior	start()	onbounce
bgColor	stop()	onfinish
direction		onstart
height		
hspace		
loop		
scrollAmount		
scrollDelay		
trueSpeed		
vspace		
width		

Syntax

Accessing marquee element object properties or methods:

```
(IE4+) [window.]document.all.elemID.property | method([parameters])
(IE5+) [window.]document.getElementById("elemID").property |
            method([parameters])
```

About this object

The marquee element began as a Microsoft proprietary element that displays scrolling text within a rectangle specified by the width and height attributes of the element. Text that scrolls in the element goes between the element's start and end tags. The IE4+ object model exposes the element and many properties to the object model for control by script. The element and some of its scriptability is implemented in NN7+/Moz and WebKit- and Presto-based browsers.

Properties

behavior

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera+, Chrome+

The behavior property controls details of the way scrolled text moves within the scrolling space. Values for this property are one of the following three strings: alternate, scroll, and slide. Presto-based browsers such as Opera allow only scroll and alternate. When set to alternate, scrolling alternates between left and right (or up and down, depending on the direction property setting). A value of scroll means that the text marches completely through the space before appearing again. A value of slide causes the text to march into view until the last character is visible. When the slide value is applied as a property (instead of as an attribute value in the tag), the scrolling stops when the text reaches an edge of the rectangle. Default behavior for the marquee element is the equivalent of scroll.

Example

Listing 33-3 contains a page that demonstrates the changes to several marquee element object properties: behavior, bgColor, direction, scrollAmount, and scrollDelay. NN7+/Moz do not react to the slide behavior and the background color settings. See the description of Listing 33-1 for details on the attribute setting script.

LISTING 33-3

Controlling marquee Object Properties

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>marquee Object Properties</title>
      <script type="text/javascript">
         // one function does all!
         function setMARQUEEAttr(select)
         {
            var choice = select.options[select.selectedIndex].value;
            if (choice)
            {

             <option value="green">Green</option>
             <option value="blue">Blue</option>
             <option value="#FA8072">Some Hex Triplet Value</option>
          </select><br />
          Select a scrolling direction:
          <select name="direction" onchange="setMARQUEEAttr(this)">
             <option></option>
             <option value="left">Left</option>
             <option value="right">Right</option>
             <option value="up">Up</option>
             <option value="down">Down</option>
          </select><br />
          Select a scroll amount:
          <select name="scrollAmount" onchange="setMARQUEEAttr(this)">
             <option></option>
             <option value="4">4</option>
             <option value="6">6 (Default)</option>
             <option value="10">10</option>
          </select><br />
          Select a scroll delay:
          <select name="scrollDelay" onchange="setMARQUEEAttr(this)">
```

```
        <option></option>
        <option value="50">Short</option>
        <option value="85">Normal</option>
        <option value="125">Long</option>
      </select>
    </form>
  </body>
</html>
```

Related Items: `direction` property of `marquee` object

bgColor

Value: Hexadecimal triplet or color name string Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera+, Chrome+

The `bgColor` property determines the color of the background of the `marquee` element's rectangular space. To set the color of the text, either surround the `marquee` element with a `font` element or apply the `color` style sheet attribute to the `marquee` element. Values for all color properties can be either the common HTML hexadecimal triplet value (for example, `"#00FF00"`) or any of the X11 color names (a list is available at `http://en.wikipedia.org/wiki/Web_colors`).

Example

See Listing 33-3, earlier in this chapter, for an example of how to apply values to the `bgColor` property.

direction

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN7+, Moz+, Safari+, Opera+, Chrome+

The `direction` property lets you get or set the horizontal or vertical direction in which the scrolling text moves. Four possible string values are `left`, `right`, `down`, `up`. NN7/Moz1 observe `left` and `right` only, whereas Moz1.5+ observes `up` and `down` as well. The default value is `left`.

Example

See Listing 33-3, earlier in this chapter, for an example of how to apply values to the `direction` property.

Related Items: `behavior` property of `marquee` object

height
width

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN7+, Moz+, Safari+, Opera+, Chrome+

The `height` and `width` properties enable you to get or set the pixel size of the rectangle occupied by the element. NN7/Moz implement `width` only. You can adjust each property independently of the other, but like most attribute-inspired properties of IE objects, if no `height` or `width` attributes are defined in the element's tag, you cannot use these properties to get the size of the element as rendered by default.

hspace
vspace

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari+, Opera+

The `hspace` and `vspace` properties let you get or set the amount of blank margin space surrounding the `marquee` element. Adjustments to the `hspace` property affect both the left and right (horizontal) margins of the element; `vspace` governs both top and bottom (vertical) margins. Margin thicknesses are independent of the height and width of the element.

loop

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari-, Opera+, Chrome-

The `loop` property allows you to discover the number of times the `marquee` element was set to repeat its scrolling, according to the `loop` attribute. Although this property is read/write, modifying it by script does not cause the text to loop only that number of times more before stopping. Treat this property as read-only.

scrollAmount
scrollDelay

Value: Integers Read/Write

Compatibility: WinIE4+, MacIE4+, NN7+, Moz+, Safari+, Opera+, Chrome+

The `scrollAmount` and `scrollDelay` properties control the perceived speed and scrolling smoothness of the `marquee` element text. The number of pixels between redrawings of the scrolling text is controlled by the `scrollAmount` property. The smaller the number, the less jerky the scrolling is (the default value is 6). At the same time, you can control the time in milliseconds between each redrawing of the text with the `scrollDelay` property. The smaller the number, the more frequently redrawing is performed (the default value is 85 or 90, depending on the operating system). Thus, a combination of low `scrollAmount` and `scrollDelay` property values presents the smoothest (albeit slowest) perceived scrolling.

Example

See Listing 33-3, earlier in this chapter, for an example of how to apply values to the `scrollAmount` and `scrollDelay` properties.

Related Items: `trueSpeed` property of `marquee` object

`trueSpeed`

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari-, Opera-, Chrome-

IE has a built-in regulator that prevents `scrolldelay` attribute or `scrollDelay` property settings below 60 from causing the `marquee` element text to scroll too quickly. If you genuinely want to use a speed faster than 60 (meaning, a value lower than 60), then also set the `trueSpeed` property to `true`.

Related Items: `scrollDelay` property of `marquee` object

Methods

`start()`
`stop()`

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN7+, Moz+, Safari+, Opera+, Chrome+

Scripts can start or stop (pause) a `marquee` element via the `start()` and `stop()` methods. Neither method takes parameters, and you are free to invoke them as often as you like after the page loads. Be aware that the `start()` method does not trigger the `onstart` event handler for the object.

Example

See Listing 33-3, earlier in this chapter, for examples of both the `start()` and `stop()` methods, which are invoked in event handlers of separate controlling buttons on the page. Notice, too, that when you have the behavior set to `slide`, stopping and restarting the `marquee` does not cause the scroll action to start from a blank region.

Event Handlers

`onbounce`

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari-, Opera-, Chrome-

The `onbounce` event handler fires only when the `marquee` element has its behavior set to `alternate`. In that back-and-forth mode, each time the text reaches a boundary and is about to

start its return trip, the onbounce event fires. If you truly want to annoy your users, you could have the onbounce event handlers play a sound at each bounce. (I'm kidding — please don't do this.)

Related Items: behavior property of marquee object

onfinish

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari-, Opera-, Chrome-

The onfinish event handler fires only when the marquee element has its loop set to a specific value of 1 or greater. After the final text loop has completed, the onfinish event fires.

Related Items: loop property of marquee object

onstart

Compatibility: WinIE4+, MacIE4+, NN-, Moz+, Safari-, Opera-, Chrome-

The onstart event handler fires as the marquee element begins its scrolling, but only as a result of the page loading. The start() method does not trigger this event handler.

Related Items: start() method of marquee object

Syntax

Creating a Range object:

```
var rangeRef = document.createRange();
```

Accessing Range object properties or methods:

```
(NN6+/Moz)    rengeRef.property | method([parameters])
```

About this object

The Range object is the W3C DOM (Level 2) version of what Microsoft had implemented earlier as its TextRange object. A number of important differences (not the least of which is an almost entirely different property and method vocabulary) distinguish the behaviors and capabilities of these two similar objects. Although Microsoft participated in the W3C DOM Level 2 working groups, no participant from the company is credited on the DOM specification chapter regarding the Range object. Because the W3C version has not been implemented as of IE8, it is unknown if or when IE will eventually implement the W3C version. In the meantime, see the WinIE TextRange object section later in this chapter for comparisons between the two objects. Neither the W3C DOM Range nor Microsoft TextRange objects are implemented in MacIE5.

The purpose of the W3C DOM Range object is to provide hooks to a different "slice" of content (most typically a portion of a document's content) that is not necessarily restricted to the node hierarchy (tree) of a document. Although a Range object can be used to access and modify nodes and elements, it can also transcend node and element boundaries to encompass arbitrary segments of a document's content. The content contained by a range is sometimes referred to as a *selection*, but this does not mean that the text is highlighted on the page, such as a user selection. Instead, the term "selection" here means a segment of the document's content that can be

addressed as a unit, separate from the node tree of the document. As soon as the range is created, a variety of methods let scripts examine, modify, remove, replace, and insert content on the page.

A range object (meaning, an instance of the static `Range` object) has a start point and an end point, which together define the boundaries of the range. The points are defined in terms of an offset count of positions within a container. These counts are usually character positions within text nodes (ignoring any HTML tag or attribute characters), but when both boundaries are at the edges of the same node, the offsets may also be counts of nodes within a container that surrounds both the start and end points. An example helps clarify these concepts.

Consider the following simplified HTML document:

```
<html>
   <body>
      <p>This paragraph has an <em>emphasized</em> segment.</p>
   </body>
</html>
```

You can create a range that encompasses the text inside the `em` element from several points of view, each with its own offset counting context:

1. From the `em` *element's only child node (a text node)*. The offset of the start point is zero, which is the location of the insertion point in front of the first character (lowercase "e"); the end point offset is 10, which is the character position (zero-based) following the lowercase "d."
2. From the `em` *element.* The point of view here is that of the child text node inside the `em` element. Only one node exists here, and the offset for the start point is `0`, whereas the offset for the end point is `1`.
3. From the `p` *element's child nodes (two text nodes and an element node)*. You can set the start point of a range to the very end (counting characters) of the first child text node of the `p` element; you can then set the end point to be in front of the first character of the last child text node of the `p` element. The resulting range encompasses the text within the `em` element.
4. From the `p` *element.* From the point of view of the `p` element, the range can be set with an offset starting with `1` (the second node nested inside the `p` element) and ending with `2` (the start of the third node).

Although these different points of view provide a great deal of flexibility, they also can make it more difficult to imagine how you can use this power. The W3C vocabulary for the `Range` methods, however, helps you figure out what kind of offset measure to use.

A range object's start point could be in one element, and its end point in another. For example, consider the following HTML:

```
<p>And now to introduce our <em>very special</em> guest:</p>
```

If the text shown in boldface indicates the content of a range object, you can see that the range crosses element boundaries in a way that would make HTML element or node object properties difficult to use for replacing that range with some other text. The W3C specification provides guidelines for browser makers on how to handle the results of removing or inserting HTML content that crosses node borders.

An important aspect of the `Range` object is that the size of a range can be zero or more characters. Start and end points always position themselves between characters. When the start point and end point of a range are at the same location, the range acts like a text insertion pointer.

Working with ranges

To create a range object, use the `document.createRange()` method and assign the range object returned by this method to a variable that you can use to control the range:

```
var rng = document.createRange();
```

With an active range stored in a variable, you can use many of the object's methods to adjust the start and end points of the range. If the range is to consist of all of the contents of a node, you have two convenience methods that do so from different points of view: `selectNode()` and `selectNodeContents()`. The sole parameter passed with both methods is a reference to the node whose contents you want to turn into a range. The difference between the two methods is how the offset properties of the range are calculated as a result (see the discussion about these methods later in the chapter for details). Another series of methods (`setStartBefore()`, `setStartAfter()`, `setEndBefore()`, and `setEndAfter()`) let you adjust each end point individually to a position relative to a node boundary. For the most granular adjustment of boundaries, the `setStart()` and `setEnd()` methods let you specify a reference node (where to start counting the offset) and the offset integer value.

If you need to select an insertion point (for example, to insert some content into an existing node), you can position either end point where you want it, and then invoke the `collapse()` method. A parameter determines whether the collapse should occur at the range's start or end point.

A suite of other methods lets your scripts work with the contents of a range directly. You can copy (`cloneContents()`), delete (`deleteContents()`, `extractContents()`), insert a node (`insertNode()`), and even surround a range's contents with a new parent node (`surroundContents()`). Several properties let your scripts examine information about the range, such as the offset values, the containers that hold the offset locations, whether the range is collapsed, and a reference to the next outermost node that contains both the start and end points.

Mozilla added a proprietary method to the `Range` object (which is actually a method of an object that is built around the `Range` object) called `createContextualFragment()`. This method lets scripts create a valid node (of type `DocumentFragment`) from arbitrary strings of HTML content — a feature that the W3C DOM does not (yet) offer. This method was devised at first as a substitute for what eventually became the NN6+/Moz `innerHTML` property.

Using the Range object can be a bit tedious, because it often requires a number of script statements to execute an action. Three basic steps are generally required to work with a Range object:

1. Create the text range.
2. Set the start and end points.
3. Act on the range.

As soon as you are comfortable with this object, you will find it provides a lot of flexibility in scripting interaction with body content. For ideas about applying the Range object in your scripts, see the examples that accompany the descriptions of individual properties and methods in the following sections.

Note

The Evaluator (see Chapter 4, "JavaScript Essentials") automatically initializes a W3C DOM Range **object in browsers that support the feature. You can access the object via the** rng **global variable to work with examples in the following sections.** ■

Properties

collapsed

Value: Boolean Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The collapsed property reports whether a range has its start and end points set to the same position in a document. If the value is true, the range's start and end containers are the same, and the offsets are also the same. You can use this property to verify that a range is in the form of an insertion pointer just prior to inserting a new node:

```
if (rng.collapsed) {
   rng.insertNode(someNewNodeReference);
}
```

Example

Use The Evaluator's predefined rng object to experiment with the collapsed property. Reload the page and set the range to encompass a node:

```
rng.selectNode(document.body)
```

Enter **a.collapsed** into the top text box. The expression returns false because the end points of the range are not the same.

Related Items: endContainer, endOffset, startContainer, startOffset properties; Range.collapse() method

commonAncestorContainer

Value: Node object reference Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `commonAncestorContainer` property returns a reference to the document tree node that both the start and end points have in common. It is not unusual for a range's start point to be in one node and the end point to be in another. Yet a more encompassing node most likely contains both of those nodes, perhaps even the `document.body` node. The W3C DOM specification also calls the shared ancestor node the *root node* for the range (a term that may make more sense to you).

Example

Use The Evaluator's predefined `rng` object to experiment with the `commonAncestorContainer` property. Reload the page. Now set the start point to the beginning of the contents of the `myEM` element, and set the end point to the end of the surrounding `myP` element:

```
rng.setStartBefore(document.getElementById("myEM").firstChild)
rng.setEndAfter(document.getElementById("myP").lastChild)
```

Verify that the text range is set to encompass content from the `myEM` node (the word "all") and end of `myP` nodes (note that while Safari 1.0 returns the wrong data here, subsequent releases do not):

```
rng.toString()
```

Verify, too, that the two end point containers are different nodes:

```
rng.startContainer.tagName
rng.endContainer.tagName
```

Finally, see what node contains both of these two end points:

```
rng.commonAncestorContainer.id
```

The result is the `myP` element, which both the `myP` and `myEM` nodes have in common.

Related Items: `endContainer`, `endOffset`, `startContainer`, `startOffset` properties; all "set" and "select" methods of the `Range` object

endContainer
startContainer

Value: Node object reference Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `endContainer` and `startContainer` properties return a reference to the document tree node that contains the range's end point and start point, respectively. Be aware that the object model calculates the container, and that the container may not be the reference you used to set the start and end points of a range. For example, if you use the `selectNode()` method to set

the start and end points of a range to encompass a particular node, the containers of the end points are most likely the next outermost nodes. Thus, if you want to expand a range to the start of the node that contains the current range's start point, you can use the value returned by the `startContainer` property as a parameter to the `setStartBefore()` method:

```
rng.setStartBefore(rng.startContainer)
```

Example

Use The Evaluator's predefined `rng` object to experiment with the `endContainer` and `startContainer` properties. Reload the page and set the range to encompass the `myEM` element:

```
rng.selectNode(document.getElementById("myEM")
```

Inspect the containers for both the start and end points of the selection:

```
rng.startContainer.id
rng.endContainer.id
```

The range encompasses the entire `myEM` element, so the start and end points are outside of the element. Therefore, the container of both start and end points is the `myP` element that also surrounds the `myEM` element.

Related Items: `commonAncestor`, `endOffset`, `startOffset` properties; all "set" and "select" methods of the `Range` object

endOffset
startOffset

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `endOffset` and `startOffset` properties return an integer count of the number of characters or nodes for the location of the range's end point and start point, respectively. These counts are relative to the node that acts as the container node for the position of the boundary (see the `Range.endContainer` and `Range.startContainer` properties earlier in this chapter).

When a boundary is at the edge of a node (or perhaps "between" nodes is a better way to say it), the integer returned is the offset of nodes (zero-based) within the boundary's container. But when the boundary is in the middle of a text node, the integer returned is an index of the character position within the text node. The fact that each boundary has its own measuring system (nodes versus characters, relative to different containers) can get confusing if you're not careful, because conceivably the integer returned for an end point could be smaller than that for the start point. Consider the following nested elements:

```
<p>This paragraph has an <em>emphasized</em> segment.</p>
```

The next script statements set the start of the range to a character within the first text node and the end of the range to the end of the em node:

```
var rng = document.createRange();
rng.setStart(document.getElementById("myP").firstChild, 19);
rng.setEndAfter(document.getElementById("myEM"));
```

Using boldface to illustrate the body text that is now part of the range, and the pipe (|) character to designate the boundaries as far as the nodes are concerned, here is the result of the preceding script execution:

```
<p id="myP">This paragraph has |an <em id="myEM">emphasized</em>| segment.</p>
```

Because the start of the range is in a text node (the first child of the p element), the range's startOffset value is 19, which is the zero-based character position of the "a" in the word "an." The end point, however, is at the end of the em element. The system recognizes this point as a node boundary, and thus counts the endOffset value within the context of the end container: the p element. The endOffset value is 2 (the p element's text node is node index 0; the em element is node index 1; and the position of the end point is at the start of the p element's final text node, at index 2).

For the endOffset and startOffset values to be of any practical use to a script, you must also use the endContainer and startContainer properties to read the context for the offset integer values.

Example

Use The Evaluator's predefined rng object to experiment with the endOffset and startOffset properties, following similar paths you just saw in the description. Reload the page and set the range to encompass the myEM element and then move the start point outward to a character within the myP element's text node:

```
rng.selectNode(document.getElementById("myEM"))
rng.setStart(document.getElementById("myP").firstChild, 7)
```

Inspect the node types of the containers for both the start and end points of the selection:

```
rng.startContainer.nodeType
rng.endContainer.nodeType
```

The startContainer node type is 3 (text node), whereas the endContainer node type is 1 (element). Now inspect the offsets for both the start and end points of the selection:

```
rng.startOffset
rng.endOffset
```

Related Items: endContainer, startContainer properties; all "set" and "select" methods of the Range object

Methods

cloneContents()
cloneRange()

Returns: `DocumentFragment` node reference; `Range` object reference

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `cloneContents()` method (available in NN7+) takes a snapshot copy of the contents of a `Range` object and returns a reference to that copy. The copy is stored in the browser's memory, but is not part of the document tree. The `cloneRange()` method (available in NN6+) performs the same action on an entire range and stores the range copy in the browser's memory. A range's contents can consist of portions of multiple nodes and may not be surrounded by an element node; that's why its data is of the type `DocumentFragment` (one of the W3C DOM's node types). Because a `DocumentFragment` node is a valid node, it can be used with other document tree methods where nodes are required as parameters. Therefore, you can clone a text range to insert a copy elsewhere in the document.

In contrast, the `cloneRange()` method deals with range objects. Although you are always free to work with the contents of a range object, the `cloneRange()` method returns a reference to a range object, which acts as a kind of wrapper to the contents (just as it does when the range is holding content in the main document). You can use the `cloneRange()` method to obtain a copy of one range to compare the end points of another range (via the `Range.compareBoundaryPoints()` method).

Example

Use The Evaluator's predefined `rng` object in NN7+/Moz/ and WebKit- and Presto-based browsers to see the `cloneContents()` method in action. Begin by reloading the page and setting the range to the `myP` paragraph element:

```
rng.selectNode(document.getElementById("myP"))
```

Next, clone the original range and preserve the copy in variable `b`:

```
b = rng.cloneContents()
```

Move the original range so that it is an insertion point at the end of the body by first expanding it to encompass the entire body and then collapsing it to the end:

```
rng.selectNode(document.body)
rng.collapse(false)
```

Now, insert the copy at the very end of the body:

```
rng.insertNode(b)
```

If you scroll to the bottom of the page, you see a copy of the text. While Safari 1.0 appears to miscalculate the range's boundary points after `collapse()`, causing a DOM hierarchy error when invoking `insertNode()`, subsequent versions do not. But you can also use `appendChild()` or `insertBefore()` on any element node to put the cloned range into the document tree.

See the description of the `compareBoundaryPoints()` method later in this chapter to see an example of the `cloneRange()` method.

Related Items: `compareBoundaryPoints()`, `extractContents()` methods

collapse([*startBoolean*])

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

Use the `collapse()` method to shrink a range from its current size down to a single insertion point between characters. Collapsing a range becomes more important than you may think at first, especially in a function that is traversing the body of the page or a large chunk of text. For example, in a typical looping word-counting script, you create a text range that encompasses the body fully. To begin counting words, you can first collapse the range to the insertion point at the very beginning of the range. Next, use the `expand()` method to set the range to the first word of text (and increment the counter if the `expand()` method returns `true`). At that point, the text range extends around the first word. You want the range to collapse at the end of the current range so that the search for the next word starts after the current one. Use `collapse()` once more, but this time include parameters.

The optional parameter of the `collapse()` method is a Boolean value that directs the range to collapse itself either at the start or end of the current range. The default behavior is the equivalent of a value of `true`, which means that unless otherwise directed, a `collapse()` method shifts the text range to the point in front of the current range. This method works great at the start of a word-counting script, because you want the text range to collapse to the start of the text. But for subsequent movements through the range, you want to collapse the range so that it is after the current range. Thus, you include a `false` parameter to the `collapse()` method.

Example

Refer to Listings 33-11 and 26-14 to see the `collapse()` method at work (albeit with the IE `TextRange` object).

Related Items: `Range.setEnd()`, `Range.setStart()` methods

compareBoundaryPoints(*typeInteger, sourceRangeRef*)

Returns: Integer (`-1`, `0`, or `1`)

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

Generating multiple range objects and assigning them to different variables is not a problem. You can then use the `compareBoundaryPoints()` method to compare the relative positions of start and end points of both ranges. One range is the object you use to invoke the

`compareBoundaryPoints()` method, and the other range is the second parameter of the method. The order in which you reference the two ranges influences the results, based on the value assigned to the first parameter.

Values for the first parameter can be one of four constant values that are properties of the static `Range` object: `Range.START_TO_START`, `Range.START_TO_END`, `Range.END_TO_START`, and `Range.END_TO_END`. What these values specify is which point of the current range is compared with which point of the range passed as the second parameter. For example, consider the following body text that has two text ranges defined within it:

```
It was the best of times.
```

The first text range (assigned in our discussion here to variable `rng1`) is shown in boldface, whereas the second text range (`rng2`) is shown in bold-italic. In other words, `rng2` is nested inside `rng1`. We can compare the position of the start of `rng1` against the position of the start of `rng2` by using the `Range.START_TO_START` value as the first parameter of the `compareBoundaryPoints()` method:

```
var result = rng1.compareBoundaryPoints(Range.START_TO_START, rng2);
```

The value returned from the `compareBoundaryPoints()` method is an integer of one of three values. If the positions of both points under test are the same, then the value returned is `0`. If the start point of the (so-called) source range is before the range on which you invoke the method, the value returned is `-1`; in the opposite positions in the code, the return value is `1`. Therefore, from the previous example, because the start of `rng1` is before the start of `rng2`, the method returns `-1`. If you change the statement to invoke the method on `rng2`, as in

```
var result = rng2.compareBoundaryPoints(Range.START_TO_START, rng1);
```

the result is `1`.

In practice, this method is helpful in knowing if two ranges are the same, if one of the boundary points of both ranges are the same, or if one range starts where the other ends.

Example

The page rendered by Listing 33-4 lets you experiment with text range comparisons in NN6+/Moz/W3C. The bottom paragraph contains a `span` element that has a `Range` object assigned to its nested text node after the page loads (in the `init()` function). That fixed range becomes a solid reference point for you to use while you select text in the paragraph.

After you make a selection, all four versions of the `compareBoundaryPoints()` method run to compare the start and end points of the fixed range against your selection. One column of the results table shows the raw value returned by the `compareBoundaryPoints()` method, whereas the third column puts the results into plain language.

To see how this page works, begin by selecting the first word of the fixed text range (carefully drag the selection from the first red character). You can see that the starting positions of both ranges are the same, because the returned value is `0`. Because all of the invocations of the

compareBoundaryPoints() method are on the fixed text range, all comparisons are from the point of view of that range. Thus, the first row of the table for the START_TO_END parameter indicates that the start point of the fixed range comes before the end point of the selection, yielding a return value of -1.

Other selections to make include:

- Text that starts before the fixed range and ends inside the range
- Text that starts inside the fixed range and ends beyond the range
- Text that starts and ends precisely at the fixed range boundaries
- Text that starts and ends before the fixed range
- Text that starts after the fixed range

Study the returned values and the plain language results and see how they align with the selection you made.

compareNode(*nodeReference*)

Returns: Integer (0, 1, 2, or 3)

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera-, Chrome+

The `compareNode()` method returns an integer code that indicates the relative position of the specified node with respect to the range. The node is passed as the only parameter to the method, and the value returned indicates the relative location of the node. The following four constants may be returned from the `compareNode()` method, and correspond to integer values in the range 0–3: `Range.NODE_BEFORE`, `Range.NODE_AFTER`, `Range.NODE_BEFORE_AND_AFTER`, `Range.NODE_INSIDE`. The first two values explain themselves, but the third value (`Range.NODE_BEFORE_AND_AFTER`) indicates that the node begins before the range and ends after the range. The final value (`Range.NODE_INSIDE`), on the other hand, indicates that the node is contained in its entirety by the range.

Related Items: `comparePoint()` method

comparePoint(*nodeReference, offset*)

Returns: Integer (-1, 0, or 1)

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `comparePoint()` method returns an integer code that indicates the relative position of the specified node at a certain offset with respect to the range. The node (as an object reference) and its offset (an integer count of an element's nodes or a text node's characters) are passed as parameters to the method, and the value returned indicates the relative location of the node. This location is specified with respect to the point (node and offset), not the range. The location of the node is indicated by the integer values -1, 0, and 1, where -1 indicates that the point comes before the start of the range, 0 indicates that the point is located within the range, and 1 reveals that the point comes after the end of the range.

Related Items: `compareNode()` method

createContextualFragment("*text*")

Returns: W3C DOM document fragment node

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `createContextualFragment()` method provides a way, within the context of the W3C DOM Level 2 node hierarchy, to create a string of HTML text (with or without HTML tags, as needed) for insertion or appendage to existing node trees. During the development of the NN6 browser, this method closed a gap that was eventually closed by Netscape's adoption of the Microsoft proprietary `innerHTML` property. The method obviates the need for tediously assembling a complex HTML element via a long series of `document.createElement()` and `document.createTextNode()` methods for each segment, plus the assembly of the node tree, prior to inserting it into the actual visible document.

Note

Although the existence of the `innerHTML` property of all `element` objects reduced the need for the `createContextualFragment()` method, the W3C approach of removing and appending child nodes in order to alter HTML content (see the `replaceHTML()` function in Listing 33-4) is now the preferred technique for altering the "inner HTML" of an element. ■

The parameter to the `createContextualFragment()` method is any text, including HTML tags. To invoke the method, however, you need to have an existing range object available. Therefore, the sequence used to generate a document fragment node is

```
var rng = document.createRange();
rng.selectNode(document.body); // any node will do
var fragment = rng.createContextualFragment("<h1>Howdy</h1>");
```

As a document fragment, the node is not part of the document node tree until you use the fragment as a parameter to one of the tree modification methods, such as `Node.insertBefore()` or `Node.appendChild()`.

Example

Use The Evaluator's predefined `rng` object to replace an existing document tree node with the fragment. Begin by creating the fragment from The Evaluator's built-in range:

```
b = rng.createContextualFragment("<span style='font-size:22pt'>a bunch
    of </span>")
```

This fragment consists of a `span` element node with a text node nested inside. At this point, you can inspect the properties of the document fragment by entering `b` into the bottom text box.

To replace the `myEM` element on the page with this new fragment, use the `replaceChild()` method on the enclosing `myP` element:

```
document.getElementById("myP").replaceChild(b, document.getElementById("myEM"))
```

The fragment now becomes a legitimate child node of the `myP` element and can be referenced like any node in the document tree. For example, if you enter the following statement into the

top text box of The Evaluator, you can retrieve a copy of the text node inside the new `span` element:

```
document.getElementById("myP").childNodes[1].firstChild.nodeValue
```

Related Items: `Node` object (Chapter 26, "Generic HTML Element Objects")

deleteContents()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `deleteContents()` method removes all contents of the current range from the document tree. After deletion, the range collapses to an insertion point where surrounding content (if any) cinches up to its neighbors.

Alignment of a range's boundaries forces the browser to make decisions about how element boundaries inside the range are treated after the deletion. An easy deletion is one for which the range boundaries are symmetrical. For example, consider the following HTML with a range highlighted in bold:

```
<p>One paragraph with an <em>emphasis</em> inside.</p>
```

After you delete the contents of this range, the text node inside the `em` element disappears, but the `em` element remains in the document tree (with no child nodes). Similarly, if the range is defined as being the entire second child node of the `p` element, as follows

```
<p>One paragraph with an <em>emphasis</em> inside.</p>
```

then deleting the range contents removes both the text node and the `em` element node, leaving the `p` element with a single, unbroken text node as a child (although, as in the previous case, an extra space would be between the words "an" and "inside" because the `em` element does not encompass a space on either side).

When range boundaries are not symmetrical, the browser does its best to maintain document tree integrity after the deletion. Consider the following HTML and range:

```
<p>One paragraph with an <em>emphasis</em> inside.</p>
```

After deleting this range's contents, the document tree for this segment looks like the following:

```
<p>One paragraph <em>phasis</em> inside.</p>
```

The range collapses to an insertion point just before the `<em>` tag. But notice that the `em` element persists to take care of the text still under its control. Many other combinations of range boundaries and nodes are possible, so be sure that you check out the results of a contents deletion for asymmetrical boundaries before applying the deletion.

Example

Use The Evaluator's predefined `rng` object to experiment with deleting contents of both a text node and a complete element node. Begin by adjusting the text range to the text node inside the `myEM` element (enter the third statement, which wraps below, as one continuous expression):

```
rng.setStart(document.getElementById("myEM").firstChild, 0)
rng.setEnd(document.getElementById("myEM").lastChild, ↩
    document.getElementById("myEM").lastChild.length)
```

Verify the makeup of the range by entering `a` into the bottom text box and inspecting its properties. Both containers are text nodes (they happen to be the same text node), and offsets are measured by character positions.

Now, delete the contents of the range:

```
rng.deleteContents()
```

The italicized word "all" is gone from the tree, but the `myEM` element is still there. To prove it, put some new text inside the element:

```
document.getElementById("myEM").innerHTML = "a band of "
```

The italic style of the `em` element applies to the text, as it should.

Next, adjust the range boundaries to include the `myEM` element tags, as well:

```
rng.selectNode(document.getElementById("myEM"))
```

Inspect the `Range` object's properties again by entering `rng` into the bottom text box. The container nodes are the `p` element that surrounds the `em` element; the offset values are measured in nodes. Delete the range's contents:

```
rng.deleteContents()
```

Not only is the italicized text gone, but the `myEM` element is gone, too. The `myP` element now has two child nodes: the two text nodes that used to flank the `em` element. The following entries into the top text box of The Evaluator verify this fact:

```
document.getElementById("myP").childNodes.length
document.getElementById("myP").childNodes[0].nodeValue
```

To combine the two sibling text nodes into one, invoke the `normalize()` method of the container:

```
document.getElementById("myP").normalize()
```

Check the number of child nodes again to verify the results.

Related Items: `Range.extractContents()` method

detach()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `detach()` method instructs the browser to release the current range object from the object model. In the process, the range object is nulled out to the extent that an attempt to access the object results in a script error. You can still assign a new range to the same variable if you like. You are not required to detach a range when you're finished with it, and the browser resources employed by a range are not that large. But it is good practice to "clean up after yourself," especially when a script repetitively creates and manages a series of new ranges.

Related Items: `document.createRange()`

extractContents()

Returns: `DocumentFragment` node reference

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `extractContents()` method deletes the contents of the range and returns a reference to the document fragment node that is held in the browser memory, but which is no longer part of the document tree. A range's contents can consist of portions of multiple nodes and may not be surrounded by an element node; that's why its data is of the type `DocumentFragment` (one of the W3C DOM's node types). Because a `DocumentFragment` node is a valid node, it can be used with other document tree methods where nodes are required as parameters. Therefore, you can extract a text range from one part of a document to insert elsewhere in the document.

Example

Use The Evaluator's predefined `rng` object in NN7+/Moz/Safari to see how the `extractContents()` method works. Begin by setting the built-in range object to contain the text of the `myP` paragraph element.

```
rng.selectNode(document.getElementById("myP"))
```

Next, extract the original range's content and preserve the copy in variable `b`:

```
b = a.extractContents()
```

Now, insert the extracted fragment at the very end of the body:

```
document.body.appendChild(b)
```

If you scroll to the bottom of the page, you see a copy of the text.

Related Items: `cloneContents()`, `deleteContents()` methods

insertNode(*nodeReference*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `insertNode()` method inserts a node at the start point of the current range. The node being inserted may be an element or text fragment, and its source can be any valid node creation mechanism, such as the `document.createTextNode()` method, or any node extraction method.

Example

Listing 33-5 demonstrates the `insertNode()` method plus some additional items from the `selection` object. The example even includes a rudimentary undo buffer for scripted changes to a text range. In the page generated by this listing, users can select any text in a paragraph and have the script automatically convert the text to all uppercase characters. The task of replacing a selection with other text requires several steps, starting with the selection, which is retrieved via the `window.getSelection()` method. After making sure the selection contains some text (that is, the selection isn't collapsed), the selection is preserved as a range object so that the starting text can be stored in a global variable (as a property of the `undoBuffer` global variable object). After that, the selection is deleted from the document tree, leaving the selection as a collapsed insertion point. A copy of that selection in the form of a range object is preserved in the `undoBuffer` object so that the undo script knows where to reinsert the original text. A new text node is created with an uppercase version of the original text, and, finally, the `insertNode()` method is invoked to stick the converted text into the collapsed range.

Undoing this operation works in reverse. Original locations and strings are copied from the `undoBuffer` object. After creating the range with the old start and end points (which represent a collapsed insertion point), the resurrected text (converted to a text node) is inserted into the collapsed range. For good housekeeping, the `undoBuffer` object is restored to its unused form.

LISTING 33-5

Inserting a Node into a Range

intersectsNode(*nodeReference*)

Returns: Boolean

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `intersectsNode()` method returns a Boolean value that indicates whether (`true`) or not (`false`) any part of the range overlaps the node whose reference is passed as the method's parameter.

Related Items: `compareNode()` method

isPointInRange(*nodeReference, offset*)

Returns: Boolean

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera-, Chrome+

The `isPointInRange()` method returns a Boolean value that indicates whether (`true`) or not (`false`) the specified node (a node object reference) and offset (integer count of an element's nodes or a text node's characters) are located entirely within the range.

selectNode(*nodeReference*)
selectNodeContents(*nodeReference*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `selectNode()` and `selectNodeContents()` methods are convenience methods for setting both end points of a range to surround a node or a node's contents. The kind of node you supply as the parameter to either method (text node or element node) has a bearing on the range's container node types and units of measure for each (see the container- and offset-related properties of the `Range` object earlier in this chapter).

Starting with the `selectNode()` method, if you specify an element node as the one to select, the start and end container node of the new range is the next outermost element node; offset values count nodes within that parent element. If you specify a text node to be selected, the container node for both ends is the parent element of that text node; offset values count the nodes within that parent.

With the `selectNodeContents()` method, the start and end container nodes are the very same element specified as the parameter; offset values count the nodes within that element. If you specify a text node's contents to be selected, the text node is the start and end parent, but the range is collapsed at the beginning of the text.

By and large, you specify element nodes as the parameter to either method, allowing you to set the range to either encompass the element (via `selectNode()`) or just the contents of the element (via `selectNodeContents()`).

Example

Use The Evaluator's predefined `rng` object to see the behavior of both the `selectNode()` and `selectNodeContents()` methods work. Begin by setting the range object's boundaries to include the `myP` element node:

```
rng.selectNode(document.getElementById("myP"))
```

Enter `a` into the bottom text box to view the properties of the range. Notice that because the range has selected the entire paragraph node, the container of the range's start and end points is the `body` element of the page (the parent element of the `myP` element).

Now change the range so that it encompasses only the contents of the `myP` element:

```
rng.selectNodeContents(document.getElementById("myP"))
```

Click the List Properties button to view the current properties of the range. The container of the range's boundary points is the `p` element that holds the element's contents.

Related Items: `setEnd()`, `setEndAfter()`, `setEndBefore()`, `setStart()`, `setStartAfter()`, `setStartBefore()` methods

setEnd(*nodeReference*, *offset*)
setStart(*nodeReference*, *offset*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

You can adjust the start and end points of a text range independently via the `setStart()` and `setEnd()` methods. Although not as convenient as the `selectNode()` or `selectNodeContents()` methods, these two methods give you the ultimate in granularity over precise positioning of a range boundary.

The first parameter to both methods is a reference to a node. This reference can be an element or text node, but your choice here also influences the kind of measure applied to the integer offset value supplied as the second parameter. When the first parameter is an element node, the offset counts are in increments of child nodes inside the specified element node. But if the first parameter is a text node, the offset counts are in increments of characters within the text node.

When you adjust the start and end points of a range with these methods, you have no restrictions to the symmetry of your boundaries. One boundary can be defined relative to a text node, and the other relative to an element node — or vice versa.

To set the end point of a range to the last node or character within a text node (depending on the unit of measure for the `offset` parameter), you can use the `length` property of the units

being measured. For example, to set the end point to the end of the last node within an element (perhaps there are multiple nested elements and text nodes within that outer element), you can use the first parameter reference to help you get there:

```
rng.setEnd(document.getElementById("myP"), ↩
   document.getElementById("myP").childNodes.length);
```

These kinds of expressions get lengthy, so you may want to make a shortcut to the reference, to simplify the values of the parameters, as shown in this version that sets the end point to after the last character of the last text node of a `p` element:

```
var nodeRef = document.getElementById("myP").lastChild;
rng.setEnd(nodeRef, nodeRef.nodeValue.length);
```

In both previous examples with the `length` properties, the values of those properties are always pointing to the node or character position after the final object because the index values for those objects' counts are zero-based. Also bear in mind that if you want to set a range end point at the edge of a node, you have four other methods to choose from (`setEndAfter()`, `setEndBefore()`, `setStartAfter()`, and `setStartBefore()`). The `setEnd()` and `setStart()` methods are best used when an end point needs to be set at a location other than at a node boundary.

Example

Use The Evaluator's predefined `rng` object to experiment with both the `setStart()` and `setEnd()` methods. For the first range, set the start and end points to encompass the second node (the `myEM` element) inside the `myP` element:

```
rng.setStart(document.getElementById("myP"), 1)
rng.setEnd(document.getElementById("myP"), 2)
```

The text encompassed by the range consists of the word "all" plus the trailing space that is contained by the `myEM` element. Prove this by entering the following statement into the top text box (while Safari 1.0 returns an incorrect value, later versions do not):

```
rng.toString()
```

If you then click the Results box to the right of the word "all," you see that the results contain the trailing space. Yet, if you examine the properties of the range (enter `a` into the bottom text box), you see that the range is defined as actually starting before the `myEM` element, and ending after it.

Next, adjust the start point of the range to a character position inside the first text node of the `myP` element:

```
rng.setStart(document.getElementById("myP").firstChild, 11)
```

Click the List Properties button to see that the `startContainer` property of the range is the text node, and that the `startOffset` measures the character position. All end boundary

properties, however, have not changed. Enter `rng.toString()` in the top box again to see that the range now encompasses text from two of the nodes inside the `myP` element.

You can continue to experiment by setting the start and end points to other element and text nodes on the page. After each adjustment, verify the properties of the `a` range object and the text it encompasses (via `rng.toString()`).

Related Items: `selectNode()`, `selectNodeContents()`, `setEndAfter()`, `setEndBefore()`, `setStartAfter()`, `setStartBefore()` methods

setEndAfter(*nodeReference*)
setEndBefore(*nodeReference*)
setStartAfter(*nodeReference*)
setStartBefore(*nodeReference*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

You can adjust the start and end points of a text range relative to existing node boundaries via your choice of these four methods. The "before" and "after" designations are used to specify which side of the existing node boundary the range should have for its boundary. For example, using `setStartBefore()` and `setEndAfter()` with the same element node as a parameter is the equivalent of the `selectNode()` method on that element. You may also specify a text node as the parameter to any of these methods. But because these methods work with node boundaries, the offset values are always defined in terms of node counts, rather than character counts. At the same time, however, the boundaries do not need to be symmetrical, so that one boundary can be inside one node and the other boundary inside another node.

Example

Use The Evaluator's predefined `rng` object to experiment with all four methods. For the first range, set the start and end points to encompass the `myEM` element inside the `myP` element:

```
rng.setStartBefore(document.getElementById("myEM"))
rng.setEndAfter(document.getElementById("myEM"))
```

The text encompassed by the range consists of the word "all" plus the trailing space that is contained by the `myEM` element. Prove this by entering the following statement into the top text box (while Safari 1.0 returns an incorrect value later versions do not):

```
rng.toString()
```

Next, adjust the start point of the range to the beginning of the first text node of the `myP` element:

```
rng.setStartBefore(document.getElementById("myP").firstChild)
```

Enter `rng` into the bottom text box to see that the `startContainer` property of the range is the `p` element node, whereas the `endContainer` property points to the `em` element.

You can continue to experiment by setting the start and end points to before and after other element and text nodes on the page. After each adjustment, verify the properties of the a range object and the text it encompasses (via `rng.toString()`).

Related Items: `selectNode()`, `selectNodeContents()`, `setEnd()`, `setStart()` methods

surroundContents(*nodeReference*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `surroundContents()` method surrounds the current range with a new parent element. Pass the new parent element as a parameter to the method. No document tree nodes or elements are removed or replaced in the process, but the current range becomes a child node of the new node; if the range coincides with an existing node, then the relationship between that node and its original parent becomes that of grandchild and grandparent. An application of this method may be to surround user-selected text with a `span` element whose class renders the content with a special font style or other display characteristic based on a style sheet selector for that class name.

When the element node being applied as the new parent has child nodes itself, those nodes are discarded before the element is applied to its new location. Therefore, for the most predictable results, using content-free element nodes as the parameter to the `surroundContents()` method is best.

Example

Listing 33-6 demonstrates how the `surroundContents()` method wraps a range inside a new element. As the page loads, a global variable (`newSpan`) stores a `span` element as a prototype for elements to be used as new surrounding parent nodes. When you select text in either of the two paragraphs, the selection is converted to a range. The `surroundContents()` method then wraps the range with the `newSpan` element. Because that `span` element has a class name of `hilite`, the element and its contents pick up the style sheet properties as defined for that class selector.

Note

Full support for this method didn't take place until Mozilla 1.6, which translates into Netscape 7.2 and Firefox 1.0 in terms of browser implementations. Prior to Mozilla 1.6, this method threw an exception when used with a range derived from a `selection` object, or when the range is not aligned with element boundaries. ■

Related Items: `Range.insertNode()` method

toString()

Returns: String

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

Use the `toString()` method to retrieve a copy of the body text that is contained by the current text range. The text returned from this method is ignorant of any HTML tags or node boundaries that exist in the document tree. You also use this method to get the text of a user selection, after it has been converted to a text range.

Syntax

Accessing `selection` object properties or methods:

```
(IE4+)     [window.]document.selection.property | method()
(NN6+/Moz) window.selection.property | method()
```

About this object

The `selection` object provides scripted access to any body text or text in a form text control that is selected either by the user or by script. A `selection` object of one character or more is always highlighted on the page, and only one `selection` object can be active at any given instant.

Take advantage of the `selection` object when your page invites a user to select text for some operation that utilizes the selected text. The best event to use for working with a selection is the `onmouseup` event handler. This event fires on every release of the mouse, and your script can investigate the `document.selection` object to see if any text has been selected (using the selection's `type` property).

If you intend to perform some action on a selection, you may not be able to trigger that action by way of a button or link. In some browser versions and operating systems, clicking one of these elements automatically deselects the body selection.

One important difference between the IE and NN/Moz and WebKit- and Presto-based browsers selections is that the NN6+/Moz/WebKit/Presto `selection` object works only on body text, and not on selections inside text-oriented form controls. An NN6+/Moz/WebKit/Presto `selection` object has relationships with the document's node tree in that the object defines itself by the nodes (and offsets within those nodes) that encase the start and end points of a selection. When a user drags a selection, the node in which the selection starts is called the *anchor* node; the node holding the text at the point of the selection release is called the *focus* node; for double- or triple-clicked selections, the direction between anchor and focus nodes is in the direction of the language script (for example, left-to-right in Latin-based script families). In many ways, an NN6+/Moz `selection` object behaves just as the W3C DOM `Range` object, complete with methods to collapse and extend the selection. Unlike a range, however, the text encompassed by a `selection` object is highlighted on the page. If your scripts need to work with the nodes inside a selection, the `getRangeAt()` method of the `selection` object returns a range object whose boundary points coincide with the selection's boundary points.

Properties

`anchorNode`
`focusNode`

Value: Node reference — Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

These two properties return a reference to the node where the user started (`anchorNode`) and ended (`focusNode`) the selection. If the selection is modified via the `addRange()` method, these properties point to the node boundaries of the most recently added range.

Related Items: `anchorOffset` and `focusOffset` properties

anchorOffset
focusOffset

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

These two properties return an integer count of the number of characters or nodes from the beginning of the selection to the anchor node (`anchorOffset`) and focus node (`focusOffset`). The count represents characters for text nodes, and nodes for element nodes. If the selection is modified via the `addRange()` method, these properties point to the node offsets of the most recently added range.

Related Items: `anchorNode` and `focusNode` properties

isCollapsed

Value: Boolean Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `isCollapsed` property returns a Boolean value indicating whether or not the anchor and focus boundaries of the selection are the same. If they are the same (`true`), it means the selection has zero length between two characters (or before the first, or after the last character of the document).

Related Items: `anchorNode` and `focusNode` properties

rangeCount

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `rangeCount` property returns an integer count of the range objects contained within the selection. A manual user selection always results in a single range being selected, but the `addRange()` method can result in multiple ranges being contained by the selection.

Related Items: `getRangeAt()` method

type

Value: String Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

The WinIE-originated `type` property returns `Text` whenever a selection exists on the page. Otherwise the property returns `None`. A script can use this information to determine if a selection is made on the page:

```
if (document.selection.type == "Text")
{
   // process selection
   // ...
}
```

selectionObject.**type**

Microsoft indicates that this property can sometimes return `Control`, but that terminology is associated with an edit mode outside the scope of this book.

Example

Listing 33-7 contains a page that demonstrates several features of the IE `selection` object. When you make a selection with the Deselect radio button selected, you see the value of the `selection.type` property (in the status bar) before and after the selection is deselected. After the selection goes away, the `type` property returns `None`. While Opera supports the `type` property, it does not support all of the methods that are used in this script.

LISTING 33-7

Using the document.selection Object

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>selection Object</title>
      <script type="text/javascript">
         function processSelection()
         {
            if (!document.selection)
            {
               alert("document.selection object is not supported by your browser");
            }
            else
            {
               if (document.choices.process[0].checked)
               {
                  status = "Selection is type: " + document.selection.type;
                  setTimeout("emptySelection()", 2000);
               }
               else if (document.choices.process[1].checked)
               {
                  var rng = document.selection.createRange();
                  document.selection.clear();
               }
            }
         }
         function emptySelection()
         {
            document.selection.empty();
            status = "Selection is type: " + document.selection.type;
         }
      </script>
   </head>
   <body>
      <h1>IE selection Object</h1>
      <h4>
```

```
        <dl>
          <dt>De-select Button</dt>
          <dd>Look at the status bar. Then, with the Deselect
            radio button selected, select some of the Latin text.
            Watch the status bar change after two seconds.
          </dd>
          <dt>Deleted Button</dt>
          <dd>The Latin text you select will be deleted.</dd>
      </h4>
      <hr />
      <form name="choices">
        <input type="radio" name="process" checked="checked" />
          De-select after two seconds<br />
        <input type="radio" name="process" />
          Delete selected text
      </form>
      <p onmouseup="processSelection()">Lorem ipsum dolor sit amet,

     </p>
   </body>
</html>
```

Related Items: `TextRange.select()` method

typeDetail

Value: See text — Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `typeDetail` property serves as a placeholder for applications that use the IE browser component, in which case the property can serve as a means of providing additional selection type information.

Related Items: `type` property

Methods

addRange(*rangeRef*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `addRange()` method is used to highlight a selection on a page based upon a `Range` object. You can add multiple ranges to a selection by making repeated calls to the `addRange()` method.

Related Items: `removeRange()` method

clear()

Returns: Nothing

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Use the `clear()` method to delete the current selection from the document. To the user, the `clear()` method has the same effect as setting the `TextRange.text` property to an empty string. The difference is that you can use the `clear()` method without having to generate a text range for the selection. After you delete a selection, the `selection.type` property returns `None`.

Example

See Listing 33-7, earlier in this chapter, to see the `selection.clear()` method at work.

Related Items: `selection.empty()` method

collapse(*nodeRef, offset*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `collapse()` method collapses the current selection to a location specified by the two parameters, which consist of a node reference and an offset. The `nodeRef` parameter is a text or element node in the document tree to which the collapsed selection is to be moved, whereas the `offset` parameter is an integer count of characters or nodes within the target node where the collapsed selection should be moved.

Related Items: `collapseToEnd()` and `collapseToStart()` methods

collapseToEnd()
collapseToStart()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

These methods collapse the current selection to a location at the start (`collapseToStart()`) or end (`collapseToEnd()`) of the selection. After the collapse, any previously highlighted selection returns to normal display, and the selection contains only one range.

Related Items: `collapse()` method

containsNode(*nodeRef, entirelyFlag*)

Returns: Boolean

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `containsNode()` method returns a Boolean value indicating whether or not the specified node is contained in the selection. The `nodeRef` parameter is the node you are checking for selection containment, whereas the `entirelyFlag` parameter specifies whether or not the node must be contained in its entirety (passing `null` for the `entirelyFlag` parameter is usually sufficient).

`createRange()`

Returns: `TextRange` object

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

To generate a text range for a user selection in WinIE, invoke the `createRange()` method of the `selection` object. We're not sure why the method for the `selection` object is called `createRange()`, whereas text ranges for other valid objects are created with a `createTextRange()` method. The result of both methods is a full-fledged `TextRange` object.

Example

Refer to Listing 26-36 to see the `selection.createRange()` method turn user selections into text ranges.

Related Items: `TextRange` object

`deleteFromDocument()`

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `deleteFromDocument()` method deletes the current selection from the document tree.

Related Items: `removeRange()` method

`empty()`

Returns: Nothing

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `empty()` method deselects the current WinIE selection. After deselection, the `selection.type` property returns `None`. The action of the `empty()` method is the same as the `UnSelect` command invoked via the `execCommand()` method for a document. If the selection was made from a `TextRange` object (via the `TextRange.select()` method), the `empty()` method affects only the visible selection and not the text range.

Example

See Listing 33-7, earlier in this chapter, to view the `selection.empty()` method at work.

Related Items: `selection.clear()` method

`extend(`*`nodeRef, offset`*`)`

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `extend()` method extends the boundary of the selection to the specified node (`nodeRef`) and offset (`offset`) within that node. The start of the boundary (anchor node) remains unaffected by this method; only the end of the boundary (focus node) is altered.

getRangeAt(*rangeIndex*)

Returns: Range object

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The getRangeAt() method obtains the range at the specified zero-based index (rangeIndex) within the selection. You can use the rangeCount property to determine how many ranges are contained within the selection.

Related Items: rangeCount property

removeAllRanges()

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The removeAllRanges() method empties the selection by removing all of the ranges from it. Upon calling this method, the selection collapses and the rangeCount property goes to zero; the document tree remains unaffected.

Related Items: removeRange() method

removeRange(*rangeRef*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The removeRange() method removes the specified range (rangeRef) from the selection, but not from the document tree.

Related Items: removeAllRanges() method

selectAllChildren(*elementNodeRef*)

Returns: Nothing

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome

The selectAllChildren() method forces the selection to encompass the specified node (elementNodeRef) and all of its children. Calling this method on an element node results in the anchor and focus nodes being set to that node.

toString()

Returns: String

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The toString() method returns a string representation of the selection, which is the body content from the selection, minus tags and attributes.

Text and TextNode Objects

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

Syntax

Accessing `Text` and `TextNode` object properties or methods:

```
(IE5+/W3C) [window.]document.getElementById("id").textNodeRef.property |
           method()
```

About this object

Discussing the `Text` object of the W3C DOM (as implemented in NN6+/Moz and WebKit- and Presto-based browsers) in the same breath as the IE5+ `TextNode` object is a little tricky. Conceptually, they are the same kind of object in that they are the document tree objects — text nodes — that contain an HTML element's text (see Chapter 25, "Document Object Model Essentials," for details on the role of the text node in the `document` object hierarchy). Generating a new text node by script is achieved the same way in both object

models: `document.createTextNode()`. What makes the discussion of the two objects tricky is that although the W3C DOM version comes from a strictly object-oriented specification (in which a text node is an instance of a `CharacterData` object, which, in turn is an instance of the generic `Node` object), the IE object model is not quite as complete. For example, whereas the W3C DOM `Text` object inherits all of the properties and methods of the `CharacterData` and `Node` definitions, the IE `TextNode` object exposes only those properties and methods that Microsoft deems appropriate.

No discrepancy in terminology gets in the way when calling these objects because their object names never become part of the script. Instead, script statements always refer to text nodes by other means, such as through a child node–related property of an element object, or as a variable that receives the result of the `document.createTextNode()` method.

Although both objects share a number of properties and one method, the W3C DOM `Text` object contains a few methods that have "data" in their names. These properties and methods are inherited from the `CharacterData` object in the DOM specification. They are discussed as a group in the section about object methods in this chapter. In all cases, check the browser version support for each property and method described here.

Properties

`data`

Value: String — Read/Write

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `data` property contains the string comprising the text node. Its value is identical to the `nodeValue` property of a text node. See the description of the `nodeValue` property in Chapter 26.

Example

In the example for the `nodeValue` property used in a text replacement script (Listing 25-2), you can substitute the `data` property for `nodeValue` to accomplish the same result.

Related Items: `nodeValue` property of all element objects (Chapter 26)

Methods

`appendData("`*`text`*`")`
`deleteData(`*`offset, count`*`)`
`insertData(`*`offset, "text"`*`)`
`replaceData(`*`offset, count, "text"`*`)`
`substringData(`*`offset, count`*`)`

Returns: See text

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

These five methods of the W3C DOM `Text` object provide scripted manipulation of the text inside a text node. Methods that modify the node's data automatically change the values of both the `data` and `nodeValue` properties.

The purposes of these methods are obvious, for the most part. Any method that requires an `offset` parameter uses this integer value to indicate where in the existing text node the deletion, insertion, or replacement starts. Offsets are zero-based, meaning that, in order to indicate that the action should take place starting with the first character, specify a zero for the parameter. A `count` parameter is another integer, but one that indicates how many characters are to be included. For example, consider a text node that contains the following data:

```
abcdefgh
```

This node could be a node of an element on the page, or a node that has been created and assigned to a variable but not yet inserted into the page. To delete the first three characters of that text node, the statement is

```
textNodeReference.deleteData(0,3)
```

This leaves the text node content as

```
defgh
```

As for the `replaceData()` method, the length of the text being put in place of the original chunk of text need not match the `count` parameter. The `count` parameter, in concert with the `offset` parameter, defines what text is to be removed and replaced by the new text.

The `substringData()` method is similar to the JavaScript core language `String.substr()` method, in that both require parameters indicating the offset within the string to start reading and the number of characters. You get the same result with the `substringData()` method of a text node as you do from a `nodeValue.substr()` method when both are invoked from a valid text node object.

Of all five methods discussed here, only `substringData()` returns a value: a string.

Example

The page created by Listing 33-8 is a working laboratory that you can use to experiment with the five data-related methods in IE6+/NN6+/Moz and WebKi- and Presto-based browsers. The text node that invokes the methods is a simple sentence in a `p` element. Each method has its own clickable button, followed by two or three text boxes into which you enter values for method parameters. Don't be put off by the length of the listing. Each method's operation is confined to its own function, and is fairly simple.

Each of the data-related methods throws exceptions of different kinds. To help handle these errors gracefully, the method calls are wrapped inside a `try/catch` construction. All caught exceptions are routed to the `handleError()` function, where details of the error are inspected,

and friendly alert messages are displayed to the user. See Chapter 21, "Control Structures and Exception Handling," for details on the `try/catch` approach to error handling in W3C DOM-capable browsers.

splitText(*offset*)

Returns: `Text` or `TextNode` object

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `splitText()` method performs multiple actions with one blow. The `offset` parameter is an integer indicating the zero-based index position within the text node at which the node is to divide into two nodes. After you invoke the method on the current text node, the node consists of the text from the beginning of the node, up to the offset position. The method returns a reference to the text node whose data starts with the character after the dividing point, and extends to the end of the original node. Users won't notice any change in the rendered text: This method influences only the text node structure of the document. Using this method means, for example, that an HTML element that starts with only one text node will have two after the `splitText()` method is invoked. The opposite action (combining contiguous text node objects into a single node) is performed by the IE7+/NN6+/Moz/Safari1.2+ `normalize()` method (see Chapter 26).

Note

Although IE6 and MacIE5 both support the `normalize()` method, IE6 in particular has a buggy implementation that we wouldn't rely on. IE7 appears to have remedied this problem. ■

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see the `splitText()` method in action. Begin by verifying that the `myEM` element has but one child node, and that its `nodeValue` is the string "all":

```
document.getElementById("myEM").childNodes.length
document.getElementById("myEM").firstChild.nodeValue
```

Next, split the text node into two pieces after the first character:

```
document.getElementById("myEM").firstChild.splitText(1)
```

Two text nodes are now inside the element:

```
document.getElementById("myEM").childNodes.length
```

Each text node contains its respective portion of the original text:

```
document.getElementById("myEM").firstChild.nodeValue
document.getElementById("myEM").lastChild.nodeValue
```

If you are using IE7+/NN6+/Moz and WebKit- and Presto-based browsers, now bring the text nodes back together:

```
document.getElementById("myEM").normalize()
document.getElementById("myEM").childNodes.length
```

At no time during these statement executions does the rendered text change.

Syntax

Creating a `TextRange` object:

```
var rangeRef = document.body.createTextRange();
var rangeRef = buttonControlRef.createTextRange();
var rangeRef = textControlRef.createTextRange();
var rangeRef = document.selection.createRange();
```

Accessing `TextRange` object properties or methods:

```
(IE4+)        rangeRef.property | method([parameters])
```

About this object

Unlike most of the objects covered in Part III of this book, the IE4+ `TextRange` object is not tied to a specific HTML element. The `TextRange` object is, instead, an abstract object that represents text content anywhere on the page (including content of a text-oriented form control) between a start point and an end point (collectively, the *boundaries* of the range). The user may not necessarily know that a `TextRange` object exists, because no requirement exists to force a `TextRange` object to physically select text on the page (although the `TextRange` object can be used to assist scripts in automating the selection of text, or a script may turn a user selection into a `TextRange` object for further processing).

The purpose of the `TextRange` object is to give scripts the power to examine, modify, remove, replace, and insert content on the page. Start and end points of an IE `TextRange` object are defined exclusively in terms of character positions within the element that is used to create the range (usually the `body` element, but also button- and text-related form control elements). Character positions of body text do not take into account source code characters that may define HTML elements. This factor is what distinguishes a `TextRange`'s behavior from, for instance, the various properties and methods of HTML elements that let you modify or copy elements and their text (for example, `innerText` and `outerText` properties). A `TextRange` object's start point can be in one element, and its end point in another. For example, consider the following HTML:

```
<p>And now to introduce our <em>very special</em> guest:</p>
```

If the text shown in boldface indicates the content of a `TextRange` object, you can see that the range crosses element boundaries in a way that makes HTML element object properties difficult to use for replacing that range with some other text. Challenges still remain in this example, however. Simply replacing the text of the range with some other text forces your script (or the browser) to reconcile the issue of what to do about the nested `em` element, because the `TextRange` object handles only its text. (Your word processing program must address the same kind of issue when you select a phrase that starts in italic but ends in normal font, and then you paste text into that selection.)

An important aspect of the `TextRange` object is that the size of the range can be zero or more characters. Start and end points always position themselves between characters. When the start point and end point of a range are at the same location, the range acts as a text insertion pointer. In fact, when the `TextRange` object represents text inside a text-related form control, the `select()` method of the `TextRange` object can be used to display the text insertion pointer where your script desires. Therefore, through the `TextRange` object you can script your forms to always display the text insertion pointer at the end of existing text in a text box or textarea when the control receives focus.

Working with text ranges

To create a `TextRange` object, use the `createTextRange()` method with the `document.body` object or any button- or text-related form control object. If you want to convert a block of selected text to a text range, use the special `createRange()` method of the `document.selection` object. Regardless of how you create it, the range encompasses the entire text of the object used to generate the range. In other words, the start point is at the very beginning of the text, and the end point is at the very end. Note that when you create a `TextRange` object from the `body` element, text that is inside text-related form controls is not part of the text of the `TextRange` (just as text field content isn't selected if you manually select the entire text of the page).

After you create a `TextRange` object (assigned to a variable), the typical next steps involve some of the many methods associated with the object that help narrow the size of the range. Some methods (`move()`, `moveEnd()`, `moveStart()`, and `sentEndPoint()`) offer manual control over the intra-character position for the start and end points. Parameters of some of these methods understand concepts, such as words and sentences, so not every action entails tedious character counts. Another method, `moveToElementText()`, automatically adjusts the range to encompass a named element. The oft-used `collapse()` method brings the start and end points together at the beginning or end of the current range — helpful when a script must iterate through a range for tasks, such as word counting or search and replace. The `expand()` method can extend a collapsed range to encompass the whole word, whole sentence, or entire range surrounding the insertion point. Perhaps the most powerful method is `findText()`, which allows scripts to perform single or global search-and-replace operations on body text.

After the range encompasses the desired text, several other methods let scripts act on the selection. The types of operations include scrolling the page to make the text represented by the range visible to the user (`scrollIntoView()`), and selecting the text (`select()`) to provide

visual feedback to the user that something is happening (or to set the insertion pointer at a location in a text form control). An entire library of additional commands are accessed through the `execCommand()` method for operations, such as copying text to the clipboard, and a host of formatting commands that can be used in place of style sheet property changes. To swap text from the range with new text accumulated by your script, you can modify the `text` property of the range.

Using the `TextRange` object can be a bit tedious, because it often requires a number of script statements to execute an action. Three basic steps are generally required to work with a `TextRange` object:

1. Create the text range.
2. Set the start and end points.
3. Act on the range.

As soon as you are comfortable with this object, you will find it provides a lot of flexibility in scripting interaction with body content. For ideas about applying the `TextRange` object in your scripts, see the examples that accompany the following descriptions of individual properties and methods.

About browser compatibility

The `TextRange` object is available only for 32-bit versions of IE4 and later. There is no support for the `TextRange` object in MacIE.

The W3C DOM and NN6+ implement a slightly different concept of text ranges in what they call the `Range` object. In many respects, the fundamental way of working with a `Range` object is the same as for a `TextRange` object: create and adjust start and end points, and act on the range. But the W3C version (like the W3C DOM itself) is more conscious of the node hierarchy of a document. Properties and methods of the W3C `Range` object reflect this node-centric point of view, so that most of the terminology for the `Range` object differs from that of the IE `TextRange` object. As of this writing, IE8 doesn't support the W3C `Range` object, and it is unknown if or when Microsoft will add support for it.

At the same time, the W3C `Range` object lacks a couple of methods that are quite useful with the IE `TextRange` object — notably `findText()` and `select()`. On the other hand, the `Range` object, as implemented in NN6+/Moz and WebKit- and Presto-based browsers, works on all OS platforms.

The bottom-line question, then, is whether you can make range-related scripts work in both browsers. Whereas the basic sequence of operations is the same for both objects, the scripting vocabulary is quite different. Table 33-1 presents a summary of the property and method behaviors that the two objects have in common, and their respective vocabulary terms. (Sometimes the value of a property in one object is accessed via a method in the other object.) Notice that the ways of moving individual end points are not listed in the table because the corresponding

methods for each object (for example, `moveStart()` in `TextRange` versus `setStart()` in `Range`) use very different spatial paradigms.

TABLE 33-1

TextRange versus Range Common Denominators

TextRange Object	Range Object
`text`	`toString()`
`collapse()`	`collapse()`
`compareEndPoints()`	`compareEndPoints()`
`duplicate()`	`clone()`
`moveToElementText()`	`selectContents()`
`parentElement()`	`commonParent`

To blend text range actions for both object models into a single scripted page, you have to include script execution branches for each category of object model, or create your own API to invoke library functions that perform the branching. On the IE side of things, too, you have to script around actions that can cause script errors when run on MacOS and other non-Windows versions of the browser.

Properties

boundingHeight
boundingLeft
boundingTop
boundingWidth

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Every text range has physical dimension and location on the page, even if you cannot see the range reflected graphically with highlighting. Even a text insertion pointer (meaning a collapsed text range) has a rectangle whose height equals the line height of the body text in which the insertion point resides; its width, however, is zero.

The pixel dimensions of the rectangle of a text range can be retrieved via the `boundingHeight` and `boundingWidth` properties of the `TextRange` object. When a text range extends across multiple lines, the dimensions of the rectangle are equal to the smallest single rectangle that can contain the text (a concept identical to the bounding rectangle of inline body text, as described in the `TextRectangle` object later in this chapter). Therefore, even a range consisting of one character at the end of one line and another character at the beginning of the next, forces the bounding rectangle to be as wide as the paragraph element.

A text range rectangle has a physical location on the page. The top-left position of the rectangle (with respect to the browser window edge) is reported by the `boundingTop` and `boundingLeft` properties.

Example

Listing 33-9 provides a simple playground to explore the four bounding properties (and two offset properties) of a `TextRange` object. As you select text in the big paragraph, the values of all six properties are displayed in the table. Values are also updated if you resize the window via an `onresize` event handler.

Notice, for example, that if you simply click in the paragraph without dragging a selection, the `boundingWidth` property shows up as zero. This action is the equivalent of a `TextRange` acting as an insertion point.

Related Items: `offsetLeft`, `offsetTop` properties of element objects (Chapter 26, "Generic HTML Element Objects")

htmlText

Value: String Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `htmlText` property returns the HTML of the text contained by a text range. If a range's start and end points are at the very edges of an element's text, the HTML tag for that element becomes part of the `htmlText` property value. Also, if the range starts in one element and ends partway in another, the tags that influence the text of the end portion become part of the `htmlText`. This property is read-only, so you cannot use it to insert or replace HTML in the text range (see the `pasteHTML()` method, and various insert commands associated with the `execCommand()` method, in the following section).

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to investigate values returned by the `htmlText` property. Use the top text box to enter the following statements, and see the values in the Results box.

Begin by creating a `TextRange` object for the entire body and store the range in local variable `a`:

```
a = document.body.createTextRange()
```

Next, use the `findText()` method to set the start and end points of the text range around the word "all," which is an `em` element inside the `myP` paragraph:

```
a.findText("all")
```

The method returns `true` (see the `findText()` method) if the text is found, and the text range adjusts to surround it. To prove that the text of the text range is what you think it is, examine the `text` property of the range:

```
a.text
```

Because the text range encompasses all of the text of the element, the `htmlText` property contains the tags for the element as well:

```
a.htmlText
```

If you want to experiment by finding other chunks of text and looking at both the `text` and `htmlText` properties, first restore the text range to encompass the entire body with the following statement:

```
a.expand("textEdit")
```

You can read about the `expand()` method later in this chapter. In other tests, use `findText()` to set the range to "for all" and just "for al." Then, see how the `htmlText` property exposes the `em` element's tags.

Related Items: `text` property

text

Value: String Read/Write

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

Use the `text` property to view or change the string of visible characters that comprise a text range. The browser makes some decisions for you if the range you are about to change has nested elements inside. By and large, the nested element (and any formatting that may be associated with it) is deleted, and the new text becomes part of the text of the container that houses the start point of the text range. By the same token, if the range starts in the middle of one element and ends in the parent element's text, the tag that governs the start point now wraps all of the new text.

Example

See Listing 33-11, later in this chapter, for the `findText()` method where the `text` property is used to perform the replace action of a search-and-replace function.

Related Items: `htmlText` property

Methods

collapse([*startBoolean*])

Returns: Nothing

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

Use the `collapse()` method to shrink a text range from its current size down to a single insertion point between characters. This method becomes more important than you may think at first, especially in a function that is traversing the body of the page or a large chunk of text. For example, in a typical looping word-counting script, you create a text range that encompasses the full body of the page (or text in a `textarea`). When the range is created, its start point is at the beginning of the text, and its end point is at the very end. To begin counting words, you can first collapse the range to the insertion point at the beginning of the range. Next, use the `expand()` method to set the range to the first word of text (and increment the counter if the `expand()` method returns `true`). At that point, the text range extends around the first word.

What you want is for the range to collapse at the end of the current range so that the search for the next word starts after the current one. Use `collapse()` once more, but this time include parameters.

The optional parameter of the `collapse()` method is a Boolean value that directs the range to collapse itself at either the start or end of the current range. The default behavior is the equivalent of a value of `true`, which means that unless otherwise directed, a `collapse()` method shifts the text range to the point in front of the current range. That works great as an early step in the word-counting example, because you want the text range to collapse to the start of the text before doing any counting. But for subsequent movements through the range, you want to collapse the range so that it is after the current range. Thus, you include a `false` parameter to the `collapse()` method.

Example

Refer to Listings 33-11 and 26-14 to see the `collapse()` method at work.

Related Items: `Range.collapse()`, `TextRange.expand()` methods

compareEndPoints("*type*", *rangeRef*)

Returns: Integer (`-1`, `0`, or `1`)

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Generating multiple `TextRange` objects and assigning them to different variables is no problem. You can then use the `compareEndPoints()` method to compare the relative positions of start and end points of two ranges. One range is the object that you use to invoke the `compareEndPoints()` method, and the other range is the second parameter of the method. The order doesn't matter, because the first parameter of the method determines which points in each range you will be comparing.

Values for the first parameter can be one of four explicit strings: `StartToEnd`, `StartToStart`, `EndToStart`, and `EndToEnd`. What these values specify is which point of the current range is compared with which point of the range passed as the second parameter. For example, consider the following body text that has two text ranges defined within it:

It was the **best of *times*.**

The first text range (assigned in our discussion here to variable `rng1`) is shown in boldface, whereas the second text range (`rng2`) is shown in bold-italic. In other words, `rng2` is nested inside `rng1`. We can compare the position of the start of `rng1` against the position of the start of `rng2` by using the `StartToStart` parameter of the `compareEndPoints()` method:

```
var result = rng1.compareEndPoints("StartToStart", rng2);
```

The value returned from the `compareEndPoints()` method is an integer of one of three values. If the positions of both points under test are the same, the value returned is `0`. If the first point is before the second, the value returned is `-1`; if the first point is after the second, the value is `1`. Therefore, from the previous example, because the start of `rng1` is before the start

of rng2, the method returns -1. If you changed the statement to invoke the method on rng2, as in

```
var result = rng2.compareEndPoints("StartToStart", rng1);
```

the result would be 1.

In practice, this method is helpful in knowing if two ranges are the same, if one of the boundary points of both ranges is the same, or if one range starts where the other ends.

Example

The page rendered by Listing 33-10 lets you experiment with text range comparisons. The bottom paragraph contains a span element that has a TextRange object assigned to its text after the page loads (in the init() function). That fixed range becomes a solid reference point for you to use while you select text in the paragraph. After you make a selection, all four versions of the compareEndPoints() method run to compare the start and end points of the fixed range against your selection. One column of the results table shows the raw value returned by the compareEndPoints() method, whereas the third column puts the results into plain language.

To see how this page works, begin by selecting the first word of the fixed text range (double-click the word). You can see that the starting positions of both ranges are the same, because the returned value is 0. Because all of the invocations of the compareEndPoints() method are on the fixed text range, all comparisons are from the point of view of that range. Thus, the first row of the table for the StartToEnd parameter indicates that the start point of the fixed range comes before the end point of the selection, yielding a return value of -1.

Other selections to make include:

- Text that starts before the fixed range and ends inside the range
- Text that starts inside the fixed range and ends beyond the range
- Text that starts and ends precisely at the fixed range boundaries
- Text that starts and ends before the fixed range
- Text that starts after the fixed range

Study the returned values and the plain language results and see how they align with the selection you make.

Related Items: `Range.compareEndPoints()` method

duplicate()

Returns: `TextRange` object

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

The `duplicate()` method returns a `TextRange` object that is a snapshot copy of the current `TextRange` object. In a way, a non-intuitive relationship exists between the two objects. If you alter the `text` property of the copy without moving the start or end points of the original, the original takes on the new text. But if you move the start or end points of the original, the `text` and `htmlText` of the original obviously change, whereas the copy retains its properties from the time of the duplication. Therefore, this method can be used to clone text from one part of the document to other parts.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") in WinIE to see how the `duplicate()` method works. Begin by creating a new `TextRange` object that contains the text of the `myP` paragraph element:

```
a = document.body.createTextRange()
a.moveToElementText(myP)
```

Next, clone the original range and preserve the copy in variable `b`:

```
b = a.duplicate()
```

The method returns no value, so don't be alarmed by the "undefined" that appears in the Results box. Move the original range so that it is an insertion point at the end of the body by first expanding it to encompass the entire body, and then collapsing it to the end:

```
a.expand("textedit")
a.collapse(false)
```

Now, insert the copy at the very end of the body:

```
a.text = b.text
```

If you scroll to the bottom of the page, you'll see a copy of the text.

Related Items: `Range.clone()`, `TextRange.isEqual()` methods

execCommand("*commandName*"[, *UIFlag*[, *value*]])

Returns: Boolean

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

IE4+ for Windows operating systems lets scripts access a very large number of commands that act on insertion points, abstract text ranges, and selections that are made with the help of the `TextRange` object. Access to these commands is through the `execCommand()` method, which works with `TextRange` objects and the `document` object (see the `document.execCommand()` method discussion in Chapter 29, "The Document and Body Objects," and list of document- and selection-related commands in Table 29-2).

The first, required, parameter is the name of the command that you want to execute. Only a handful of these commands offer unique capabilities that aren't better accomplished within the IE object model using style sheets. Of particular importance is the command that lets you copy a text range into the Clipboard. Most of the rest of the commands modify styles or insert HTML tags at the position of a collapsed text range. These actions are better handled by other means, but they are included in Table 33-2 for the sake of completeness only (see Table 29-2 for additional commands).

An optional second parameter is a Boolean flag to instruct the command to display any user interface artifacts that may be associated with the command. The default is `false`. For the third parameter, some commands require an attribute value for the command to work. For example, to insert a new paragraph at an insertion point, you pass the identifier to be assigned to the `id` attribute of the `p` element. The syntax is

```
myRange.execCommand("InsertParagraph", true, "myNewP");
```

The `execCommand()` method returns Boolean `true` if the command is successful, `false` if not successful. Some commands can return values (for example, finding out the font name of a selection), but these values are accessed through the `queryCommandValue()` method.

TABLE 33-2

TextRange.execCommand() Commands

Command	Parameter	Description
`Bold`	None	Encloses the text range in a `<b>` tag pair
`Copy`	None	Copies the text range into the Clipboard
`Cut`	None	Copies the text range into the Clipboard and deletes it from the document or text control
`Delete`	None	Deletes the text range
`InsertButton`	ID String	Inserts a `<button>` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertFieldset`	ID String	Inserts a `<fieldset>` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertHoritontalRule`	ID String	Inserts an `<hr>` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertIFrame`	ID String	Inserts an `<iframe>` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputButton`	ID String	Inserts an `<input type="button">` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputCheckbox`	ID String	Inserts an `<input type="checkbox">` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputFileUpload`	ID String	Inserts an `<input type="FileUpload">` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputHidden`	ID String	Inserts an `<input type="hidden">` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputImage`	ID String	Inserts an `<input type="image">` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputPassword`	ID String	Inserts an `<input type="password">` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputRadio`	ID String	Inserts an `<input type="radio">` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputReset`	ID String	Inserts an `<input type="reset">` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputSubmit`	ID String	Inserts an `<input type="submit">` tag at the insertion point, assigning the parameter value to the `id` attribute
`InsertInputText`	ID String	Inserts an `<input type="text">` tag at the insertion point, assigning the parameter value to the `id` attribute

Command	Parameter	Description
InsertMarquee	ID String	Inserts a <marquee> tag at the insertion point, assigning the parameter value to the id attribute
InsertOrderedList	ID String	Inserts an tag at the insertion point, assigning the parameter value to the id attribute
InsertParagraph	ID String	Inserts a <p> tag at the insertion point, assigning the parameter value to the id attribute
InsertSelectDropdown	ID String	Inserts a <select type="select-one"> tag at the insertion point, assigning the parameter value to the id attribute
InsertSelectListbox	ID String	Inserts a <select type="select-multiple"> tag at the insertion point, assigning the parameter value to the id attribute
InsertTextArea	ID String	Inserts an empty <textarea> tag at the insertion point, assigning the parameter value to the id attribute
InsertUnorderedList	ID String	Inserts a tag at the insertion point, assigning the parameter value to the id attribute
Italic	None	Encloses the text range in an <i> tag pair
OverWrite	Boolean	Sets the text input control mode to overwrite (true) or insert (false)
Paste	None	Pastes the current Clipboard contents into the insertion point or selection
PlayImage	None	Begins playing dynamic images if they are assigned to the dynsrc attribute of the img element
Refresh	None	Reloads the current page
StopImage	None	Stops playing dynamic images if they are assigned to the dynsrc attribute of the img element
Underline	None	Encloses the text range in a <u> tag pair

Although the commands in Table 33-2 work on text ranges, even the commands that work on selections (Table 29-2) can frequently benefit from some preprocessing with a text range. Consider, for example, a function whose job it is to find every instance of a particular word in a document and set its background color to a yellow highlight. Such a function utilizes the powers of the findText() method of a text range to locate each instance. Then the select() method selects the text in preparation for applying the BackColor command. Here is a sample:

```
function hiliteIt(txt)
{
   var rng = document.body.createTextRange();
   for (var i = 0; rng.findText(txt); i++)
{
```

```
            rng.select();
            rng.execCommand("BackColor", "false", "yellow");
            rng.execCommand("Unselect");
            // prepare for next search
            rng.collapse(false);
        }
    }
```

This example is a rare case that makes the `execCommand()` method way of modifying HTML content more efficient than trying to wrap some existing text inside a new tag. The downside is that you don't have control over the methodology used to assign a background color to a span of text (in this case, IE wraps the text in a `<font>` tag with a `style` attribute set to `background-color:yellow` — probably not the way you'd do it on your own).

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see how to copy a text range's text into the client computer's Clipboard. Begin by setting the text range to the `myP` element:

```
a = document.body.createTextRange()
a.moveToElementText(myP)
```

Now use `execCommand()` to copy the range into the Clipboard:

```
a.execCommand("Copy")
```

To prove that the text is in the Clipboard, click the bottom text field and choose Paste from the Edit menu (or type Ctrl+V).

Related Items: Several query command methods of the `TextRange` object

expand("*unit*")

Returns: Boolean

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The single `expand()` method can open any range — collapsed or not — to the next largest character, word, or sentence, or to the entire original range (for example, encompassing the text of the `body` element if the range was generated by `document.body.createTextRange()`). The parameter is a string designating which unit to expand outward to: `character`, `word`, `sentence`, or `textedit`. If the operation is successful, the method returns `true`; otherwise it returns `false`.

When operating from an insertion point, the `expand()` method looks for the word or sentence that encloses the point. The routine is not very smart about sentences, however. If you have some text prior to a sentence that you want to expand to, but that text does not end in a period, the `expand()` routine expands outward until it can find either a period or the beginning of the range. Listing 26-14 demonstrates a workaround for this phenomenon. When expanding from an insertion point to a character, the method expands forward to the next character in character set

order. If the insertion point is at the end of the range, it cannot expand to the next characters, and the `expand()` method returns `false`.

It is not uncommon, in an extensive script that needs to move the start and end points all over the initial range, to perform several `collapse()` and `expand()` method operations from time to time. Expanding to the full range is a way to start some range manipulation with a clean slate, as if you just created the range.

Example

You can find examples of the `expand()` method in Listing 26-14.

Related Items: `TextRange.collapse()` method

findText("*searchString*"[, *searchScope*, *flags*])

Returns: Boolean

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

One of the most useful methods of the `TextRange` object is `findText()`, whose default behavior is to look through a text range, starting at the range's start point, up to the end of the range, in search of a case-insensitive match for a search string. If an instance is found in the range, the start and end points of the range are cinched up to the found text and the method returns `true`; otherwise it returns `false`, and the start and end points do not move. Only the rendered text is searched and not any of the tags or attributes.

Optional parameters let you exert some additional control over the search process. You can restrict the distance from a collapsed range to be used for searching. The `searchScope` parameter is an integer value indicating the number of characters from the start point. The larger the number, the more text of the range is included in the search. Negative values force the search to operate backward from the current start point. If you want to search backward to the beginning of the range, but you don't know how far away the start of the range is, you can specify an arbitrary number that's big enough to encompass the text.

The optional `flags` parameter lets you set whether the search is to be case-sensitive and/or to match whole words only. The parameter is a single integer value that uses bit-wise math to calculate the single value that accommodates one or both settings. The value for matching whole words is `2`; the value for matching case is `4`. If you want only one of those behaviors, then supply just the desired number. But for both behaviors, use the bit-wise XOR operator (the `^` operator) on the values to reach a value of `6`.

The most common applications of the `findText()` method include a search-and-replace action, and format changes to every instance of a string within the range. This iterative process requires some extra management. Because searching always starts with the range's current start point, advancing the start point to the end of the text found in the range is necessary. This advancing allows a successive application of `findText()` to look through the rest of the range for another

match. And because findText() ignores the arbitrary end point of the current range and continues to the end of the initial range, you can use the collapse(false) method to force the starting point to the end of the range that contains the first match.

A repetitive search can be accomplished by a while or for repeat loop. The returned Boolean value of the findText() method can act as the condition for continuing the loop. If the number of times the search succeeds is not essential to your script, a while loop works nicely:

```
while (rng.findText(searchString))
{
   // ...
   rng.collapse(false);
}
```

Or you can use a for loop counter to maintain a count of successes, such as a counter of how many times a string appears in the body:

```
for (var i = 0; rng.findText(searchString); i++)
{
   // ...
   rng.collapse(false);
}
```

Some of the operations you want to perform on a range (including many of the commands invoked by the execCommand() method) require that a selection exists for the command to work. Be prepared to use the select() method on the range after the findText() method locates a matching range of text.

Example

Listing 33-11 implements two varieties of text search-and-replace operations, while showing you how to include extra parameters for case-sensitive and whole-word searches. Both approaches begin by creating a TextRange for the entire body, but they immediately shift the starting point to the beginning of the div element that contains the text to search.

One search-and-replace function prompts the user to accept or decline replacement for each instance of a found string. The select() and scrollIntoView() methods are invoked to help the user see what is about to be replaced. Notice that even when the user declines to accept the replacement, the text range is collapsed to the end of the found range so that the next search can begin after the previously found text. Without the collapse() method, the search can get caught in an infinite loop as it keeps finding the same text over and over (with no replacement made). Because no counting is required, this search-and-replace operation is implemented inside a while repeat loop.

The other search-and-replace function goes ahead and replaces every match, and then displays the number of replacements made. After the loop exits (because there are no more matches), the loop counter is used to display the number of replacements.

   var srchString = form.searchString.value;
      if (srchString)
      {
         var args = getArgs(form);
         rng = document.body.createTextRange();
         rng.moveToElementText(rights);
         for (i = 0; rng.findText(srchString, 10000, args); i++)
         {
            rng.text = replString;
            pushUndoNew(rng, srchString, replString);
            rng.collapse(false);
         }
         if (i > 1)
         {
            clearUndoBuffer();
         }
      }
   replaceHTML(document.getElementById("counter"), i);
}

// BEGIN UNDO BUFFER CODE
// buffer global variables
var newRanges = new Array();
var origSearchString;

// store original search string and bookmarks of each replaced range
function pushUndoNew(rng, srchString, replString)
{
   origSearchString = srchString;
   rng.moveStart("character", -replString.length);
   newRanges[newRanges.length] = rng.getBookmark();
}

// empty array and search string global
function clearUndoBuffer()
{
   replaceHTML(document.getElementById("counter"), "0");
   origSearchString = "";
   newRanges.length = 0;
}

// perform the undo
function undoReplace()
```

continued

LISTING 33-11 *(continued)*

```
{
   if (newRanges.length && origSearchString)
   {
      for (var i = 0; i < newRanges.length; i++)
      {
         rng.moveToBookmark(newRanges[i]);
         rng.text = origSearchString;
      }
      replaceHTML(document.getElementById("counter"), i);
      clearUndoBuffer();
   }
}
```

Having a search-and-replace function available in a document is only one half of the battle. The other half is offering the facilities to undo the changes. To that end, Listing 33-11 includes an undo buffer that accurately undoes only the changes made in the initial replacement actions.

The undo buffer stores its data in two global variables. The first, `origSearchString`, is simply the string used to perform the original search. This variable is the string that has to be put back in the places where it had been replaced. The second global variable is an array that stores `TextRange` bookmarks (see `getBookmark()` later in this chapter). These references are string values that don't mean much to humans, but the browser can use them to re-create a range with its desired start and end point. Values for both the global search string and bookmark specifications are stored in calls to the `pushUndoNew()` method each time text is replaced.

A perhaps unexpected action of setting the `text` property of a text range is that the start and end points collapse to the end of the new text. Because the stored bookmark must include the replaced text as part of its specification, the start point of the current range must be adjusted back to the beginning of the replacement text before the bookmark can be saved. Thus, the `pushUndoNew()` function receives the replacement text string so that the `moveStart()` method can be adjusted by the number of characters matching the length of the replacement string.

After all of the bookmarks are stored in the array, the undo action can do its job in a rather simple `for` loop inside the `undoReplace()` function. After verifying that the undo buffer has data stored in it, the function loops through the array of bookmarks and replaces the bookmarked text with the old string. The benefit of using the bookmarks this time, rather than the replacement function, is that only those ranges originally affected by the search-and-replace operation are touched in the undo operation. For example, in this document, if you replace a case-sensitive "states" with "States," two replacements are performed. At that point, however, the document has four instances of "States," two of which existed before. Redoing the replacement function by inverting the search-and-replace strings would convert all four back to the lowercase version — not the desired effect.

Related Items: `TextRange.select()` method

getBookmark()

Returns: Bookmark string

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

In the context of a `TextRange` object, a bookmark is not to be confused with the kinds of bookmarks you add to a browser list of favorite web sites. Instead, a bookmark is a string that represents a definition of a text range, including its location in a document, its text, and so on. Viewing the string is futile, because it contains string versions of binary data, so the string means nothing in plain language. But, a bookmark allows your scripts to save the current state of a text range so that it may be restored at a later time. The `getBookmark()` method returns the string representation of a snapshot of the current text range. Some other script statement can adjust the `TextRange` object to the exact specifications of the snapshot with the `moveToBookmark()` method (described later in this chapter).

Example

Listing 33-11, earlier in this chapter, shows how the `getBookmark()` method is used to preserve specifications for text ranges so that they can be called upon again to be used to undo changes made to the text range. The `getBookmark()` method is used to save the snapshots, whereas the `moveToBookmark()` method is used during the undo process.

Related Items: `TextRange.moveToBookmark()` method

inRange(*otherRangeRef*)

Returns: Boolean

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

You can compare the physical stretches of text contained by two different text ranges via the `inRange()` method. Typically, you invoke the method on the larger of the two ranges and pass a reference to the smaller range as the sole parameter to the method. If the range passed as a parameter is either contained by or equal to the text range that invokes the method, the method returns `true`; otherwise the method returns `false`.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see the `inRange()` method in action. The following statements generate two distinct text ranges, one for the `myP` paragraph element and the other for the `myEM` element nested within:

```
a = document.body.createTextRange()
a.moveToElementText(myP)
b = document.body.createTextRange()
b.moveToElementText(myEM)
```

Because the `myP` text range is larger than the other, we invoke the `inRange()` method on it, fully expecting the return value of `true`:

```
a.inRange(b)
```

But if you switch the references, you see that the larger text range is not “in” the smaller one:

```
b.inRange(a)
```

Related Items: `TextRange.isEqual()` method

isEqual(*otherRangeRef*)

Returns: Boolean

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

If your script has references to two independently adjusted `TextRange` objects, you can use the `isEqual()` method to test whether the two objects are identical. This method tests for a very literal equality, requiring that the text of the two ranges be character-for-character and position-for-position equal in the context of the original ranges (for example, body or text control content). To see if one range is contained by another, use the `inRange()` method instead.

Example

Use The Evaluator (Chapter 4, “JavaScript Essentials”) to try the `isEqual()` method. Begin by creating two separate `TextRange` objects, one for the `myP` element and one for `myEM`:

```
a = document.body.createTextRange()
a.moveToElement(myP)
b = document.body.createTextRange()
b.moveToElement(myEM)
```

Because these two ranges encompass different sets of text, they are not equal, as the results show from the following statement:

```
a.isEqual(b)
```

But if you now adjust the first range boundaries to surround the `myEM` element, both ranges are the same values:

```
a.moveToElement(myEM)
a.isEqual(b)
```

Related Items: `TextRange.inRange()` method

move("*unit*"[, *count*])

Returns: Integer

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

The `move()` method performs two operations. First, the method collapses the current text range to become an insertion point at the location of the previous end point. Next, it moves that insertion point to a position forward or backward any number of character, word, or sentence units.

The first parameter is a string specifying the desired unit (`character`, `word`, `sentence`, or `textedit`). A value of `textedit` moves the pointer to the beginning or end of the entire initial text range. If you omit the second parameter, the default value is 1. Otherwise, you can specify an integer indicating the number of units the collapsed range should be moved ahead (positive integer) or backward (negative). The method returns an integer revealing the exact number of units the pointer is able to move — if you specify more units than are available, the returned value lets you know how far it can go.

Bear in mind that the range is still collapsed after the `move()` method executes. Expanding the range around the desired text is the job of other methods.

You can also use the `move()` method in concert with the `select()` method to position the flashing text insertion pointer within a text box or textarea. Thus, you can script a text field that, upon receiving focus or when the page loads, has the text pointer waiting for the user at the end of existing text. A generic function for such an action is shown in the following code:

```
function setCursorToEnd(elem)
{
   if (elem)
   {
      if (elem.type && (elem.type == "text" || elem.type == "textarea"))
      {
         var rng = elem.createTextRange();
         rng.move("textedit");
         rng.select();
      }
   }
}
```

You can then invoke this method from a text field's `onfocus` event handler:

```
<input type="text" ... onfocus="setCursorToEnd(this)" />
```

The function previously shown includes a couple of layers of error checking, such as making sure that the function is invoked with a valid object as a parameter, and that the object has a `type` property whose value is capable of having a text range made for its content.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `move()` method in IE. To see how the method returns just the number of units it moves the pointer, begin by creating a text range and set it to enclose the `myP` element:

```
a = document.body.createTextRange()
a.moveToElementText(myP)
```

Now enter the following statement to collapse and move the range backward by 20 words:

```
a.move("word", -20)
```

Continue to click the Evaluate button and watch the returned value in the Results box. The value shows `20` while it can still move backward by 20 words. But eventually the last movement will be some other value closer to zero. And after the range is at the beginning of the `body` element, the range can move no more in that direction, so the result is zero.

Related Items: `TextRange.moveEnd()`, `TextRange.moveStart()` methods

moveEnd("*unit*"[, *count*])
moveStart("*unit*"[, *count*])

Returns: Integer

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

The `moveEnd()` and `moveStart()` methods are similar to the `move()` method, but they each act only on the end and starting points of the current range, respectively. In other words, the range does not collapse before the point is moved. These methods allow you to expand or shrink a range by a specific number of units by moving only one of the range's boundaries.

The first parameter is a string specifying the desired unit (`character`, `word`, `sentence`, or `textedit`). A value of `textedit` moves the pointer to the beginning or end of the entire initial text range. Therefore, if you want the end point of the current range to zip to the end of the body (or text form control), use `moveEnd("textedit")`. If you omit the second parameter, the default value is `1`. Otherwise you can specify an integer indicating the number of units the collapsed range is to move ahead (positive integer) or backward (negative). Moving either point beyond the location of the other, forces the range to collapse and move to the location specified by the method. The method returns an integer revealing the exact number of units the pointer is able to move — if you specify more units than are available, the returned value lets you know how far it can go.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `moveEnd()` and `moveStart()` methods. Begin by creating a text range and set it to enclose the `myEM` element:

```
a = document.body.createTextRange()
a.moveToElementText(myEM)
```

To help you see how movements of the pointers affect the text enclosed by the range, type `a` into the bottom text box and view all the properties of the text range. Note especially the `htmlText` and `text` properties.

Now enter the following statement to move the end of the range forward by one word:

```
a.moveEnd("word")
```

Click the List Properties button to see that the text of the range now includes the word following the `em` element. Try each of the following statements in the top text box and examine both the

integer results and (by clicking the List Properties button) the properties of the range after each statement:

```
a.moveStart("word", -1)
a.moveEnd("sentence")
```

Notice that for a sentence, a default unit of 1 expands to the end of the current sentence. And if you move the start point backward by one sentence, you'll see that the lack of a period-ending sentence prior to the `myP` element causes strange results.

Finally, force the start point backward in increments of 20 words and watch the results as the starting point nears and reaches the start of the `body`:

```
a.moveStart("word", -20)
```

Eventually the last movement will be some other value closer to zero. And as soon as the range is at the beginning of the `body` element, the range can move no more in that direction, so the result is zero.

Related Items: `TextRange.move()` method

moveToBookmark("*bookmarkString*")

Returns: Boolean

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

If a snapshot of a text range specification has been preserved in a variable (with the help of the `getBookmark()` method), the `moveToBookmark()` method uses that bookmark string as its parameter to set the text range to exactly the way it appeared when the bookmark was originally obtained. If the method is successful, it returns a value of `true`, and the text range is set to the same string of text as originally preserved via `getBookmark()`. It is possible that the state of the content of the text range has been altered to such an extent that resurrecting the original text range is not feasible. In that case, the method returns `false`.

Example

Listing 33-11, earlier in this chapter, shows how to use the `moveToBookmark()` method to restore a text range so that changes that created the state saved by the bookmark can be undone. The `getBookmark()` method is used to save the snapshots, whereas the `moveToBookmark()` method is used during the undo process.

Related Items: `TextRange.getBookmark()` method

moveToElementText(*elemObjRef*)

Returns: Nothing

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

The fastest way to cinch up a text range to the boundaries of an HTML element on the page is to use the `moveToElementText()` method. Any valid reference to the HTML element object is

accepted as the sole parameter — just don't try to use a string version of the object ID unless it is wrapped in the W3C `document.getElementById()` method (IE5+). When the boundaries are moved to the element, the range's `htmlText` property contains the tags for the element.

Example

A majority of examples for other `TextRange` object methods in this chapter use the `moveToElementText()` method. Listings 33-10 and 33-11, earlier in this chapter, show the method within an application context.

Related Items: `TextRange.parentElement()` method

moveToPoint(*x*, *y*)

Returns: Nothing

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `moveToPoint()` method shrinks the current text range object to an insertion point and then moves it to a position in the current browser window or frame. You control the precise position via the `x` (horizontal) and `y` (vertical) pixel coordinates specified as parameters. The position is relative to the visible window, and not the document, which may have been scrolled to a different position. Invoking the `moveToPoint()` method is the scripted equivalent of the user clicking that spot in the window. Use the `expand()` method to flesh out the collapsed text range to encompass the surrounding character, word, or sentence.

Note

Using the `moveToPoint()` method on a text range defined for a text form control may cause a browser crash in versions of IE prior to 7. The method appears safe with the `document.body` text ranges, even if the x,y position falls within the rectangle of a text control. Such a position, however, does not drop the text range into the form control or its content. ■

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see the `moveToPoint()` method in action. Begin by creating a text range for the entire `body` element:

```
a = document.body.createTextRange()
```

Now, invoke the `moveToPoint()` method to a location `100,100`, which turns out to be in the rectangle space of the Results textarea:

```
a.moveToPoint(100,100)
```

If you type `a` into the bottom text box and view the properties, both the `htmlText` and `text` properties are empty because the insertion point represents no visible text content. But if you gradually move, for example, the start point backward one character at a time, you will see the `htmlText` and `text` properties begin to fill in with the body text that comes before the `textarea` element, namely the "Results:" label, the `<br>` tag between it, and the `textarea`

element. Enter the following statement into the top text box and click the Evaluate button several times:

```
a.moveStart("character", -1)
```

Enter `a` into the bottom text box after each evaluation to list the properties of the range.

Related Items: `TextRange.move()`, `TextRange.moveStart()`, `TextRange.moveEnd()` methods

parentElement()

Returns: Element object reference

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

The `parentElement()` method returns a reference to the next outermost HTML element container that holds the text range boundaries. If the text range boundaries are at the boundaries of a single element, the `parentElement()` method returns that element's reference. But if the boundaries straddle elements, the object returned by the method is the element that contains the text of the least-nested text portion. In contrast to the `expand()` and various move-related methods, which understand text constructs, such as words and sentences, the `parentElement()` method is concerned solely with element objects. Therefore, if a text range is collapsed to an insertion point in body text, you can expand it to encompass the HTML element by using the `parentElement()` method as a parameter to `moveToElementText()`:

```
rng.moveToElementText(rng.parentElement());
```

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `parentElement()` method. Begin by setting the text range to the `myEM` element:

```
a = document.body.createTextRange()
a.moveToElementText(myEM)
```

To inspect the object returned by the `parentElement()` method, enter the following statement in the lower text box:

```
a.parentElement()
```

If you scroll down to the `outerHTML` property, you see that the parent of the text range is the `myEM` element, tag and all.

Next, extend the end point of the text range by one word:

```
a.moveEnd("word")
```

Because part of the text range now contains text of the `myP` object, the `outerHTML` property of `a.parentElement()` shows the entire `myP` element and tags.

Related Items: `TextRange.expand()`, `TextRange.move()`, `TextRange.moveEnd()`, `TextRange.moveStart()` methods

pasteHTML("*HTMLText*")

Returns: Nothing

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Although the `execCommand()` method offers several commands that insert HTML elements into a text range, it is probably more convenient to simply paste fully-formed HTML into the current text range (assuming you need to be working with a text range instead of even more simply setting new values to an element object's `outerHTML` property). Provide the HTML to be inserted as a string parameter to the `pasteHTML()` method.

Use the `pasteHTML()` method with some forethought. Some HTML that you may attempt to paste into a text range may force the method to wrap additional tags around the content you provide, to ensure the validity of the resulting HTML. For example, if you were to replace a text range consisting of a portion of the text of a `p` element with, for instance, an `li` element, the `pasteHTML()` method has no choice but to divide the `p` element into two pieces, because a `p` element is not a valid container for a solo `li` element. This division can greatly disrupt your document object hierarchy, because the divided `p` element assumes the same ID for both pieces. Existing references to that `p` element will break, because the reference now returns an array of two like-named objects.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `pasteHTML()` method. The goal of the following sequence is to change the `<em>` tag to a `<span>` tag whose `style` attribute sets the color of the original text that was in the `em` element.

Begin by creating the text range and setting the boundaries to the `myEM` element:

```
a = document.body.createTextRange()
a.moveToElementText(myEM)
```

Although you can pass the HTML string directly as a parameter to `pasteHTML()`, it may be more convenient (and more easy to test) to store the HTML string in its own temporary variable, like this:

```
b = "<span style='color:red'>" + a.text + "</span>"
```

Notice that we concatenate the text of the current text range, because it has not yet been modified. Now we can paste the new HTML string into the current text range:

```
a.pasteHTML(b)
```

At this point the `em` element is gone from the object model, and the `span` element is in its place. Prove it to yourself by looking at the HTML for the `myP` element:

```
myP.innerHTML
```

As noted earlier, the `pasteHTML()` method is not the only way to insert or replace HTML in a document. This method makes excellent sense when the user selects some text in the document to be replaced, because you can use the `document.selection.createRange()` method to get the text range for the selection. But if you're not using text ranges for other related operations, consider the other generic object properties and methods available to you.

Related Items: `outerHTML` property; `insertAdjacenHTML()` method

queryCommandEnabled("*commandName*")
queryCommandIndeterm("*commandName*")
queryCommandState("*commandName*")
queryCommandSupported("*commandName*")
queryCommandText("*commandName*")
queryCommandValue("*commandName*")

Returns: See `document.queryCommandEnabled()` in Chapter 29, "The Document and Body Objects."

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

See descriptions under `document.queryCommandEnabled()` in Chapter 29.

select()

Returns: Nothing

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera+, Chrome-

The `select()` method selects the text inside the boundaries of the current text range. For some operations, such as prompted search and replace, it is helpful to show the user the text of the current range to highlight what text is about to be replaced. In some other operations, especially several commands invoked by `execCommand()`, the operation works only on a text selection in the document. Thus, you can use the `TextRange` object facilities to set the boundaries, followed by the `select()` method to prepare the text for whatever command you like. Text selected by the `select()` method becomes a `selection` object (covered earlier in this chapter).

Example

See Listing 33-11, earlier in this chapter, for an example of the `select()` method in use.

Related Items: `selection` object

setEndPoint("*type*", *otherRangeRef*)

Returns: Nothing.

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

In contrast to the `moveEnd()` method, which adjusts the end point of the current range with respect to characters, words, sentences, and the complete range, the `setEndPoint()` method sets a boundary of the current range (not necessarily the ending boundary) relative to a boundary

of another text range whose reference is passed as the second parameter. The first parameter is one of four types that control which boundary of the current range is to be adjusted and which boundary of the other range is the reference point. Table 33-3 shows the four possible values and their meanings.

TABLE 33-3

setEndPoint() Method Types

Type	Description
`StartToEnd`	Moves the start point of the current range to the end of the other range
`StartToStart`	Moves the start point of the current range to the start of the other range
`EndToStart`	Moves the end point of the current range to the start of the other range
`EndToEnd`	Moves the end point of the current range to the end of the other range

Note that the method moves only one boundary of the current range at a time. If you want to make two ranges equal to each other, you have to invoke the method twice, once with `StartToStart` and once with `EndToEnd`. At that instant, the `isEqual()` method applied to those two ranges returns `true`.

Setting a boundary point with the `setEndPoint()` method can have unexpected results when the revised text range straddles multiple elements. Don't be surprised to find that the new HTML text for the revised range does not include tags from the outer element container.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `setEndPoint()` method. Begin by creating two independent text ranges, one for the `myP` element and one for `myEM`:

```
a = document.body.createTextRange()
a.moveToElementText(myP)
b = document.body.createTextRange()
b.moveToElementText(myEM)
```

Before moving any end points, compare the HTML for each of those ranges:

```
a.htmlText
b.htmlText
```

Now, move the start point of the `a` text range to the end point of the `b` text range:

```
a.setEndPoint("StartToEnd", b)
```

If you now view the HTML for the `a` range,

```
a.htmlText
```

you see that the <p> tag of the original `a` text range is nowhere to be found. This demonstration is a good lesson in using the `setEndPoint()` method primarily if you are concerned only with visible body text being inside ranges, rather than an element with its tags.

Related Items: `TextRange.moveEnd()`, `TextRange.moveStart()`, `TextRange.moveToElementText()` methods

TextRectangle Object

Compatibility: WinIE5+, MacIE-, NN-, Moz5+, Safari4+, Opera9.5+, Chrome3+

Properties	Methods	Event Handlers
`bottom`		
`left`		
`right`		
`top`		

Syntax

Accessing `TextRectangle` object properties:

```
(IE5+) [window.]document.getElementById("elemID").
          getBoundingClientRect().property
(IE5+) [window.]document.getElementById("elemID").
          getClientRects()[i].property
```

About this object

The `TextRectangle` object exposes to scripts a concept that is described in the HTML 4.0 specification, whereby an element's rendered text occupies a rectangular space on the page just large enough to contain the text. For a single word, the rectangle is as tall as the line height for the font used to render the word, and no wider than the space occupied by the text. But for a sequence of words that wraps to multiple lines, the rectangle is as tall as the line height times the number of lines, and as wide as the distance between the leftmost and rightmost character edges, even if it means that the rectangle encloses some other text that is not part of the element.

If you extract the `TextRectangle` object for an element by way of, for example, the `getBoundingClientRect()` method, be aware that the object is but a snapshot of the rectangle when the method was invoked. Resizing the page may very well alter dimensions of the actual rectangle enclosing the element's text, but the `TextRectangle` object copy that you made previously does not change its values to reflect the element's physical changes. After a window resize or modification of body text, any dependent `TextRectangle` objects should be recopied from the element.

Properties

bottom
left
right
top

Values: Integers Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari4+, Opera9.5+, Chrome3+

The screen pixel coordinates of its four edges define every `TextRectangle` object. These coordinates are relative to the window or frame displaying the page. Therefore, if you intend to align a positioned element with an inline element's `TextRectangle`, your position assignments must take into account the scrolling of the body.

To our eyes, the left edge of a `TextRectangle` does not always fully encompass the left-most pixels of the rendered text. You may have to fudge a few pixels in the measure when trying to align a real element with the `TextRectangle` of another element.

Example

Listing 33-12 lets you click one of four nested elements to see how the `TextRectangle` is treated. When you click one of the elements, that element's `TextRectangle` dimension properties are used to set the size of a positioned element that highlights the space of the rectangle. Be careful not to confuse the visible rectangle object that you see on the page with the abstract `TextRectangle` object that is associated with each of the clicked elements.

An important part of the listing is the way the action of sizing and showing the positioned element is broken out as a separate function (`setHiliter()`) from the one that is the `onclick` event handler function (`handleClick()`). This is done so that the `onresize` event handler can trigger a script that gets the current rectangle for the last element clicked, and the positioned element can be sized and moved to maintain the highlight of the same text. As an experiment, try removing the `onresize` event handler from the `<body>` tag and watch what happens to the highlighted rectangle after you resize the browser window: the rectangle that represents the `TextRectangle` remains unchanged, and loses track of the abstract `TextRectangle` associated with the actual element object.

The Form and Related Objects

IN THIS CHAPTER

The form object as a container of form controls

Processing form validations

label, fieldset, and legend element objects

Putting Web Forms 2.0 to work

Prior to the advent of dynamic object models and automatic page reflow, the majority of scripting in an HTML document took place in and around forms. Even with all the modern DHTML powers, forms remain the primary user interface elements of HTML documents because they enable users to input information and make choices in a very familiar way, using buttons, option lists, and so on.

Expanded object models of W3C-compatible browsers include scriptable access to form-related elements that are part of the HTML 4.0 specification. One pair of elements, `fieldset` and `legend`, provides both contextual and visual containment of form controls in a document. Another element, `label`, provides context for text labels that usually appear adjacent to form controls. Although there is generally little reason to script these objects, the browsers give you access to them just as they do for virtually every HTML element supported by the browser.

An interesting new twist in the form equation is Web Forms 2.0, which is a dramatically improved form technology based upon the original form features in HTML 4.0. Web Forms 2.0 establishes a powerful and consistent set of form controls that includes built-in validation and much-needed standard controls, such as an interactive date picker, among other things. Only Opera 9+ supports the new features, but other browsers will likely adopt them in the future.

The Form in the Object Hierarchy

Take another look at the JavaScript object hierarchy in the lowest common denominator object model (refer to Figure 25-1). The `form` element object can contain a wide variety of form element objects (sometimes called *form controls*), which we cover in Chapters 34 through 36. In this chapter, however, we focus primarily on the container.

The good news on the compatibility front is that much of the client-side scripting works on all scriptable browsers. We encourage you to use the newer `getElementById()` approach of addressing forms and their nested elements when your audience uses newer browsers exclusively. However, it can serve you well to be comfortable with the old-fashioned reference syntax. In fact, one of the older approaches to form referencing is still endorsed by the W3C, so you can use it without worrying about your code being antiquated for the sake of compatibility. Knowing this, almost all example code in this and the next three chapters uses syntax that is compatible across all browsers, including the earliest scriptable browsers.

form Object

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
acceptCharset	handleEvent()	onreset
action	reset()	onsubmit
autocomplete	submit()	
elements[]		
encoding		
enctype		
length		
method		
name		
target		

Syntax

Accessing `form` object properties or methods:

```
(All)       [window.]document.formName. property | method([parameters])
(All)       [window.]document.forms[index]. property | method([parameters])
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(All/W3C)   [window.]document.forms["formName"]. property |
            method([parameters])
(All/W3C)   [window.]document.forms["formName"].elements["property"] |
            method([parameters])
(IE5+/W3C)  [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

About this object

Forms and their elements are the most common two-way gateways between users and JavaScript scripts. A form control element provides the only way that users can enter textual information across all browsers. Form controls also provide somewhat standardized and recognizable user interface elements for the user to make a selection from a predetermined set of choices. Those choices appear in the form of an on/off check box, in a set of mutually exclusive radio buttons, or as a selection from a list.

As you have seen in many web sites, the form is the avenue for the user to enter information that is sent to the server housing the web files. Just what the server does with this information depends on the programs running on the server. If your web site runs on a server directly under your control (that is, it is *in-house* or *hosted* by a service), you have the freedom to set up all kinds of data-gathering or database search programs to interact with the user. But with some of the more consumer-oriented Internet service providers (ISPs), you may have no server-side application support available — or, at best, a limited set of popular but inflexible CGI (Common Gateway Interface) programs, which are available to all customers of the service. Custom databases or transactional services are rarely provided for this kind of Internet service.

Regardless of your Internet server status, you can find plenty of uses for JavaScript scripts in forms. For instance, rather than using data exchanges (and Internet bandwidth) to gather raw user input and report any input errors, a JavaScript-enhanced document can preprocess the information to make sure that it employs the format that your back-end database or other programs most easily process. All corrective interaction takes place in the browser, without one extra bit flowing across the Net. We devote all of Chapter 46 (on the CD-ROM) to these kinds of form data-validation techniques. Additionally, Web Forms 2.0, which you meet later in this chapter, includes built-in support for many of the common validation tasks that are typically solved via JavaScript.

How you define a `form` element (independent of the user interface elements described in subsequent chapters) depends a great deal on how you plan to use the information from the form's controls. If you intend to use the form exclusively for JavaScript purposes (that is, no queries or postings going to the server), you do not need to use the `action`, `target`, and `method` attributes. But if your web page will be feeding information or queries back to a server, you need to specify at least the `action` and `method` attributes. You need to also specify the `target` attribute if the resulting data from the server is to be displayed in a window other than the calling window, and the `enctype` attribute if your form's scripts fashion the server-bound data in a MIME type other than in a plain ASCII stream.

References to form control elements

For most client-side scripting, user interaction comes from the elements within a form; the `form` element object is merely a container for the various control elements. If your scripts perform any data validation checks on user entries prior to submission or other calculations, many statements have the `form` object as part of the reference to the element.

A complex HTML document can have multiple `form` objects. Each `<form>...</form>` tag pair defines one form. You don't receive any penalties (except for potential confusion on the part of

someone reading your script) if you reuse a name for an element in each of a document's forms. For example, if each of three forms has a grouping of radio buttons with the name "choice," the object reference to each button ensures that JavaScript doesn't confuse them. The reference to the first button of each of those button groups is as follows:

```
document.forms[0].choice[0]
document.forms[1].choice[0]
document.forms[2].choice[0]
```

If you assign identifiers to `id` attributes, however, you should not reuse an identifier on the same page.

Passing forms and elements to functions

When a form or form element contains an event handler that calls a function defined elsewhere in the document, you can use a couple of shortcuts to simplify the task of addressing the objects while the function does its work. Failure to grasp this concept not only causes you to write more code than you have to, but also to get hopelessly lost you when you try to trace somebody else's code in his or her JavaScripted document. The watchword in event handler parameters is

```
this
```

which represents a reference to the current object that contains the event handler attribute. For example, consider the function and form definition in Listing 34-1. The entire user interface for this listing consists of form elements, as shown in Figure 34-1.

LISTING 34-1

Passing the form Object as a Parameter

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Beatle Picker</title>
      <script type="text/javascript">
      function processData(form)
      {
         for (var i = 0; i < form.Beatles.length; i++)
         {
            if (form.Beatles[i].checked)
            {
               break;
            }
         }
         var chosenBeatle = form.Beatles[i].value;
         var chosenSong = form.song.value;
         alert("Looking to see if " + chosenSong + " was written by " +
```

```
            chosenBeatle + "...");
      }

      function checkSong(songTitle)
      {
         var enteredSong = songTitle.value;
         alert("Making sure that " + enteredSong +
            " was recorded by the Beatles.");
      }
      </script>
   </head>
   <body>
      <form name="Abbey Road">
         Choose your favorite Beatle:
         <input type="radio" name="Beatles" id="Beatles1"
                value="John Lennon" checked="true" />John
         <input type="radio" name="Beatles" id="Beatles2"
                value="Paul McCartney" />Paul
         <input type="radio" name="Beatles" id="Beatles3"
                value="George Harrison" />George
         <input type="radio" name="Beatles" id="Beatles4"
                value="Ringo Starr" />Ringo
         <p>Enter the name of your favorite Beatles song:<br />
            <input type="text" name="song" id="song" value="Eleanor Rigby"
                   onchange="checkSong(this)" />
         </p>
         <p><input type="button" name="process" id="process"
                   value="Process Request..." onclick="processData(this.form)" />
         </p>
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique in the previous example is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32. Several other chapters use the modern technique extensively. ■

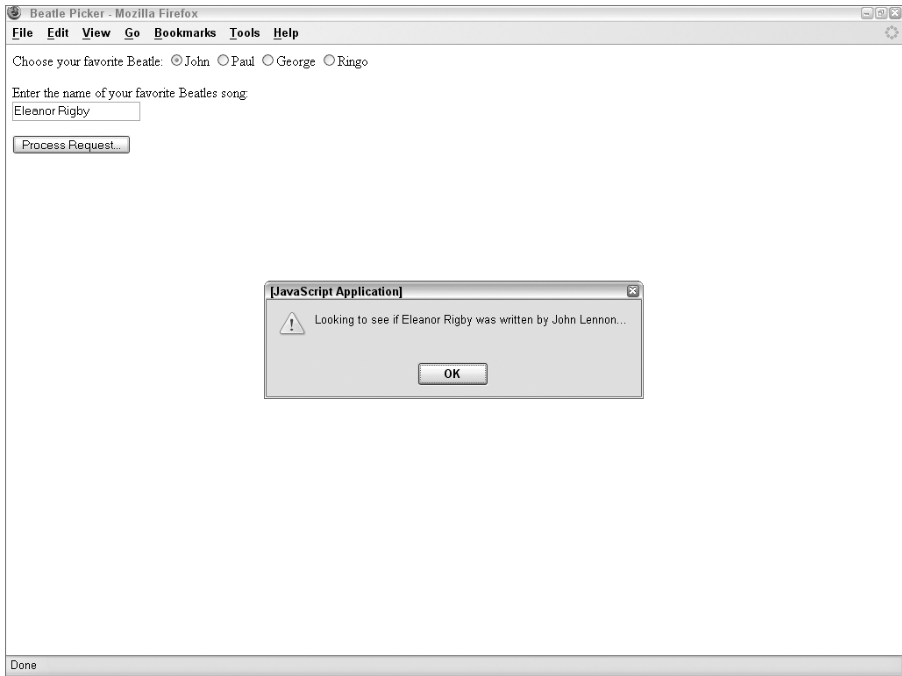
The `processData()` function, which needs to read and write properties of multiple form control elements, can reference the controls in two ways. One way is to have the `onclick` event handler (in the button element at the bottom of the document) call the `processData()` function, and not pass any parameters. Inside the function, all references to objects (such as the radio buttons or the song field) must be complete references, as in

```
document.forms[0].song.value
```

to retrieve the value entered into the `song` field.

FIGURE 34-1

Controls pass different object references to functions in Listing 34-1.



A more efficient way is to send a reference to the `form` object as a parameter with the call to the function (as shown in Listing 34-1). By specifying `this.form` as the parameter, you tell JavaScript to send along everything it knows about the form from which the function is called. This works because `form` is a property of every form control element; the property is a reference to the form that contains the control. Therefore, `this.form` passes the value of the `form` property of the control.

At the function, the reference to the `form` object is assigned to a variable name (arbitrarily set to `form` here) that appears in parentheses after the function name. We use the parameter variable name `form` here because it represents an entire form. But you can use any valid variable name you like.

The reference to the form contains everything the browser needs to know to find that form within the document. Any statements in the function can therefore use the parameter value in place of the longer, more cumbersome reference to the form. Thus, here we can use `form` to take the place of `document.forms[0]` or `document.forms["Beatles"]` in any address. To get the value of the `song` field, the reference is:

```
form.song.value
```

Had we assigned the `form` object to a parameter variable called `sylvester`, the reference would have been:

```
sylvester.song.value
```

When a function parameter is a reference to an object, statements in the function can retrieve or set properties of that object, as well as invoke the object's methods.

Another version of the `this` parameter-passing style simply uses the word `this` as the parameter. Unlike `this.form`, which passes a reference to the entire form connected to a particular element, `this` passes a reference only to that one element. In Listing 34-1, you can add an event handler to the `song` field to do some validation of the entry (to make sure that the entry appears in a database array of Beatles' songs created elsewhere in the document). Therefore, you want to send only the `field` object to the function for analysis:

```
<input type="text" name="song" id="song" onchange="checkSong(this)" />
```

You then have to create a function to catch this call:

```
function checkSong(songTitle)
{
   var enteredSong = songTitle.value;
   alert("Making sure that " + enteredSong + " was recorded by the Beatles.");
}
```

Within this function, you can go straight to the heart — the `value` property of the field element — without a long reference.

One further extension of this methodology passes only a single property of a form control element as a parameter. In the last example, the `checkSong()` function needs only the `value` property of the field, so the event handler can pass `this.value` as a parameter. Because `this` refers to the very object in which the event handler appears, the `this.propertyName` syntax enables you to extract and pass along a single property:

```
<input type="text" name="song" id="song" onchange="checkSong(this.value)" />
```

A benefit of this way of passing form element data is that the function doesn't have to do as much work:

```
function checkSong(songTitle)
{
   alert("Making sure that " + songTitle + " was recorded by the Beatles.");
}
```

Unlike passing object references (like the form and text field objects above), passing property value (for example, `this.value`) passes the value with no reference to the object from which it came. This suffices when the function just needs the value to do its job. However, if part of that job is to modify the object's property (for example, converting all text from a field to uppercase and redisplaying the converted text), the value passed to the function does not maintain a "live" connection with its object. To modify a property of the object that invokes an event handler

function, you need to pass some object reference so that the function knows where to go to work on the object.

Tip

Many programmers with experience in other languages expect parameters to be passed either by reference or by value, but not both ways. The rule of thumb in JavaScript, however, is fairly simple: object references are passed by reference; property values are passed by value. ■

Here are some guidelines to follow when deciding what kind of value to pass to an event handler function:

- Pass the entire form control object (`this`) when the function needs to make subsequent access to that same element (perhaps reading an object's `value` property, converting the value to all uppercase letters, and then writing the result back to the same object's `value` property).
- Pass only one property (`this.propertyName`) when the function needs read-only access to that property.
- Pass the entire `form` element object (`this.form`) for the function to access multiple elements inside a form (for example, a button click means that the function must retrieve a field's content). Remember, too, that control objects all have a `form` property, which is a reference to the containing `form` object. Therefore, if you pass only `this`, the function can still obtain the form reference.

Also be aware that you can submit multiple parameters (for example, `onclick="someFunction(this.form, this.name)"`) or even an entirely different object from the same form (for example, `onclick="someFunction(this.form.emailAddr.value)"`). Simply adjust your function's incoming parameters accordingly. (See Chapter 23 for more details about custom functions.)

Emailing forms

A common request among scripters is how to send a form via email to the page's author. This includes the occasional desire to send "secret" email to the author whenever someone visits the web site. Let us address the privacy issue first.

A site visitor's email address is valuable personal information that you should not retrieve without the visitor's permission or knowledge. Early browser versions employed various approaches to help safeguard email addresses. Some were more effective than others. Due to the unreliable nature and occasionally awkward user interface of mailing a form via the `mailto:` URL, we do not recommend its use.

Many ISPs that host web sites provide standard CGIs for forwarding forms to an email address of your choice. Search the Web for "formmail service" to locate third-party suppliers of this feature if you don't have access to server programming for yourself.

The remaining discussion about mailing forms focuses primarily on modern browsers and assumes that an ideally-configured email program is installed. You should be aware that mailing forms in the following ways is controversial in some web standards circles, since making an assumption about what the user has installed is somewhat of a leap of faith. Consequently, the W3C HTML specification does not endorse these techniques specifically. Use these facilities judiciously, and only after extensive testing on the client browsers you intend to support.

If you want to have forms submitted as email messages, you must attend to three `<form>` tag attributes. The first is the `method` attribute. You must set it to `post`. Next comes `enctype`. If you omit this attribute, the email client sends the form data as an attachment consisting of escaped name-value pairs, as in this example:

```
name=Danny+Goodman&rank=Scripter+First+Class&serialNumber=042
```

But, if you set the `enctype` attribute to text/plain, the form name-value pairs are placed in the body of the mail message in a more human-readable format:

```
name=Danny Goodman
rank=Scripter First Class
serialNumber=042
```

The last attribute of note is the `action` attribute, which is normally the spot to place a URL pointing to another file or server CGI. Substitute the URL with the special `mailto:` URL, followed by an optional parameter for the subject. Here is an example:

```
action="mailto:prez@whitehouse.gov?subject=Opinion%20Poll"
```

To sum up, the following example shows the complete `<form>` tag for emailing the form:

```
<form name="entry"
   method="post"
   enctype="text/plain"
   action="mailto:prez@whitehouse.gov?subject=Opinion Poll">
```

None of this requires any JavaScript at all. But seeing how you can use the attributes — and the fact that these attributes are exposed as properties of the `form` element object — you might see some extended possibilities for script control over forms.

Changing form attributes

All modern browsers expose `form` element attributes as modifiable properties. Therefore, you can change, say, the action of a form via a script in response to user interaction on your page. For example, you can have two different CGI programs invoked on your server depending on whether a form's check box is checked.

Tip

The best opportunity to change the properties of a `form` element object is in a function invoked by the form's `onsubmit` event handler. The modifications are performed at the last instant prior to actual submission, leaving no room for user-induced glitches to get in the way. ■

Buttons in forms

A common mistake that newcomers to scripting make is defining all clickable buttons as the submit type of `input` object (`<input type="submit">`). The Submit button does exactly what it says — it submits the form. If you don't set any `method` or `action` attributes of the `<form>` tag, the browser inserts its default values for you: `method="get"` and `action="pageURL"`. When you submit a form with these attributes, the page reloads itself and resets all field values to their initial values.

Use a Submit button only when you want the button to actually submit the form. If you want a button for other types of action, use the button style (`<input type="button">`). A regular button can invoke a function that performs some internal actions, and then invokes the `form` element object's `submit()` method to submit the form under script control.

Redirection after submission

Undoubtedly, you have submitted a form to a site and seen a "Thank You" page come back from the server to verify that your submission was accepted. This is warm and fuzzy, if not logical, feedback for the submission action. It is not surprising that you would want to re-create that effect, even if the submission is to a `mailto:` URL. Unfortunately, a problem gets in the way.

A common sense approach to the situation calls for a script to perform the submission (via the `form.submit()` method) and then navigate to another page that does the "Thank You." Here is such a scenario from inside a function triggered by clicking a link surrounding a nice, graphical Submit button:

```
function doSubmit()
{
   document.forms[0].submit();
   location.href = "thanks.html";
}
```

The problem is that when another statement executes immediately after the `form.submit()` method, the submission is canceled. In other words, the script does not wait for the submission to complete itself and verify to the browser that all is well (even though the browser appears to know how to track that information, given the status bar feedback during submission). The point is, because JavaScript does not provide an event that is triggered by a successful submission, there is no sure-fire way to display your own "Thank You" page.

Don't be tempted by the `window.setTimeout()` method to change the location after some number of milliseconds following the `form.submit()` method. You cannot predict how fast the network and/or server is for every visitor. If the submission does not complete before the timeout ends, the submission is still canceled — even if it is partially complete.

Form element arrays

Document object models provide a feature that is beneficial to a lot of scripters. If you create a series of like-named objects, they automatically become an array of objects accessible via array syntax (see Chapter 9). This is particularly helpful when you create forms with columns and rows of fields, such as in an order form. By assigning the same name to all fields in a column, you can employ `for` loops to cycle through each row, using the loop index as an array index.

As an example, the following code shows a typical function that calculates the total for an order form row (and calls another custom function to format the value):

```
function extendRows(form)
{
   for (var i = 0; i < Qty.length; i++)
   {
      var rowSum = form.Qty[i].value * form.Price[i].value;
      form.Total[i].value = formatNum(rowSum,2);
   }
}
```

All fields in the Qty column are named `Qty`. The item in the first row has an array index value of zero and is addressed as `form.Qty[i]`.

About <input> element objects

Whereas this chapter focuses strictly on the `form` element as a container of controls, the next three chapters discuss different types of controls that nest inside a form. Many of these controls share the same HTML tag: `<input>`. Only the `type` attribute of the `<input>` tag determines whether the browser shows you a clickable button, a check box, a text field, or other input field. The fact that one element has so many guises makes the system seem illogical at times.

An `input` element has some attributes (and corresponding scriptable object properties) that simply don't apply to every type of form control. For example, although the `maxLength` property of a text box makes perfect sense in limiting the number of characters that a user can type into it, the property has no bearing whatsoever on form controls that act as clickable buttons. Similarly, you can switch a radio button or check box on or off by adjusting the `checked` property; however, that property simply doesn't apply to a text box.

As the document object models have evolved, they have done so in an increasingly object-oriented way. The result in this form-oriented corner of the model is that all elements created via the `<input>` tag have a long list of characteristics that they all share by virtue of being types of `input` elements — they inherit the properties and methods that are defined for any `input` element. To try to limit the confusion, we divide the chapters in this book that deal

with `input` elements along functional lines (clickable buttons in one chapter, text fields in the other), and only list and discuss those `input` element properties and methods that apply to the specific control type.

In the meantime, this chapter continues with details of the `form` element object.

Properties

acceptCharset

Value: String — Read/Write

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `acceptCharset` property represents the `acceptcharset` attribute of the `form` element in HTML 4.0. The value is a list of one or more recognized character sets that the server receiving the form must support. For a list of registered character set names, see `http://www.iana.org/assignments/character-sets`.

Related Items: None

action

Value: URL string — Read/Write (see text)

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `action` property (along with the `method` and `target` properties) primarily functions for HTML authors whose pages communicate with server-based CGI scripts. This property is the same as the value you assign to the `action` attribute of a `<form>` tag. The value is typically a URL on the server where queries or postings are sent for submission.

User input may affect how you want your page to access a server. For example, a checked box in your document may set a form's `action` property so that a CGI script on one server handles all the input, whereas an unchecked box means the form data goes to a different CGI script, or a CGI script on an entirely different server. Or, one setting may direct the action to one `mailto:` address, whereas another setting sets the `action` property to a different `mailto:` address.

Although the specifications for all three related properties indicate that you can set them on the fly, such changes are ephemeral. A soft reload eradicates any settings you make to these properties, so you should make changes to these properties only in the same script function that submits the form (see `form.submit()` later in this chapter).

Related Items: `form.method`, `form.target`, `form.encoding` properties

autocomplete

Value: String — Read/Write

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Microsoft added a feature to forms, starting with WinIE5, that allows the browser to supply hints for filling out form controls, if the controls' names map to a set of single-line text controls

defined via some additional attributes linked to the vCard XML schema. For details on implementing this browser feature, see `http://msdn.microsoft.com/library/default.asp?url=/workshop/author/dhtml/reference/properties/autocomplete.asp`. Values for the `autoComplete` property are your choice of two strings: `on` or `off`. In either case, the `form` element object does not report knowing about this property unless you set the `autocomplete` attribute in the form's tag.

Related Items: None

elements[]

Value: Array of form control elements Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Elements include all the user interface elements defined for a form: text fields, buttons, radio buttons, check boxes, selection lists, and more. The `elements` property is an array of all form control items defined within the current form. For example, if a form defines three `<input>` items, the `elements` property for that form is an array consisting of three entries (one for each item in source code order). Each entry is a valid reference to that element; so, to extract properties or call methods for those elements, your script must dig deeper in the reference. Therefore, if the first element of a form is a text field, and you want to extract the string currently showing in the field (a text element's `value` property), the reference looks like this:

```
document.forms[0].elements[0].value
```

Notice that this reference summons two array-oriented properties along the way: one for the document's `forms` property and one for the form's `elements` property.

In practice, we suggest you refer to form controls (and forms) by their names (or IDs if you prefer to use `document.getElementById()`). This allows you the flexibility to move controls around the page as you fine-tune the design, without worrying about the source code order of the controls. The `elements` array comes in handy when you need to iterate through all of the controls within a form. If your script needs to loop through all elements of a form in search of particular kinds of elements, use the `type` property of every `form` control object to identify which kind of object it is. The `type` property consists of the same string used in the `type` attribute of an `<input>` tag.

Overall, we prefer to generate meaningful names for each form control element and use those names in references throughout our scripts. The `elements` array helps with form control names as well. Instead of a numeric index to the `elements` array, you can use the string name of the control element as the index. Thus, you can create a generic function that processes any number of form control elements, and simply pass the string name of the control as a parameter to the function. Then, use that parameter as the `elements` array index value. For example:

```
function putVal(controlName, val)
{
   document.forms[0].elements[controlName].value = val;
}
```

***formObject*.elements[]**

If you want to modify the number of controls within a form, you should use the element and/or node management facilities of the browser(s) of your choice. For example, in modern browsers you can assemble the HTML string for an entirely new set of form controls, and then assign that string to the `innerHTML` property of the `form` element object.

Note

As handy as it may be, in a strict W3C approach to JavaScript, you wouldn't use the `innerHTML` property, since it isn't officially part of the W3C standard. However, it is often too powerful a convenience property to ignore, as much of the code throughout this book is a testament. The book does show the W3C node manipulation alternative to `innerHTML` in some examples. Refer to Chapter 29 for a thorough explanation and examples of the W3C alternative to `innerHTML`. ■

The document in Listing 34-2 demonstrates a practical use of the `elements` property. A form contains four fields and some other elements mixed in between (see Figure 34-2). The first part of the function that acts on these items repeats through all the elements in the form to find out which ones are text box objects, and which text box objects are empty. Notice how we use the `type` property to separate text box objects from the rest, even when radio buttons appear amid the fields. If one field has nothing in it, we alert the user and use that same index value to place the insertion point in the field with the field's `focus()` method.

LISTING 34-2

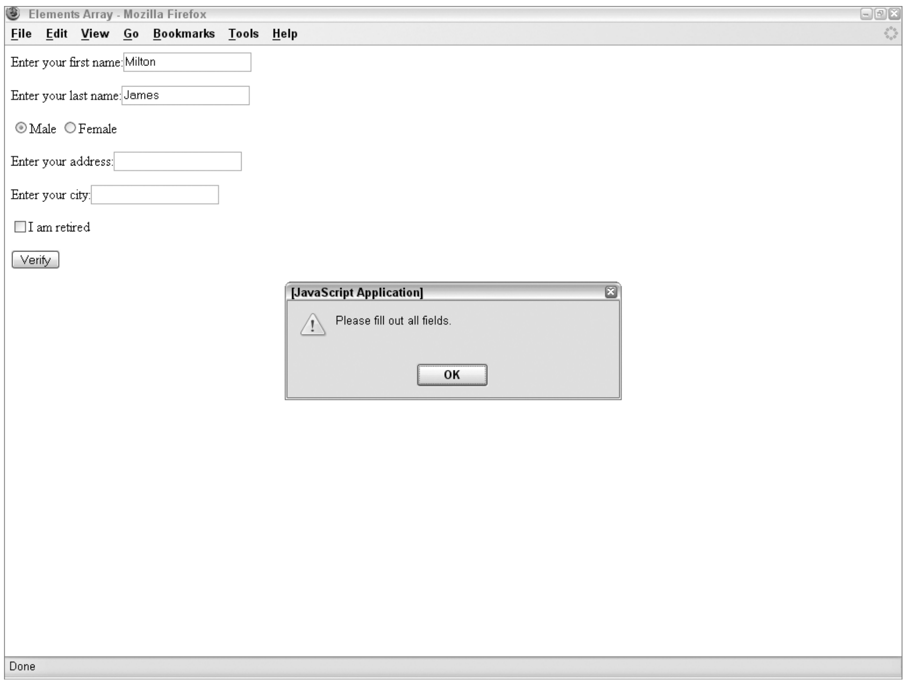
Using the form.elements Array

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Elements Array</title>
      <script type="text/javascript">
      function verifyIt()
      {
         var form = document.forms[0];
         for (i = 0; i < form.elements.length; i++)
         {
            if (form.elements[i].type == "text"
                && form.elements[i].value == "")
            {
               alert("Please fill out all fields.");
               form.elements[i].focus();
               break;
            }
            // more tests
         }
         // more statements
      }
      </script>
   </head>
   <body>
    <form>
```

```
        Enter your first name:<input type="text" name="firstName"
                                     id="firstName" />
        <p>Enter your last name:<input type="text" name="lastName"
                                       id="lastName" />
        </p>
        <p><input type="radio" name="gender" id="gender1" />Male
           <input type="radio" name="gender" id="gender2" />Female
        </p>
        <p>Enter your address:<input type="text" name="address" id="address"/></p>
        <p>Enter your city:<input type="text" name="city" id="city" /></p>
        <p><input type="checkbox" name="retired" id="retired" />I am
           retired
        </p>
      </form>
      <form>
         <input type="button" name="act" id="act" value="Verify"
                onclick="verifyIt()" />
       </form>
    </body>
</html>
```

FIGURE 34-2

The elements array helps find text fields for validation.



Related Items: `text`, `textarea`, `button`, `radio`, `checkbox`, `select` objects

encoding
enctype

Value: MIME type string Read/Write (see text)

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

You can define a form to alert a server when the data you submit is in a MIME type. The `encoding` property reflects the setting of the `enctype` attribute in the form definition. The `enctype` property name is defined for `form` element objects in the W3C DOM (with `encoding` removed), but NN6+ provides both properties for backward and forward compatibility.

For `mailto:` URLs, we recommend setting this value (in the tag or via script) to `"text/plain"` to have the form contents placed in the mail message body. If the definition does not have an `enctype` attribute, this property is an empty string.

Related Items: `form.action`, `form.method` properties

length

Value: Integer Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `length` property of a `form` element object provides the same information as the `length` property of the form's `elements` array. The property provides a convenient, if not entirely logical, shortcut to retrieving the number of controls in a form.

Related Items: `form.elements` property

method

Value: String (`get` or `post`) Read/Write (see text)

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

A form's `method` property is either the `get` or `post` value (not case-sensitive) assigned to the `method` attribute in a `<form>` definition. Terminology overlaps here a bit, so be careful to distinguish a form's method of transferring its data to a server from the object-oriented method (action or function) that all JavaScript forms have.

The `method` property is of primary importance to HTML documents that submit a form's data to a server-based CGI script, because it determines the format used to convey this information. For example, to submit a form to a `mailto:` URL, the `method` property must be `post`. Details of forms posting and CGI processing are beyond the scope of this book. Consult HTML or CGI documentation to determine which is the appropriate setting for this attribute in your web server environment. If a form does not have a `method` attribute explicitly defined for it, the default value is `get`.

Related Items: `form.action`, `form.target`, `form.encoding` properties

name

Value: Identifier string Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Assigning a name to a form via the `name` attribute is optional, but highly recommended when your scripts need to reference a form or its elements. This attribute's value is retrievable as the `name` property of a form. You don't have much need to read this property unless you inspect another source's document for its form construction, as in:

```
var formName = parent.frameName.document.forms[0].name;
```

Moreover, because server-side CGI programs frequently rely on the name of the form for validation purposes, it is unlikely that you will need to change this property.

target

Value: Identifier string Read/Write (see text)

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Whenever an HTML document submits a query to a server for processing, the server typically sends back an HTML page — whether it is a canned response or, more likely, a customized page based on the input provided by the user. You see this situation all the time when you perform a search on web sites. In a multiframe or multiwindow environment, you may want to keep the form part of this transaction in view for the user, but leave the responding page in a separate frame or window for viewing. The purpose of the `target` attribute of a `<form>` definition is to enable you to specify where the output from the server's query should be displayed.

The value of the `target` property is the name of the window or frame. For instance, if you define a frameset with three frames and assign the names `Frame1`, `Frame2`, and `Frame3` to them, you need to supply one of these names (as a quoted string) as the parameter of the `target` attribute of the `<form>` definition. Browsers also observe four special window names that you can use in the `<form>` definition: `_top`, `_parent`, `_self`, and `_blank`. To set the target as a separate subwindow opened via a script, use the window name from the `window.open()` method's second parameter, and not the window object reference that the method returns.

If you code your page to validate according to strict XHTML, you won't be able to include a `target` attribute for a form. But you can still use a script to assign a value to the property without interfering with the validation.

Related Items: `form.action`, `form.method`, `form.encoding` properties

Methods

reset()

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

***formObject*.reset()**

A common practice, especially with a long form, is to provide a button that enables the user to return all the form elements to their default settings. The standard Reset button (a separate object type described in Chapter 34) does that task just fine. But if you want to clear the form using script control, you must do so by invoking the `reset()` method for the form. More than likely, such a call is initiated from outside the form, perhaps from a function or graphical button. In such cases, make sure that the reference to the `reset()` method includes the complete reference to the form you want to reset — even if the page only has one form defined for it.

In Listing 34-3, we assign the act of resetting the form to the `href` attribute of a link object (that is attached to a graphic called `reset.jpg`). We use the `javascript:` URL to invoke the `reset()` method for the form directly (in other words, without doing it via a function). Note that the form's action in this example is to a nonexistent URL. If you click the Submit icon, you receive an "unable to locate" error from the browser.

LISTING 34-3

form.reset() and form.submit() Methods

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Registration Form</title>
   </head>
   <body>
    <form name="entries" method="post"
          action="http://www.u.edu/pub/cgi-bin/register">
      Enter your first name:<input type="text" name="firstName"
                             id="firstName" />
      <p>Enter your last name:<input type="text" name="lastName"
                               id="lastName" />
      </p>
      <p>Enter your address:<input type="text" name="address"
                             id="address" />
      </p>
      <p>Enter your city:<input type="text" name="city" id="city" /></p>
      <p><input type="radio" name="gender" id="gender1" checked="checked" />Male
         <input type="radio" name="gender" id="gender2" />Female
      </p>
      <p><input type="checkbox" name="retired" id="retired" />I am retired</p>
     </form>
     <p><a href="javascript:document.forms[0].submit()">
        <img alt="image" src="submit.jpg" height="25" width="100" border="0" />
      </a>
      <a href="javascript:document.forms[0].reset()">
        <img alt="image" src="reset.jpg" height="25" width="100" border="0" />
       </a>
    </p>
   </body>
</html>
```

Related Items: `onreset` event handler, `reset` object

submit()

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The most common way to send a form's data to a server's CGI program for processing is to have a user click a Submit button. The standard HTML Submit button is designed to send data from all named elements of a form according to the specifications listed in the `<form>` definition's attributes. But if you want to submit a form's data to a server automatically for the user, or you want to use a graphical button for submission, you can accomplish the submission with the `form.submit()` method.

Invoking this method is almost the same as a user clicking a form's Submit button (except that the `onsubmit` event handler is not triggered). Therefore, you may have an image on your page that is a graphical submission button. If that image is surrounded by a link object, you can capture a mouse click on that image, and trigger a function whose content includes a call to a form's `submit()` method (see Listing 34-3).

In a multiple-form HTML document, however, you must reference the proper form, either by name or according to its position in a `document.forms` array. Always make sure that the reference you specify in your script points to the desired form before you submit any data to a server.

As a security and privacy precaution for people visiting your site, JavaScript ignores all `submit()` methods whose associated form actions are set to a `mailto:` URL. Many web page designers would love to have secret email addresses captured from visitors. Because such a capture can be considered an invasion of privacy, that power has been disabled since early browser versions. You can, however, still use an explicit Submit button object to mail a form to yourself from the browser. (See the section "Emailing forms" earlier in this chapter.)

Because the `form.submit()` method does not trigger the form's `onsubmit` event handler, you must perform any presubmission processing and forms validation in the same script that ends with the `form.submit()` statement. You also do not want to interrupt the submission process after the script invokes the `form.submit()` method. Script statements inserted after one that invokes `form.submit()` — especially those that navigate to other pages or attempt a second submission — cause the first submission to cancel itself.

Related Item: `onsubmit` event handler

Event handlers

onreset

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Immediately before a Reset button returns a form to its default settings, JavaScript sends a `reset` event to the form. By including an `onreset` event handler in the form definition, you can trap that event before the reset takes place.

A friendly way of using this feature is to provide a safety net for a user who accidentally clicks the Reset button after filling out a form. The event handler can run a function that asks the user to confirm the action.

The `onreset` event handler must evaluate to `return true` for the event to continue to the browser. This may remind you of the way `onmouseover` and `onmouseout` event handlers work for links and image areas. This requirement is far more useful here because your function can control whether the reset operation ultimately proceeds to conclusion.

Listing 34-4 demonstrates one way to prevent accidental form resets or submissions. Using standard Reset and Submit buttons as interface elements, the `<form>` object definition includes both event handlers. Each event handler calls its own function that offers a choice for users. Notice how each event handler includes the word `return` and takes advantage of the Boolean values that come back from the `confirm()` method dialog boxes in both functions.

LISTING 34-4

The Onreset and Onsubmit Event Handlers

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Submit and Reset Confirmation</title>
      <script type="text/javascript">
         function allowReset()
         {
            return window.confirm("Go ahead and clear the form?");
         }
         function allowSend()
         {
            return window.confirm("Go ahead and mail this info?");
         }
      </script>
   </head>
   <body>
     <form method="post" enctype="text/plain"
           action="mailto:trash4@dannyg.com" onreset="return allowReset()"
           onsubmit="return allowSend()">
      Enter your first name:<input type="text" name="firstName"
                                 id="firstName" />
      <p>Enter your last name:<input type="text" name="lastName"
                                   id="lastName" />
      </p>
      <p>Enter your address:<input type="text" name="address"
                                 id="address" />
      </p>
      <p>Enter your city:<input type="text" name="city" id="city" /></p>
      <p><input type="radio" name="gender" id="gender1" checked="checked" />Male
```

```
        <input type="radio" name="gender" id="gender2" />Female
      </p>
      <p><input type="checkbox" name="retired" id="retired" />I am retired</p>
      <p><input type="reset" /> <input type="submit" /></p>
    </form>
  </body>
</html>
```

onsubmit

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

No matter how a form's data is actually submitted (by a user clicking a Submit button or by a script invoking the `form.submit()` method), you may want your JavaScript-enabled HTML document to perform some data validation on the user input, especially with text fields, before the submission heads for the server. You have the option of doing such validation while the user enters data (see Chapter 46 on the CD-ROM), or in batch mode before sending the data to the server (or both). The place to trigger this last-ditch data validation is the form's `onsubmit` event handler. Note, however, that this event fires only from a genuine Submit type `<input>` element, and not from the form's `submit()` method.

When you define an `onsubmit` event handler as an attribute of a `<form>` definition, JavaScript sends the `submit` event to the form just before it dashes off the data to the server. Therefore, any script or function that is the parameter of the `onsubmit` attribute executes before the data is actually submitted. Note that this event handler fires only in response to a genuine Submit-style button, and not from a `form.submit()` method.

Any code executed for the `onsubmit` event handler must evaluate to an expression consisting of the word `return`, plus a Boolean value. If the Boolean value is `true`, the submission executes as usual; if the value is `false`, no submission is made. Therefore, if your script performs some validation prior to submitting data, make sure that the event handler calls that validation function as part of a return statement (as shown in Listing 34-4).

Even after your `onsubmit` event handler traps a submission, JavaScript's security mechanism can present additional alerts to the user, depending on the server location of the HTML document and the destination of the submission.

fieldset and legend Element Objects

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
`align`		
`form`		

Syntax

Accessing `fieldset` or `legend` element object properties or methods:

```
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)  [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About these objects

The `fieldset` and `legend` elements go hand in hand to provide some visual context to a series of form controls within a form. Browsers that implement the `fieldset` element draw a rectangle around the document space occupied by the form controls nested inside the `fieldset` element. The rectangle renders the full width of the body, unless its width is controlled by appropriate stylesheet properties (for example, `width`). To that rectangle is added a text label that is assigned via the `legend` element nested inside the `fieldset` element. None of this HTML-controlled grouping is necessary if you design a page layout that already provides graphical elements to group the form controls together.

Nesting the elements properly is essential to obtaining the desired browser rendering. A typical HTML sequence looks like the following:

```
<form>
  <fieldset>
    <legend>Legend Text</legend>
    All your form controls and their labels go here.
  </fieldset>
</form>
```

You can have more than one `fieldset` element inside a form. Each set has a rectangle drawn around it. This can help organize a long form into more easily digestible blocks of controls for users — yet the single form retains its integrity for submission to the server.

A `fieldset` element acts like any HTML container with respect to stylesheets and the inheritance thereof. For example, if you set the `color` style property of a `fieldset` element, the color affects the text of elements nested within; however, the color of the border drawn by the browser is unaffected. Assigning a color to the `fieldset` style's `border-color` property colors just the border and not the textual content of nested elements.

Note that the content of the `legend` element can be any HTML. Alternatively, you can assign a distinctive stylesheet rule to the `legend` element. If your scripts need to modify the text of the legend, you can accomplish this in modern browsers with the `nodeValue` properties of HTML element objects.

Only two element-specific properties are assigned to this object pair. The first is the `align` property of the `legend` object. This property matches the capabilities of the `align` attribute for the element as specified in the HTML 4.0 recommendation (albeit the property is deprecated in favor

of stylesheet rules). MacIE5+ and WinIE5.5+ enable you to adjust this property on the fly (generally between your choices of “right” and “left”) to alter the location of the legend at the top of the fieldset rectangle.

Because these elements are children of a `form` element, it makes sense that the DOM Level 2 specification supplies the read-only `form` property to both of these objects. That property returns a reference to the `form` element object that encloses either element. The `form` property for the `fieldset` and `legend` objects is implemented in modern browsers.

label Element Object

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
`form`		
`htmlFor`		

Syntax

Accessing `label` element object properties or methods:

```
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)  [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

With the push in the HTML 4.0 specification to provide context-oriented tags for just about every bit of content on the page, the W3C HTML working group filled a gap with respect to text that usually hangs in front of, or immediately after, `input`, `select`, and `textarea` form control elements. You use these text chunks as labels for the items to describe the purpose of the control. The only `input` element that had an attribute for its label was the button input type. But even the newer `button` element did away with that.

A `label` element enables you to surround a control’s label text with a contextual tag. In addition, one of the element’s attributes — `for` — enables you to associate the label with a particular form control element. In the HTML, the `for` attribute is assigned the ID of the control with which the label is associated. A `label` element can be associated with a form control if the form control’s tag is contained between the `label` element’s start and end tags.

At first glance, browsers do nothing special (from a rendering point of view) for a `label` element. But for some kinds of elements, especially check box and radio input type elements,

browsers help restore to users a vital user-interface convention: clicking the label is the same as clicking the control. For text elements, focus events are passed to the text input element associated with the label. In fact, all events that are directed at a label bubble upward to the form control associated with it. The following page fragment demonstrates how `fieldset`, `legend`, and `label` elements look in a form consisting of two radio buttons:

```
<form ...>
   <fieldset id="form1set1">
      <legend id="form1set1legend">Choose the Desired Performance</legend>
      <input type="radio" name="speed" id="speed1" />
         <label for="speed1">Fastest (lower quality)</label><br />
      <input type="radio" name="speed" id="speed2" />
         <label for="speed2">Slower (best quality)</label>
   </fieldset>
</form>
```

Even so, a `label` and its associated form control element do not have to be adjacent to each other in the source code. For example, you can have a label in one cell of a table row, with the form control in another cell (in the same or different row).

Properties

htmlFor

Value: Element object reference — Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `htmlFor` property is the scripted equivalent of the `for` attribute of the `label` element. An acceptable value is a full reference to a form control element (`input`, `textarea`, or `select` element objects). It is highly unlikely that you would modify this property for an existing `label` element. However, if your script is creating a new `label` element (perhaps a replacement form), use this property to associate the label with a form control.

Scripting and Web Forms 2.0

Standard HTML forms have been with us for some time, which means it shouldn't necessarily come as a surprise that there is an effort to revamp the handling of forms on the Web. Although there are several form technologies vying for the limelight, Web Forms 2.0 is the one with the most momentum, at least for now.

It's difficult to mention Web Forms 2.0 without also mentioning XForms, which is in many ways a competing form technology. Unlike Web Forms 2.0, which is based on traditional HTML code and scripting, XForms relies on a specialized XML syntax to describe form components. This doesn't necessarily make either technology better or worse than the other, except for the fact that Web Forms 2.0 is already supported by a production web browser (Opera 9). And, as history has shown, early adoption is one of the best ways for an emerging technology to take hold.

Speaking of browsers and forms, it's worth noting that Microsoft doesn't appear to be very eager to back either Web Forms 2.0 or XForms. They have their own XML-based form technology known as XAML that has ties to the next generation Windows operating system. The Mozilla Foundation was involved in developing the Web Forms 2.0 specification and has stated a commitment to supporting it natively in the Gecko browser engine that forms the core of Mozilla-based browsers. The same goes for Apple and its desire to support Web Forms 2.0 in its Safari browser. So, expect to see much broader support for Web Forms 2.0 in the very near future, and in the meantime there are plug-ins available for several major browsers.

What Is Web Forms 2.0?

Like HTML and JavaScript, Web Forms 2.0 is a specification that describes how a technology is supposed to work. In this case, the specification describes a set of rich user interface components that carry out common information gathering tasks such as allowing the user to select a date or enter text. Traditional HTML supports such tasks via forms as well, but those forms are fairly limited and require a decent amount of scripting in order to provide any significant degree of user friendliness. Thanks to modern user interface design, web users have come to expect form validation, an auto-completion feature for frequently-entered text, and visual user interfaces for common data entry tasks such as the selection of a date.

Web Forms 2.0 addresses the limitations of HTML forms by offering advanced form validation without scripting: auto-completion, careful control over the input focus, and a host of new form control types, such as specialized date/time and URL input controls, among others. You can begin using Web Forms 2.0 right away in the Opera browser (as of version 9); there are browser add-ons that support it in other major browsers.

Web Forms 2.0 and JavaScript

Scripting's role in Web Forms 2.0 is primarily that of a programmatic equivalent to operations and behaviors that are built into any browser that supports the standard. For example, Web Forms 2.0 includes a facility known as *repetition blocks*, whereby a form can grow or shrink as needed, such as a tabular order form whose rows of input elements grow as the user adds new items to the order. The Web Forms mechanism takes care of adding repeated rows of form controls and assigning names to elements indicating row numbers (there is a special button type whose tag attributes link it to the template that is repeated). The DOM interface provided with Web Forms allows script access to adding and subtracting rows if the page design requires it.

If it sounds as though Web Forms 2.0 is trying to displace JavaScript, in a way that's true. The purpose is to rely less on scripting for form validation and other Dynamic HTML surrounding forms, offering page authors a more standardized way of handling these common tasks. But the creators of Web Forms 2.0 also know that scripters will want to get their hands on the new forms "stuff," and they therefore provide ample script access.

For more information about Web Forms 2.0, visit `http://www.whatwg.org/specs/web-forms/current-work`. Web Forms 2.0 has recently been subsumed by the ongoing HTML5 working draft. This link will give you more information: `http://www.whatwg.org/specs/web-apps/current-work/multipage/`.

CHAPTER

Button Objects

IN THIS CHAPTER

Triggering action from a user's click of a button

Assigning hidden values to radio and checkbox buttons

Distinguishing between radio button families and their individual buttons

This chapter is devoted to those lovable buttons that invite users to initiate action and make choices with a single click of the mouse. In this category fall the standard system-looking buttons with labels on them, as well as radio buttons and checkboxes. For such workhorses of the HTML form, these objects have a limited vocabulary of object-specific properties, methods, and event handlers.

We group together the button, submit, and reset objects for an important reason: They look alike, yet they are intended for very different purposes. Knowing when to use which button is important — especially in choosing between the button and submit objects. Many a newcomer get the two confused and wind up with scripting error headaches. That confusion won't be an issue for you by the time you finish this chapter.

The button Element Object, and the Button, Submit, and Reset Input Objects

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects".

Properties	Methods	Event Handlers
form	click()	onclick
name		onmousedown
type		onmouseup
value		

Syntax

Accessing button object properties or methods:

```
(All)       [window.]document.formName.buttonName.property |
            method([parameters])
(All)       [window.]document.formName.elements[index].property |
            method([parameters])
(All)       [window.]document.forms[index].buttonName.property |
            method([parameters])
(All)       [window.]document.forms["formName"].buttonName.property |
            method([parameters])
(All)       [window.]document.forms["formName"].elements[index].property |
            method([parameters])
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)  [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About these objects

Button objects generate standard, pushbutton-style user interface elements on the page, depending on the operating system on which the particular browser runs. In the early days, the browsers called upon the operating systems to generate these standard interface elements. In more recent versions, the browsers define their own look, albeit frequently still different for each operating system. More recently, the appearance of a button may also be influenced by browser-specific customizations that manufacturers put into their products. Even so, any computer user will recognize a button when the browser produces it on the page.

There are two ways to put standard buttons into a page. The first, and completely backward-compatible way, is to use `input` elements nested inside a `form` container. The modern approach involves the `button` HTML element, which provides a slightly different way of specifying a button in a page, including the option of putting a button outside of a `form` (presumably for some client-side script execution, independent of form submission). From an

HTML point of view, the difference between the two concerns itself with the way the label of the button is specified. With an `input` element, the string assigned to the `value` attribute becomes the label of the button; but a `button` element is a container (meaning it has an end tag), whose content becomes the button's label. You can still assign a value to the `value` attribute, which, if a form contains the button, gets submitted to the server, independent of the label text.

Always give careful thought to the label that you assign to a button. Because a button initiates some action, make sure that the verb in the label clearly defines what happens after you click it. Also, take cues from experienced user interface designers who craft operating system and commercial software buttons: be concise. If you find your button labels going longer than two or three words, reconsider the design of your page so that the user can clearly understand the purpose of any button from a shorter label.

Browsers automatically display a button sized to accommodate the label text. But only modern browsers (IE4+/Moz+/W3C) allow you to control more visual aspects of the button, such as size, label font, and coloration. As for the position on the page, buttons, like all in-line elements, appear where they occur in the source code. You can, of course, use element positioning (see Chapter 43, "Positioned Objects," on the CD-ROM) to make a button appear wherever you want it. But if your pages run on multiple operating systems and generations of browsers, be aware that the appearance (and size) of a button will not be identical on all screens. Check out the results on as many platforms as possible.

Buttons in the Windows environment follow normal behavior, in that they indicate the focus with highlighted button-label text (usually with a dotted rectangle). Some newer browsers running on other operating systems offer this kind of highlighting and selection as a user option. IE5+ provides additional `input` element features that prevent buttons from receiving this kind of visible focus.

The lone `button` object event handler that works on all browser versions is one that responds to a user clicking the pointer on the button: the `onclick` event handler. Virtually all action surrounding a `button` object comes from this event handler. You rarely need to extract property values or invoke the `click()` method. Modern browsers include support for the individual component events of a click: `mousedown` and `mouseup`; there's also a plethora of user-initiated events for buttons that you can use.

Two special variants of the `button` input object are the *submit* and *reset* input objects. With heritages going back to early incarnations of HTML, these two button types perform special operations on their own. The submit-style button automatically sends the data within the same form object to the URL listed in the `action` attribute of the `<form>` definition. The `method` attribute dictates the format in which the button sends the data. Therefore, you don't have to script this action if your HTML page is communicating with a program (often a CGI script) on the server.

If the form's `action` attribute is set to a `mailto:` URL, you must provide the page visitor with a Submit button to carry out the action. Setting the form's `enctype` attribute to `text/plain` is also helpful so that the form data arrives in a more readable form than the normal encoded name-value pairs. See Chapter 33, "Form and Related Objects," for details about submitting form content via email.

The partner of the Submit button is the Reset button. This button, too, has special powers. A click of this button type restores all elements within the form to their default values. That goes for text objects, radio button groups, checkboxes, and selection lists. The most common application of the button is clearing entry fields of any data entered by the user.

All that distinguishes these three types of buttons from each other in the `<input>` tag or `<button>` tag is the parameter of the `type` attribute. For buttons not intended to send data to a server, use the "button" style (this is the default value for the `button` element). You should reserve "submit" and "reset" for when you need their special powers.

If you want an image to behave like a button in all scriptable browsers, consider either associating a link with an image (see the discussion on the link object in Chapter 31, "Link and Anchor Objects") or creating a client-side image map (see the `area` object discussion in Chapter 32, "Image, Area, Map, and Canvas Objects"). An even better idea that applies solely to modern browsers is to use the `input` element with a `type` attribute set to `image` (discussed later in this chapter).

Probably the biggest mistake scripters make with these buttons is using a Submit button to do the work of a plain button. Because these two buttons look alike, and the submit type of input element has a longer tradition than the plain button, confusing the two is easy. But if all you want is to display a button that initiates client-side script execution, use a plain button. The Submit button attempts to submit the form. If no `action` attribute is set, then the page reloads, and all previous processing and field entries are erased. The plain button does its job quietly without reloading the page (unless the script it triggers intentionally does so).

Properties

`form`

Value: Form object reference Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

A property of every `input` element object is a reference to the `form` element that contains the control. This property can be very convenient in a script when you are dealing with one form control that is passed as a parameter to the function, and you want to either access another control in the same form or invoke a method of the form. An event handler of any `input` element can pass `this` as the parameter, and the function can still get access to the form without having to hard-wire the script to a particular form name or document layout.

Related Items: `form` object

`name`

Value: Identifier string Read/Write (see text)

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

A button's name is fixed in the `input` or `button` element's `name` attribute and can be adjusted via scripting in modern browsers. You may need to retrieve this property in a general-purpose

function handler called by multiple buttons in a document. The function can test for a button name and perform the necessary statements for that button:

```
if (button.name == "Calculate")
{
   // Perform calculation
}
```

If you change the name of the object, even a soft reload or window resize restores its original name.

Related Items: `name` property of all `form` elements

type

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The precise value of the `type` property echoes the setting of the `type` attribute of the `<input>` or `<button>` tag that defines the object: `button`, `submit`, or `reset`.

value

Value: String Read/Write (see text)

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Both `input` and `button` elements have the `value` attribute, which is represented by the `value` property in the object model. But the purpose of the attribute/property in the two elements differs. For the `input` element, the `value` property represents the label displayed on the button. For a `button` element, however, the label text is created by the HTML text between the element's start and end tags. When the `input` element has a `name` value associated with it, the name-value pair is submitted along with the form.

If you do not assign a `value` attribute to a reset or submit style button, browsers automatically assign the labels `Reset` and `Submit` without assigning a value. A value property can be any string, including multiple words.

You can modify this text on the fly in a script. Modern browsers are smart enough to resize the button and reflow the page to meet the new space needs; the new label survives a window resizing, but not a soft reload of the page.

Related Items: `value` property of text object

Methods

click()

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

A button's `click()` method simulates, via scripting, the human action of clicking that button, triggering a `click` event.

Related Items: `onclick` event handler

Event handlers

onclick

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Virtually all button action takes place in response to the `onclick` event handler. A *click* is defined as a press and release of the mouse button while the screen pointer rests on the button. The event goes to the button only after the user releases the mouse button.

For a Submit button, you should probably omit the `onclick` event handler and allow the form's `onsubmit` event handler to take care of last-minute data entry validation before sending the form. By triggering validation with the `onsubmit` event handler, your scripts can cancel the submission if something is not right (see the `form` object discussion in Chapter 33).

Listing 35-1 demonstrates not only the `onclick` event handler of a button, but also how you may need to extract a particular button's `name` or `value` properties from a general-purpose function that services multiple buttons. In this case, each button passes its own object as a parameter to the `displayTeam()` function. The function then displays the results in an alert dialog box. A real-world application would probably perform more sophisticated actions based on the button clicked.

LISTING 35-1

Three Buttons Sharing One Function

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Button Click</title>
      <script type="text/javascript">
      function displayTeam(btn)
      {
         switch (btn.value)
         {
            case "Starsky":
               alert("Starsky & Hutch");
               break;
            case "Tango":
               alert("Tango & Cash");
               break;
            case "Turner":
               alert("Turner & Hooch");
               break;
```

continued

LISTING 35-1 *(continued)*

```
         }
      }
      </script>
   </head>
   <body>
      Click on your favorite half of a popular crime fighting team:
      <form>
         <input type="button" value="Starsky" onclick="displayTeam(this)" />
         <input type="button" value="Tango" onclick="displayTeam(this)" />
         <input type="button" value="Turner" onclick="displayTeam(this)" />
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique used in the previous example and throughout the chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 37, "Event Objects." Several other chapters use the modern technique extensively. ■

Related Items: `button.onmousedown`, `button.onmouseup`, `form.onsubmit` event handlers

onmousedown
onmouseup

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

Modern browsers have event handlers for the components of a `click` event: the `onmousedown` and `onmouseup` event handlers. These events fire in addition to the `onclick` event handler.

The system-level buttons provided by the operating system perform their change of appearance while a button is being pressed. Therefore, trapping for the components of a click action won't help you in changing the button's appearance via scripting. Remember that a user can roll the cursor off the button while the button is still down. When the cursor leaves the region of the button, the button's appearance returns to its unpressed look, but any setting you make with the `onmousedown` event handler won't undo itself with an `onmouseup` counterpart, even after the user releases the mouse button elsewhere. On the other hand, you can use these events to fire pre-cached click-on and click-off sounds in response to the respective mouse button actions.

(All)        [window.]document.forms["formName"].boxName.property |
             method([parameters])
(All)        [window.]document.forms["formName"].elements[index].property |
             method([parameters])
(IE4+)       [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)   [window.]document.getElementById("elemID").property |
             method([parameters])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

About this object

Checkboxes have a very specific purpose in modern graphical user interfaces: to toggle between "on" and "off" settings. As with a checkbox on a printed form, a mark in the box indicates that the label text is true, or should be included for the individual who made that mark. When the box is unchecked or empty, the text is false or should not be included. If two or more check-boxes are physically grouped together, they should have no interaction: Each is an independent setting (see the discussion on the radio object for interrelated buttons).

We make these user-interface points at the outset because, in order to present a user interface in your HTML pages consistent with the user's expectations based on exposure to other programs,

you must use checkbox objects only for on/off choices that the user makes. Using a checkbox as an action button that, for example, navigates to another URL, is not good form. Just as they do in a Windows or Mac dialog box, users make settings with checkboxes and radio buttons, and initiate action by clicking a standard button or image map.

That's not to say that a checkbox object cannot perform some limited action in response to a user's click, but such actions are typically related to the context of the checkbox button's label text. For example, in some Windows and Macintosh dialog boxes, turning on a checkbox may activate a bunch of otherwise inactive settings elsewhere in the same dialog box. Modern browsers allow disabling (dimming) or hiding of form elements, so a checkbox may control those visible attributes of related controls. Or, in a two-frame window, a checkbox in one frame may control whether the viewer is an advanced user. If so, the content in the other frame may be more detailed. Toggling the checkbox changes the complexity level of a document showing in the other frame (using different URLs for each level). The bottom line, then, is that you should use checkboxes for toggling between on/off settings. Provide regular buttons for users to initiate processing.

In the `<input>` tag for a checkbox, you can preset the checkbox to be checked when the page appears by adding the constant `checked` attribute to the definition. If you omit this attribute, the button takes on its default, unchecked appearance. As for the checkbox label text, its definition lies outside the `<input>` tag, usually as text that appears next to the tag. If you look at the way checkboxes behave in HTML browsers, this location makes sense: The label is not an active part of the checkbox (as it typically is in Windows and Macintosh user interfaces, where clicking the label is the same as clicking the box).

Naming a checkbox can be an important part of the object definition, depending on how you plan to use the information in your script or document. For forms whose content goes to a program running on the server, you must word the box name as needed for use by the server program so that the program can parse the form data and extract the setting of the checkbox. For JavaScript client-side use, you can assign not only a name that describes the button, but also a value useful to your script for making `if...else` decisions, or for assembling strings that are eventually displayed in a window or frame.

Properties

checked

Value: Boolean Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The simplest property of a checkbox reveals (or lets you set) whether or not a checkbox is checked. The value is `true` for a checked box and `false` for an unchecked box. To check a box via a script, simply assign `true` to the checkbox's `checked` property:

```
document.forms[0].boxName.checked = true;
```

Setting the `checked` property from a script does not trigger a `click` event for the checkbox object. So, the `onclick` event handler won't get called in response to a checkbox being checked via the `checked` property.

You may need an instance in which one checkbox automatically checks or unchecks another checkbox elsewhere in the same form (or in another form) of the document. To accomplish this task, create an `onclick` event handler for the one checkbox and build a statement, similar to the preceding one, to set the other related checkbox to `true`. Don't get too carried away with this feature, however: For a group of interrelated, mutually exclusive choices, use a group of radio buttons instead.

If your page design requires that a checkbox be checked after the page loads, don't bother trying to script this checking action. Simply add the one-word `checked` attribute to the `<input>` tag. Because the `checked` property is a Boolean value, you can use its results as an argument for an `if` clause, as shown in the next example.

The simple example in Listing 35-2 passes a form object reference to the JavaScript function. The function, in turn, reads the `checked` value of the form's checkbox object (`checkThis.checked`) and uses its Boolean value as the test result for the `if...else` construction.

LISTING 35-2

The checked Property as a Conditional

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Checkbox Inspector</title>
      <script type="text/javascript">
         function inspectBox(form)
         {
            if (form.checkThis.checked)
            {
               alert("The box is checked.");
            }
            else
            {
               alert("The box is not checked at the moment.");
            }
         }
      </script>
   </head>
   <body>
      <form>
         <input type="checkbox" name="checkThis" />Check here
         <p><input type="button" name="boxChecker" value="Inspect Box"
                  onclick="inspectBox(this.form)" />
         </p>
      </form>
   </body>
</html>
```

Related Items: `defaultChecked`, `value` properties

defaultChecked

Value: Boolean Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Sometimes you may find it beneficial to know if the initial setting of a checkbox has changed. The `checked` property alone can't tell you this because it reflects only the current state of a checkbox. Another property, `defaultChecked`, keeps up with the initial state of a checkbox.

If you add the `checked` attribute to the `<input>` definition for a checkbox, the `defaultChecked` property for that object is `true`; otherwise, the property is `false`. Having access to this property enables your scripts to examine checkboxes to see if they have been adjusted (presumably by the user, if your script does not set properties).

The following function is designed to compare the current setting of a checkbox against its default value:

```
function compareBrowser(thisBox)
{
   if (thisBox.checked != thisBox.defaultChecked)
   {
      // statements about using a different set of HTML pages
   }
}
```

The `if` construction compares the current status of the box against its default status. Both are Boolean values, so they can be compared against each other. If the current and default settings don't match, the function goes on to handle the case in which the current setting is other than the default.

Related Items: `checked`, `value` properties

type

Value: String (`checkbox`) Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Use the `type` property to help you identify a checkbox object from an unknown group of form elements. Just look for the string `checkbox` as the type of a form element to determine if it is indeed a checkbox.

Related Items: `form.elements` property

value

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

A checkbox object's `value` property is a string of any text that you want to associate with the box. Note that the checkbox's `value` property is not the label, as it is for a regular button, but hidden text associated with the checkbox. For instance, the label that you attach to a checkbox may not be worded in a way that is useful to your script. But if you place useful wording in the `value` attribute of the checkbox tag, you can extract that string via the `value` property.

When a checkbox object's data is submitted to a CGI program, the `value` property is sent as part of the name-value pair if the box is checked (nothing about the checkbox is sent if the box is unchecked). If you omit the `value` attribute in your definition, the property always yields the string "on," which is submitted to a CGI program when the box is checked. From the JavaScript side, don't confuse this string with the on and off settings of the checkbox: Use the `checked` property to determine a checkbox's status.

The scenario for the skeleton HTML page in Listing 35-3 is a form with a checkbox whose selection determines which of two actions to follow for submission to the server. After the user clicks the Submit button, a JavaScript function examines the checkbox's `checked` property. If the property is `true` (the button is checked), the script sets the `action` property for the entire form to the content of the value property — thus influencing where the form goes on the server side. If you try this listing on your computer, the result you see varies widely with the browser version you use. For most browsers, you see some indication (an error alert or other screen notation) that a file with the name `primaryURL` or `alternateURL` doesn't exist. The names and the error message come from the submission process for this demonstration.

LISTING 35-3

Adjusting a Server Submission Action

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Checkbox Submission</title>
      <script type="text/javascript">
         function setAction(form)
         {
            if (form.checkThis.checked)
            {
               form.action = form.checkThis.value;
            }
            else
            {
               form.action = "file://primaryURL";
            }
            return true;
         }
      </script>
   </head>
   <body>
      <form method="POST" action="">
         <input type="checkbox" name="checkThis"
```

continued

LISTING 35-3 *(continued)*

```
            value="file://alternateURL" />Use alternate
        <p><input type="submit" name="boxChecker"
            onclick="return setAction(this.form)" /></p>
      </form>
   </body>
</html>
```

Related Items: `checked` property

Methods

`click()`

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The intention of the `click()` method is to enact, via script, the physical act of clicking a checkbox (but without triggering the `onclick` event handler). However, your scripts are better served by setting the `checked` property so that you know exactly what the setting of the box is at any time.

Related Items: `checked` property; `onclick` event handler

Event handlers

`onclick`

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Because users regularly click checkboxes, the objects have an event handler for the `click` event. Use this event handler only if you want your page (or variable values hidden from view) to respond in some way to the action of clicking a checkbox. Most user actions, as mentioned earlier, are initiated by clicking standard buttons rather than checkboxes, so be careful not to overuse event handlers in checkboxes.

The page in Listing 35-4 shows how to trap the click event in one checkbox to influence the visibility and display of other form controls. After you turn on the Monitor checkbox, a list of radio buttons for monitor sizes appears. Similarly, engaging the Communications checkbox makes two radio buttons visible. Your choice of radio button brings up one of two further choices within the same table cell (see Figure 35-1).

Notice how the `toggle()` function was written as a generalizable function. This function can accept a reference to any checkbox object and any related span. If five more groups like this were added to the table, no additional functions would be needed.

In the `swap()` function, a nested `if...else` shortcut construction is used to convert the Boolean values of the `checked` property to the strings needed for the `display` style property.

The nesting is used to allow a single statement to take care of two conditions: the group of buttons to be controlled and the `checked` property of the button invoking the function. This function is not generalizable, because it contains explicit references to objects in the document. The `swap()` function can be made generalizable, but due to the special relationships between pairs of span elements (one has to be hidden while the other is displayed in its place), the function would require more parameters to fill in the blanks where explicit references are needed.

FIGURE 35-1

Clicking each checkbox reveals additional relevant choices.

About this object

A radio button is an unusual object within the body of JavaScript applications. In every other case of form control elements, one object equals one visual element on the screen. But a radio object actually consists of a group of radio buttons. Because of the nature of radio buttons — a mutually exclusive choice among two or more selections — a group always has multiple visual elements. All buttons in the group share the same name — which is how the browser knows to group buttons together and to let the clicking of a button deselect any other selected button within the group. Beyond that, however, each button can have unique properties, such as `value` or `checked` properties.

Use JavaScript array syntax to access information about an individual button within the button group. Look at the following example of defining a button group, and see how to reference each button. This button group lets the user select an image size from a group of standard sizes, which includes as the value the number of megapixels used by that size:

```
<form>
   <b>Select your desired image size:</b><br />
   <input type="radio" name="sizes" value="0.073" checked="checked" />320x240
   <input type="radio" name="sizes" value="0.293" />640x480
   <input type="radio" name="sizes" value="0.75" />1024x768
   <input type="radio" name="sizes" value="1.25" />1280x1024
</form>
```

After this group displays on the page, the first radio button is preselected for the user. Only one property of a radio button object (`length`) applies to all members of the group. However, the other properties apply to individual buttons within the group. To access any button, use an array index value as part of the button group name. For example:

```
firstBtnValue = document.forms[0].sizes[0].value;  // "0.073"
secondBtnValue = document.forms[0].sizes[1].value; // "0.293"
```

Any time you access the `checked`, `defaultChecked`, `type`, or `value` property, you must point to a specific button within the group according to its order in the array (or each button can also have a unique ID). The order of buttons in the group depends on the sequence in which the individual buttons are defined in the HTML document. In other words, to uncover the currently selected radio button, your script has to iterate through all radio buttons in the radio group. Examples of this come later in the discussion of this object.

Supplying a `value` attribute to a radio button can be very important in your script. Although the text label for a button is defined outside the `<input>` tag, the `value` attribute lets you store

any string in the button's hip pocket. In the earlier example, the radio button labels were just first names, whereas the `value` properties were set in the definition to the full names of the actors. The values could have been anything that the script needed, such as birth dates, shoe sizes, URLs, or the first names again (because a script has no way to retrieve the labels except through `innerHTML` in IE or node property access in more modern browsers). The point is that the `value` attribute should contain whatever string the script needs to derive from the selection made by the user. The `value` attribute contents are also what is sent to a server-side program in a submit action for the form.

How you decide to orient a group of buttons on the screen is entirely up to your design and the real estate available within your document. You can string them in a horizontal row (as shown earlier), place `<br />` tags after each one to form a column, or place `<br />` tags after every other button to form a double column. Numeric order within the array is determined only by the order in which the buttons are defined in the source code, not by where they appear. To determine which radio button of a group is checked before doing processing based on that choice, you need to construct a repeat loop (shown in the next example) to cycle through the buttons in the group. For each button, your script examines the checked property.

Properties

checked

Value: Boolean Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Only one radio button in a group can be highlighted (checked) at a time (the browser takes care of highlighting and unhighlighting buttons in a group for you). That one button's `checked` property is set to `true`, whereas all others in the group are set to `false`. By setting the `checked` property of one button in a group to `true`, all other buttons automatically uncheck themselves.

Listing 35-5 uses a repeat loop in a function to look through all buttons in a group of image sizes, in search of the checked button. After the loop finds the one whose checked property is `true`, it returns the value of the index. In one instance, that index value is used to extract the `value` property for display in the alert dialog box; in the other instance, the value helps determine which button in the group is next in line to have its `checked` property set to `true`.

LISTING 35-5

Finding the Selected Button in a Radio Group

```
         function getSelectedButton(buttonGroup)
         {
            for (var i = 0; i < buttonGroup.length; i++)
            {
               if (buttonGroup[i].checked)
               {
                  return i;
               }
            }
            return 0;
         }
         function showMegapixels(form)
         {
            var i = getSelectedButton(form.sizes);
            alert("That image size requires " + form.sizes[i].value
              + " megapixels.");
         }
         function cycle(form)
         {
            var i = getSelectedButton(form.sizes);
               if (i+1 == form.sizes.length)
               {
                  form.sizes[0].checked = true;
               }
               else
               {
                  form.sizes[i+1].checked = true;
               }
         }
      </script>
   </head>
   <body>
      <form>
         <b>Select your desired image size:</b>
         <p><input type="radio" name="sizes" value="0.073"
               checked="checked" />320x240
            <input type="radio" name="sizes" value="0.293" />640x480
            <input type="radio" name="sizes" value="0.75" />1024x768
            <input type="radio" name="sizes" value="1.25" />1280x1024
         </p>
         <p><input type="button" name="Viewer" value="View Megapixels..."
                 onclick="showMegapixels(this.form)" />
         </p>
         <p><input type="button" name="Cycler" value="Cycle Buttons"
                 onclick="cycle(this.form)" />
         </p>
      </form>
   </body>
</html>
```

Related Items: `defaultChecked` property

defaultChecked

Value: Boolean Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

If you add the `checked` attribute to the `<input>` definition for a radio button, the `defaultChecked` property for that object is `true`; otherwise, the property is `false`. Having access to this property enables your scripts to examine individual radio buttons to see if they have been adjusted (presumably by the user, if your script does not perform automatic clicking).

In the following script fragment, a function is passed a reference to a form containing radio buttons for choosing between image sizes:

```
function groupChanged(form)
{
   for (var i = 0; i < form.sizes.length; i++)
   {
      if (form.sizes[i].defaultChecked)
      {
         if (!form.sizes[i].checked)
         {
            alert("This radio group has been changed.");
         }
      }
   }
}
```

The goal in this code is to see, in as general a way as possible (supplying the radio button group name where needed), if the user changed the default setting. Looping through each of the radio buttons, you look for the one whose `checked` attribute is set in the `<input>` definition. With that index value (`i`) in hand, you then look to see if that entry is still checked. If not (notice the `!` negation operator), you display an alert dialog box about the change.

Related Items: `checked`, `value` properties

length

Value: Integer Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

A radio button group has a *length* — the number of individual radio buttons defined for that group. Attempting to retrieve the length of an individual button yields a `null` value. The `length` property is valuable for establishing the maximum range of values in a repeat loop that must cycle through every button within that group. If you specify the `length` property to fill that value (rather than hard-wiring the value), the loop construction will be easier to maintain — as you make changes to the number of buttons in the group during page construction, the loop adjusts to the changes automatically. Just remember that while the `length` property is the number of radio buttons in the array, the array itself (as usual) is zero-based.

Related Items: None

name

Value: Identifier string　　Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The `name` property, although associated with an entire radio button group, can be read only from individual buttons in the group, such as

```
btnGroupName = document.forms[0].groupName[2].name;
```

In that sense, each radio button element in a group inherits the name of the group. Your scripts have little need to extract the `name` property of a button or group. More often than not, you will hard-wire a button group's name into your script to extract other properties of individual buttons. Getting the `name` property of an object whose name you know is obviously redundant. But understanding the place of radio button group names in the scheme of JavaScript objects is important for all scripters.

Related Items: `value` property

type

Value: String (`radio`)　　Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Use the `type` property to help identify a radio object from an unknown group of form elements. To find out if a form element is a radio object, just look for the string `radio` as the type of the element.

Related Items: `form.elements` property

value

Value: String　　Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

As described earlier in this chapter in the discussion of the checkbox object, the `value` property contains arbitrary information that you assign when mapping out the `<input>` definition for an individual radio button. Using this property is a handy shortcut to correlating a radio button label with detailed or related information of interest to your script or server-side application. If you like, the `value` property can contain the same text as the label.

Related Items: `name` property

Methods

click()

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

The intention of the `click()` method is to enact, via a script, the physical act of clicking a radio button. However, you better serve your scripts by setting the `checked` properties of all buttons in a group so that you know exactly what the setting of the group is at any time.

Related Items: `checked` property; `onclick` event handler

Event handlers

onclick

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Radio buttons, more than any user interface element available in HTML, are intended for use in making choices that other objects, such as submit or standard buttons, act upon later. You may see cases in Windows or Mac programs in which highlighting a radio button — at most — activates or brings into view additional, related settings (see Listing 35-4).

We strongly advise you not to use scripting handlers that perform significant actions at the click of any radio button. At most, you may want to use knowledge about a user's clicking of a radio button to adjust a global variable or `document.cookie` setting that influences subsequent processing. Be aware, however, that if you script such a hidden action for one radio button in a group, you must also script similar actions for others in the same group. That way, if a user changes the setting back to a previous condition, the global variable is reset to the way it was. JavaScript, however, tends to run fast enough that a batch operation can make such adjustments after the user clicks a more action-oriented button.

Every time a user clicks one of the radio buttons in Listing 35-6, he or she sets a global variable to `true` or `false`, depending on whether the person chose the smallest image size. This action is independent of the action that is taking place if the user clicks on the View Megapixels action button. An `onunload` event handler in the `<body>` definition triggers a function that displays an informational warning message just before the page clears (click the browser's Reload button to leave the current page prior to reloading). Here we use an initialize function triggered by `onload` so that the current radio button selection sets the global value upon a reload.

LISTING 35-6

An onclick Event Handler for Radio Buttons

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Radio Button onClick Handler</title>
      <script type="text/javascript">
         var LoRes = false
         function initValue()
         {
            LoRes = document.forms[0].sizes[0].checked;
```

continued

LISTING 35-6 *(continued)*

```
         }
         function showMegapixels(form)
         {
            for (var i = 0; i < form.sizes.length; i++)
            {
               if (form.sizes[i].checked)
               {
                  break;
               }
            }
            alert("That image size requires " + form.sizes[i].value + "
               megapixels.");
         }
         function setLoRes(setting)
         {
            LoRes = setting;
         }
         function exitMsg()
         {
            if (LoRes)
            {
               alert("You should probably use a higher resolution image.");
            }
         }
      </script>
   </head>
   <body onload="initValue()" onunload="exitMsg()">
      <form>
         <b>Select your desired image size:</b>
         <p><input type="radio" name="sizes" value="0.073"
                  checked="checked" onclick="setLoRes(true)" />320x240
            <input type="radio" name="sizes" value="0.293"
                  onclick="setLoRes(false)" />640x480
            <input type="radio" name="sizes" value="0.75"
                  onclick="setLoRes(false)" />1024x768
            <input type="radio" name="sizes" value="1.25"
                  onclick="setLoRes(false)" />1280x1024
         </p>
         <p><input type="button" name="Viewer" value="View Megapixels..."
                  onclick="showMegapixels(this.form)" />
         </p>
      </form>
   </body>
</html>
```

image Input Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
`complete`		
`form`†		
`name`†		
`src`		
`type`		

†See `Button` object.

Syntax

Accessing `image` input object properties or methods:

```
(All)       [window.]document.formName.imageName.property |
            method([parameters])
(All)       [window.]document.formName.elements[index].property |
            method([parameters])
(All)       [window.]document.forms[index].imageName.property |
            method([parameters])
(All)       [window.]document.forms["formName"].imageName.property |
            method([parameters])
(All)       [window.]document.forms["formName"].elements[index].property |
            method([parameters])
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)  [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

Modern browsers support the `image` input element among scriptable objects. The `image` input object most closely resembles the button input object, but replaces the `value` property (which defines the label for the button) with the `src` property, which defines the URL for the image that is to be displayed in the form control. This is a much simpler way to define a clickable image icon, for example, than the way required for compatibility with older browsers: wrapping an `img` element inside an `a` element so that you can use the `a` element's event handlers.

Although this element loads a regular Web image in the document, you have virtually no control over the image (unlike when you use the `img` element). Be sure the rendering is as you predict.

Properties

`complete`

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `complete` property works as it does for an `img` element, reporting `true` if the image has finished loading. Otherwise the property returns `false`. Interestingly, there is no `onload` event handler for this object.

Related Items: `image.complete` property

`src`

Value: URL string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Like the `img` element object, the `image` input element's `src` property controls the URL of the image being displayed in the element. The property can be used for image swapping in a form control, just as it is for a regular `img` element. Because the `image` input element has all necessary mouse event handlers available (for example, `onmouseover`, `onmouseout`, `onmousedown`) you can script rollovers, click-downs, or any other user interface technique that you feel is appropriate for your buttons and images. To adapt code written for link-wrapped images, move the event handlers from the `a` element to the `image` input element, and make sure the name of the `image` input element is the same as your old `img` element.

Older browsers load images into an `image` input element, but no event handlers are recognized.

Related Items: `image.src` property

`type`

Value: String (`image`) Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Use the `type` property to help you identify an image input object from an unknown group of form elements. Just look for the string `image` as the type of a form element to know if it is indeed an image input object.

Related Items: `form.elements` property

CHAPTER

36

Text-Related Form Objects

IN THIS CHAPTER

Capturing and modifying text field contents

Triggering action by entering text

Capturing individual keystroke events

The document object model for forms includes four text-related user interface objects — `text`, `password`, and `hidden` input element objects, plus the `textarea` element object. All four of these objects are used for entry, display, or temporary storage of text data. Although all these objects can have text placed in them by default as the page loads, scripts can also modify the contents of these objects. Importantly, all but the `hidden` objects retain their user- or script-modified content during a soft reload (for example, clicking the Reload button) in Mozilla and Internet Explorer; `hidden` objects revert to their default values on all reloads.

A more obvious difference between the `hidden` object and the rest is that its invisibility removes it from the realm of user events and actions. Therefore, the range of scripted possibilities is much smaller for the `hidden` object.

The persistence of `text` and `textarea` object data through reloads (and window resizes), however, is neither reliable enough nor consistent enough across all modern browsers to be used in lieu of a temporary cookie. This is a change from past implementations.

Text Input Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
defaultValue	select()	onafterupdate
form	blur()	onbeforeupdate
maxLength	focus()	onchange
name		onerrorupdate
readOnly		onselect
size		onblur
type		onfocus
value		

Syntax

Accessing `text` input object properties or methods:

```
(All)       [window.]document.formName.fieldName.property |
            method([parameters])
(All)       [window.]document.formName.elements[index].property |
            method([parameters])
(All)       [window.]document.forms[index].fieldName.property |
            method([parameters])
(All)       [window.]document.forms["formName"].fieldName.property |
            method([parameters])
(All)       [window.]document.forms["formName"].elements[index].property |
            method([parameters])
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)  [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

About this object

The `text` input object is the primary medium for capturing single-line, user-entered text. By default, browsers tend to display entered text in a monospaced font (usually Courier or a derivative) so that you can easily specify the width (`size`) of a field based on the anticipated number of characters that a user may put into the field. Until you get to modern (IE4+ and W3C) browsers, the font is a fixed size and is always left-aligned in the field. In those later browsers, style sheets can control the font characteristics of a text field. If your design requires multiple lines of text, use the `textarea` object that comes later in this chapter.

Text object methods and event handlers use terminology that may be known to Windows users but not to Macintosh users. A field is said to have *focus* whenever the user clicks or tabs into the field. When a field has focus, either the text insertion pointer flashes, or any text in the

field may be selected. Only one text object on a page can have focus at a time. The inverse user action — clicking or tabbing away from a text object — is called a *blur*. Clicking another object, whether it is another field or a button of any kind, causes a field that currently has focus to blur.

If you don't want the contents of a field to be changed by the user, you have three options, depending on the vintage of browsers you need to support: forcing the field to lose focus; disabling the field; or setting the field's `readOnly` property.

The tactic that is completely backward compatible uses the following event handler in a field you want to protect:

```
onfocus="this.blur()"
```

Starting with IE4 and NN6/Moz1, the object model provides a `disabled` property for form controls. Setting the property to `true` leaves the element visible on the page, but the user cannot access the control. The same browsers provide a `readOnly` property, which doesn't dim the field, but prevents typing in the field.

Text fields and events

Focus and blur also interact with other possible user actions to a text object: selecting and changing. *Selecting* occurs when the user clicks and drags across any text in the field; *changing* occurs when the user makes any alteration to the content of the field and then either tabs or clicks away from that field.

When you design event handlers for fields, be aware that a user's interaction with a field may trigger more than one event with a single action. For instance, clicking a field to select text may trigger both a `focus` and `select` event. If you have conflicting actions in the `onfocus` and `onselect` event handlers, your scripts can do some weird things to the user's experience with your page. Displaying alert dialog boxes, for instance, also triggers `blur` events, so a field that has both an `onselect` handler (which displays the alert) and an `onblur` handler gets a nasty interaction from the two.

As a result, you should be very judicious with the number of event handlers you specify in any text object definition. If possible, pick one user action that you want to use to initiate some JavaScript code execution and deploy it consistently on the page. Not all fields require event handlers — only those you want to perform some action as the result of user activity in that field.

Many newcomers also become confused by the behavior of the `change` event. To prevent this event from being sent to the field for every character the user types, any change to a field is determined only *after* the field loses focus by the user's clicking or tabbing away from it. At that point, instead of a `blur` event being sent to the field, only a `change` event is sent, triggering an `onchange` event handler if one is defined for the field. This extra burden of having to click or tab away from a field may entice you to shift any `onchange` event handler tasks to a separate button that the user must click to initiate action on the field contents.

Starting with version 4 browsers, text fields also have event handlers for keyboard actions, namely `onkeydown`, `onkeypress`, and `onkeyup`. With these event handlers, you can intercept

keystrokes before the characters reach the text field. Thus, you can use keyboard events to prevent anything but numbers from being entered into a text box while the user types the characters.

To extract the current content of a text object, summon the property `document.formName.fieldName.value`. After you have the string value, you can use JavaScript's string object methods to parse or otherwise massage that text as needed for your script. If the field entry is a number and you need to pass that value to methods requiring numbers, you have to convert the text to a number with the help of the `parseInt()` or `parseFloat()` global functions.

Text Boxes and the Enter/Return Key

Early browsers established a convention that continues to this day. When a form consists of only one text box, a press of the Enter/Return key acts the same as clicking a Submit button for the form. You have probably experienced this many times when entering a value into a single search field of a form. Press the Enter/Return key, and the search request goes off to the server.

The flip side is that if the form contains more than one text box, the Enter/Return key does no submission from any of the text boxes (IE for the Mac and Safari are exceptions: they submit no matter how many text boxes there are). But with the advent of keyboard events, you can script this action (or the invocation of a client-side script) into any text boxes of the form you like. To make it work with all flavors of browsers capable of keyboard events requires a small conversion function that extracts the DOM-specific desired code from the keystroke. The following listing shows a sample page that demonstrates how to implement a function that inspects each keystroke from a text field and initiates processing if the key pressed is the Enter/Return key:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Enter/Return Event Trigger</title>
      <script type="text/javascript">
         // Event object processor
         function isEnterKey(evt)
         {
            evt = (evt) ? evt : ((window.event) ? window.event : null);
            var keyCode;
               if (evt)
               {
                  keyCode = (evt.keyCode) ? evt.keyCode : evt.which;
               }
            return (keyCode == 13);
         }

         function processOnEnter(fld, evt)
         {
            if (isEnterKey(evt))
```

```
            {
               alert("Ready to do some work with the form.");
               return false;
            }
            return true;
         }
      </script>
   </head>
   <body>
      <h1>Enter/Return Event Trigger</h1>
      <hr />
      <form onsubmit="return false">
         Field 1: <input type="text" name="field1"
                         onkeydown="processOnEnter(this, event)" />
         Field 2: <input type="text" name="field2"
                         onkeydown="processOnEnter(this, event)" />
         Field 3: <input type="text" name="field3"
                         onkeydown="processOnEnter(this, event)" />
      </form>
   </body>
</html>
```

Properties

`defaultValue`

Value: String Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Though your users and your scripts are free to muck with the contents of a `text` object by assigning strings to the value property, you can always extract (and thus restore, if necessary) the string assigned to the text object in its `<input>` definition. The `defaultValue` property yields the string parameter of the `value` attribute.

Note

Listings 36-1, 36-2, and 36-3 feature a form with only one `text` input element. The rules of HTML forms say that such a form submits itself if the user presses the Enter key whenever the field has focus. Such a submission to a form whose action is undefined causes the page to reload, thus stopping any scripts that are running at the time. `form` elements for these example listings contain an `onsubmit` event handler that both blocks the submission and attempts to trigger the text box `onchange` event handler to run the demonstration script. In some browsers, such as MacIE5, you may have to press the Tab key or click outside of the text box to trigger the `onchange` event handler after you enter a new value. ■

Listing 36-1 has a simple form with a single field that has a default value set in its tag. A function (`resetField()`) restores the contents of the page's lone field to the value assigned to it in

the <input> definition. For a single-field page such as this, defining a `type="reset"` button or calling `form.reset()` works the same way because such buttons reestablish the default values of all elements of a form. But if you want to reset only a subset of fields in a form, follow the example button and function in Listing 36-1.

LISTING 36-1

Resetting a Text Object to Default Value

```
<html>
   <head>
      <title>Text Object DefaultValue</title>
      <script type="text/javascript">
      function upperMe(field) {
         field.value = field.value.toUpperCase();
      }
      function resetField(form) {
         form.converter.value = form.converter.defaultValue;
      }
      </script>
   </head>
   <body>
      <form onsubmit="window.focus(); return false">
         Enter lowercase letters for conversion to uppercase: <input
         type="text" id="convert" name="converter" value="sample"
         onchange="upperMe(this)" /> <input type="button" id="reset"
         value="Reset Field" onclick="resetField(this.form)" />
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique used in this example and throughout the chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." Several other chapters use the modern technique extensively. ■**

Related Items: `value` property

form

Value: Form object reference　　　Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

A property of every input element object is a reference to the `form` element that contains the control. This property can be very convenient in a script when you are dealing with one form control that is passed as a parameter to the function, and you want to either access another control in the same form or invoke a method of the form. An event handler of any

input element can pass `this` as the parameter, and the function can still get access to the form without having to hard-wire the script to a particular form name or document layout.

The following function fragment receives a reference to a text element as the parameter. The text element reference is needed to decide which branch to follow; then the form is submitted.

```
function setAction(fld)
{
   if (fld.value.indexOf("@") != -1)
   {
      fld.form.action = "mailto:" + fld.value;
   }
   else
   {
      fld.form.action = "cgi-bin/normal.pl";
   }
   fld.form.submit();
}
```

Notice how this function doesn't have to worry about the form reference, because its job is to work with whatever form encloses the text field that triggers this function.

Related Items: `form` object

maxLength

Value: Integer — Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `maxLength` property controls the maximum number of characters allowed to be typed into the field. There is no interaction between the `maxLength` and `size` properties. This value is normally set initially via the `maxlength` attribute of the input element.

Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with the `maxLength` property. The top text field has no default value, but you can temporarily set it to only a few characters and see how it affects entering new values:

```
document.forms[0].input.maxLength = 3;
```

Try typing this into the field to see the results of the change. To restore the default value, reload the page.

Related Items: `size` property

name

Value: Identifier string — Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Text object names are important for two reasons. First, if your HTML page submits information to a CGI script or server application, the input device passes the name of the text object along

with the data to help the server program identify the data being supplied by the form. Second, you can use a text object's name in its reference within JavaScript coding. If you assign distinctive, meaningful names to your fields, these names will help you read and debug your JavaScript listings (and will help others follow your scripting tactics).

Be as descriptive about your text object names as you can. Borrowing text from the field's on-page label may help you mentally map a scripted reference to a physical field on the page. Like all JavaScript object names, text object names must begin with a letter and can be followed by any number of letters or numbers. Avoid punctuation symbols, with the exception of the very safe underscore character.

Although we urge you to use distinctive names for all objects you define in a document, you can make a case for assigning the same name to a series of interrelated fields — and JavaScript is ready to help. Within a single form, any reused name for the same object type is placed in an indexed array for that name. For example, if you define three fields with the name `entry`, the following statements retrieve the `value` property for each field:

```
data = document.forms[0].entry[0].value;
data = document.forms[0].entry[1].value;
data = document.forms[0].entry[2].value;
```

This construction may be useful if you want to cycle through all of a form's related fields to determine which ones are blank. Elsewhere, your script probably needs to know what kind of information each field is supposed to receive so that it can process the data intelligently. We don't often recommend reusing object names, but you should be aware of how the object model handles them in case you need this construction. See Chapter 34, "Form and Related Objects," for more details.

Consult Listing 36-2 later in this chapter, where we use the text object's name, `convertor`, as part of the reference when assigning a value to the field. To extract the name of a text object, you can use the property reference. Therefore, assuming that your script doesn't know the name of the first object in the first form of a document, the statement is

```
var objectName = document.forms[0].elements[0].name;
```

Related Items: `form.elements` property; all other `form` element objects' `name` properties

readOnly

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

To display text in a text field, yet prevent users from modifying it, newer browsers offer the `readOnly` property (and tag attribute). When set to `true`, the property prevents users from changing or removing the content of the text field. Unlike a disabled text field, a read-only text field looks just like an editable one.

Use The Evaluator (Chapter 4, "JavaScript Essentials") to set the bottom text box to be read-only. Begin by typing anything you want in to the bottom text box. Then enter the following statement into the top text box:

```
document.forms[0].inspector.readOnly = true;
```

Although existing text in the box is selectable (and therefore can be copied into the clipboard), it cannot be modified or removed.

Related Items: `disabled` property

size

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Unless otherwise directed, a text box is rendered to accommodate approximately 20 characters of text for the font family and size assigned to the element's style sheet. You can adjust this under script control (in case the `size` attribute of the tag wasn't enough) via the `size` property, whose value is measured in characters (not pixels). Be forewarned, however, that browsers don't always make completely accurate estimates of the space required to display a set number of characters. If you are setting the `maxlength` attribute of a text box, making the `size` one or two characters larger is often a safe bet.

Resize the bottom text box of The Evaluator by entering the following statements into the top text box:

```
document.forms[0].inspector.size = 20;
document.forms[0].inspector.size = 400;
```

To return the size back to normal, reload the page (or set the value to `80`).

Related Items: `maxLength` property

type

Value: String (`text`) Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Use the `type` property to help you identify a `text` input object from an unknown group of form elements.

Related Items: `form.elements` property

value

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

A text object's `value` property is the two-way gateway to the content of the field. A reference to an object's value property returns the string currently showing in the field. Note that all values coming from a text object are string values. If your field prompts a user to enter a number, your script may have to perform data conversion of the number-as-string value ("42" instead of

plain old 42) before a script can perform math operations on it. JavaScript tries to be as automatic about this data conversion as possible and follows some rules about it (see Chapter 15, "The String Object"). If you see an error message that says a value is not a number (for a math operation), the value is still a string.

Your script places text of its own into a field for display to the user by assigning a string to the `value` property of a text object. Use the simple assignment operator. For example:

```
document.forms[0].ZIP.value = "90210";
```

JavaScript is more forgiving about data types when assigning values to a text object. JavaScript does its best to convert a value to a string on its way to a text object display. Even Boolean values get converted to their string equivalents, `true` or `false`. Scripts can place numeric values into fields without a hitch. But remember that if a script later retrieves these values from the text object, they will come back as strings. About the only values that don't get converted are objects. They typically show up in text boxes as `[object]` or, in some browsers, a more descriptive label for the object.

Storing arrays in a field requires special processing. You need to use the `array.join()` method to convert an array into a string. Each array entry is delimited by a character you establish in the `array.join()` method. Later, you can use the `string.split()` method to turn this delimited string into an array.

As a demonstration of how to retrieve and assign values to a text object, Listing 36-2 shows how the action in an `onchange` event handler is triggered. Enter any lowercase letters into the field, and then click out of the field. We pass a reference to the entire form object as a parameter to the event handler. The function extracts the value, converts it to uppercase (using one of the JavaScript string object methods), and assigns it back to the same field in that form.

LISTING 36-2

Getting and Setting a Text Object's Value

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Text Object Value</title>
      <script type="text/javascript">
         function upperMe(form)
         {
            inputStr = form.converter.value;
            form.converter.value = inputStr.toUpperCase();
         }
      </script>
   </head>
   <body>
```

```
      <form onsubmit="window.focus(); return false">
         Enter lowercase letters for conversion to uppercase:
         <input type="text" name="converter" value="sample"
               onchange="upperMe(this.form)" />
      </form>
   </body>
</html>
```

We also show two other ways to accomplish the same task, each one more efficient than the previous example. Both utilize the shortcut object reference to get at the heart of the text object. Listing 36-3 passes the text object — contained in the `this` reference — to the function handler. Because that text object contains a complete reference to it (out of sight, but there just the same), you can access the `value` property of that object and assign a string to it in a simple assignment statement.

LISTING 36-3

Passing a Text Object (as this) to the Function

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Text Object Value</title>
      <script type="text/javascript">
         function upperMe(field)
         {
            field.value = field.value.toUpperCase();
         }
      </script>
   </head>
   <body>
      <form onsubmit="window.focus(); return false">
         Enter lowercase letters for conversion to uppercase:
         <input type="text" name="converter" value="sample"
               onchange="upperMe(this)" />
      </form>
   </body>
</html>
```

Yet another way is to deal with the field values directly in an embedded event handler — instead of calling an external function (which is possibly a little cleaner since there is just a single line of code in the function anyway). With the `upperMe()` function removed from the document, the event handler attribute of the `<input>` tag changes to do all the work:

```
<input type="text" name="converter" value="sample"
      onchange="this.value = this.value.toUpperCase()" />
```

The right-hand side of the assignment expression extracts the current contents of the field and (with the help of the `toUpperCase()` method of the string object) converts the original string to all uppercase letters. The result of this operation is assigned to the `value` property of the field.

The application of the `this` keyword in the previous examples may be confusing at first, but these examples represent the range of ways in which you can use such references effectively. Using `this` by itself as a parameter to an object's event handler refers only to that single object — a text object, in Listing 36-3. If you want to pass along a broader scope of objects that contain the current object, use the `this` keyword along with the outer object layer that you want. In Listing 36-2, we sent along a reference to the entire form by specifying `this.form` — meaning the form that contains "this" object, which is being defined in the line of HTML code.

At the other end of the scale, you can use similar-looking syntax to specify a particular property of the `this` object. Thus, in the last example, we zeroed in on just the `value` property of the current object being defined — `this.value`. Although the formats of `this.form` and `this.value` appear the same, the fact that one is a reference to an object and the other to just a value, can influence the way your functions work. When you pass a reference to an object, the function can read and modify properties of that object (as well as invoke its functions); but when the parameter passed to a function is just a property value, you cannot modify that value without building a complete reference to the object and its value.

Related Items: `form.defaultValue` property

Methods

`blur()`

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Just as a camera lens blurs when it goes out of focus, a text object blurs when it loses focus — when someone clicks or tabs out of the field. Under script control, `blur()` deselects whatever may be selected in the field, and the text insertion pointer leaves the field. The pointer does not proceed to the next field in tabbing order, as it does if you perform a blur by tabbing out of the field manually.

The following statement invokes the `blur()` method on a text box named `vanishText`:

```
document.forms[0].vanishText.blur();
```

Related Items: `focus()` method; `onblur` event handler

`focus()`

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

For a text object, having focus means that the text insertion pointer is flashing in that text object's field (having focus means something different for buttons in a Windows environment). Giving a field focus is like opening it up for human editing.

Setting the focus of a field containing text does not let you place the cursor at any specified location in the field. The cursor usually appears at the beginning of the text (although in WinIE4+, you can use the `TextRange` object to position the cursor wherever you want in the field, as shown in Chapter 33, "Body Text Objects"). To prepare a field for the user to remove the existing text, use both the `focus()` and `select()` methods.

See Listing 36-4 for an example of an application of the `focus()` method in concert with the `select()` method.

Related Items: `select()` method; `onfocus` event handler

`select()`

Returns: Nothing

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Selecting a field under script control means selecting all text within the text object. A typical application is one in which an entry validation script detects a mistake on the part of the user. After alerting the user to the mistake (via a `window.alert()` dialog box), the script finishes its task by selecting the text of the field in question. Not only does this action draw the user's eye to the field needing attention (especially important if the validation code is checking multiple fields), but it also keeps the old text there for the user to examine for potential problems. With the text selected, the next key the user presses erases the former entry.

Trying to select a text object's contents with the click of a button is problematic. One problem is that clicking a button brings the document's focus to the button, which disrupts the selection process. For more reliable selection, the script should invoke both the `focus()` and the `select()` methods for the field, in that order. No penalty exists for issuing both methods, and the extra insurance of the second method provides a more consistent user experience with the page.

Some versions of WinIE are known to exhibit anomalous (meaning buggy) behavior when using the technique of focusing and selecting a text field after the appearance of an alert dialog box. The fix is not elegant, but it works: inserting an artificial delay via the `setTimeout()` method before invoking a separate function that focuses and selects the field. Better-behaved browsers accept the workaround with no penalty.

***textObject*.select()**

Selecting a text object via script does *not* trigger the same `onselect` event handler for that object as the one that triggers if a user manually selects text in the field. Therefore, no event handler script is executed when a user invokes the `select()` method.

A click of the Verify button in Listing 36-4 performs a validation on the contents of the text box, making sure the entry consists only of numbers. All work is controlled by the `checkNumeric()` function, which receives a reference to the field needing inspection as a parameter. Because of the way the delayed call to the `doSelection()` function has to be configured, various parts of what will become a valid reference to the form are extracted from the field's and form's properties. If the validation (performed in the `isNumber()` function) fails, the `setSelection()` method is invoked after an artificial delay of zero milliseconds. As goofy as this sounds, this method is all that IE needs to recover from the display and closure of the alert dialog box. Because the first parameter of the `setTimeout()` method must be a string, the example assembles a string invocation of the `setSelection()` function via string versions of the form and field names. All that the `setSelection()` function does is focus and select the field whose reference is passed as a parameter. This function is now generalizable for multiple text boxes in a more complex form.

LISTING 36-4

Selecting a Field

</html>
```

Related Items: `focus()` method; `onselect` event handler

Event handlers

onafterupdate
onbeforeupdate
onerrorupdate

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

If you are using WinIE data binding on a text element, the element is subject to three possible events in the course of retrieving updated data. The `onbeforeupdate` and `onafterupdate` events fire immediately before and after (respectively) the update takes place. If an error occurs in the retrieval of data from the database, the `onerrorupdate` event fires.

All three events may be used for advisory purposes. For example, an `onafterupdate` event handler may temporarily change the font characteristics of the element to signify the arrival of fresh data. Or, an `onerrorupdate` event handler may fill the field with hyphens because no valid data exists for the field. These events apply only to input elements of type `text` (meaning not `password` or `hidden` types).

Related Items: `dataFld`, `dataSrc` properties (Chapter 26, "Generic HTML Element Objects")

onblur
onfocus
onselect

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

All three of these event handlers should be used only after you have a firm understanding of the interrelationships between the events that reach text objects. You must use extreme care and conduct lots of user testing before including more than one of these three event handlers in a text object. Because some events cannot occur without triggering others, either immediately before or after (for example, an `onfocus` occurs immediately before an `onselect` if the field did not have focus before), whatever actions you script for these events should be as distinct as possible to avoid interference or overlap.

In particular, be careful about displaying modal dialog boxes (for example, `window.alert()` dialog boxes) in response to the `onfocus` event handler. Because the text field loses focus when the alert displays and then regains focus after the alert is closed, you can get yourself into a loop that is difficult to break out of. If you get trapped in this manner, try the keyboard shortcut for reloading the page (Ctrl+R or ~CM-R) repeatedly as you keep closing the dialog box window.

A question often arises about whether data-entry validation should be triggered by the `onblur` event handler or the `onchange` event handler. An `onblur` validation cannot be fooled, whereas an `onchange` validation can (the user simply doesn't change the bad entry as he or she tabs out of the field). What we don't like about the `onblur` way is that it can cause a frustrating experience for a user who wants to tab through a field now, and come back to it later (assuming your validation requires data to be entered into the field before submission). As in Chapter 46's discussion (on the CD-ROM) about form data validation, we recommend using `onchange` event handlers to trigger immediate data checking, and then using another last-minute check in a function called by the form's `onsubmit` event handler.

To demonstrate one of these event handlers, Listing 36-5 shows how you may use the window's status bar as a prompt message area after a user activates any field of a form. When the user tabs in to or clicks on a field, the prompt message associated with that field appears in the status bar. In Figure 36-1, the user has tabbed to the second text box, which caused the status bar message to display a prompt for the field.

Note

Some people frown upon the idea of using the browser's status bar to convey information via JavaScript, with the logic being that you shouldn't tamper with its built-in purpose of displaying status messages directly from the browser itself. There are a few browsers out there that don't have a status bar. In still another approach, Mozilla browsers by default prevent you from altering the status text. You can easily change this setting by navigating to the `about:config` URL in your Mozilla-based browser, and then changing the `dom.disable_window_status_change` preference to `false`; just double-click a preference to change its value. ■

         <p>Enter your city:<input type="text" name="city"
                                    onfocus="prompt('city')" /></p>
      </form>
   </body>
</html>
```

onchange

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Of all the event handlers for a text object, the `onchange` handler is the one you will probably use most in your forms (see Listing 36-6). This event is the one we prefer for triggering the validation of whatever entry the user just typed in the field. The potential hazard of trying to do only a batch-mode data validation of all entries before submitting an entire form is that the user's mental focus is away from the entry of a given field as well. When you immediately validate an entry, the user is already thinking about the information category in question. See Chapter 46, "Data-Entry Validation" (on the CD-ROM) for more about data-entry validation, including a technique that validates user input in real time as a user types each character.

password Input Object

Properties	Methods	Event Handlers
See the "Text Input Object" section earlier in this chapter.		

Syntax

See the "Text Input Object" section earlier in this chapter.

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

About this object

A password-style field looks like a text object, but when the user types something into the field, only asterisks or bullets (depending on your operating system) appear in the field. For the sake of security, any password exchanges should be handled by a server-side program (CGI, Java servlet, and so on).

Scripts can treat a `password` object exactly like a `text` input object. This may lead a scripter to capture a user's web site password for storage in the `document.cookie` of the client machine. A

`password` object value property is returned in plain language, so that such a captured password would be stored in the cookie file the same way. Because a client machine's cookie file can be examined on the local computer (perhaps by a snoop during lunch hour), plain-language storage of passwords is a potential security risk. Instead, develop a scripted encryption algorithm for your page for reading and writing the password in the cookie. Most password-protected sites, however, usually have a server program (CGI, for example) encrypt the password prior to sending it back to the cookie.

See the `text` object discussion for the behavior of the `password` object's properties, methods, and event handlers. The `type` property for this object returns `password`.

hidden Input Object

Properties	Methods	Event Handlers
See the "Text Input Object" section earlier in the chapter.		

Syntax

See "Text Input Object" section earlier in the chapter.

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

A `hidden` object is a simple string holder within a form object whose contents are not visible to the user of your web page. Despite the long list of properties, methods, and event handlers that this input element type inherits by virtue of being an input element, you will be doing little with a `hidden` element beyond reading and writing its `value` property.

The `hidden` object plays a vital role in applications that rely on CGI programs on the server. Very often, the server has data that it needs to convey to itself the next time the client makes a submission (for example, a user ID captured at the application's login page). A CGI program can generate an HTML page with the necessary data hidden from the user, but located in a field transmitted to the server at submit time.

Along the same lines, a page for a server application may present a user-friendly interface that makes data-entry easy for the user. But on the server end, the database, or other application, requires that the data be in a more esoteric format. A script located in the page generated for the user can use the `onsubmit` event handler to perform last-minute assembly of user-friendly data into database-friendly data in a hidden field. When the CGI program receives the request from the client, it passes along the hidden field value to the database.

We are not fans of the `hidden` object for use on client-side-only JavaScript applications. If we want to deliver some default data collections or values with our JavaScript-enabled pages, we do so in JavaScript variables and arrays as part of the script.

Because scripted changes to the contents of a hidden field are fragile (for example, a soft reload erases the changes), the only place you should consider making such changes is in the same script that submits a form to a CGI program, or in a function triggered by an `onsubmit` event handler. In effect, you're just using the hidden fields as holding pens for the scripted data to be submitted. For more persistent storage, use the `document.cookie` property or genuine text fields in hidden frames, even if just for the duration of the visit to the page.

For information about the properties of the `hidden` object, consult the earlier listing for the `text` input object. The `type` property for this object returns `hidden`.

textarea Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

            method([parameters])
(All)       [window.]document.forms["formName"].textareaName.property |
            method([parameters])
(All)       [window.]document.forms["formName"].elements[index].property |
            method([parameters])
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)  [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

About this object

Although not in the same HTML syntax family as other `<input>` elements of a form, a `textarea` object is indeed a form input element, providing multiple-line text input facilities. Although some browsers let you put a `textarea` element anywhere in a document, it really should be contained by a `form` element.

A `textarea` object closely resembles a text object, except for attributes that define its physical appearance on the page. Because the intended use of a `textarea` object is for multiple-line text input, the attributes include specifications for height (number of rows) and width (number of columns in the monospaced font). No matter what size you specify, the browser displays a textarea with horizontal and vertical scrollbars in older browsers; more recent browsers tend to be smarter about displaying scrollbars only when needed (although there are exceptions). Text entered in the textarea wraps by default in all modern browsers, although the wrapping can be adjusted via the `wrap` attribute in IE. The `wrap` attribute can be set to `soft` (the default), `hard`, or `off`. The `soft` and `hard` settings result in word wrapping, whereas the `off` setting causes text to scroll for a significant distance horizontally (the horizontal scrollbar appears automatically). This field is, indeed, a primitive text field by GUI computing standards, in that font specifications made possible in newer browsers by way of style sheets apply to all text in the box.

Use The Evaluator Sr. (Chapter 4, "JavaScript Essentials") to play with the `cols` and `rows` property settings for the Results textarea on that page. Shrink the width of the textarea by entering the following statement into the top text box:

```
document.forms[0].output.cols = 30;
```

And make the textarea one row deeper:

```
document.forms[0].output.rows++;
```

All properties, methods, and event handlers of text objects apply to the `textarea` object. They all behave exactly the same way (except, of course, for the `type` property, which is `textarea`). Therefore, refer to the previous listings for the text object for scripting details for those items. Some additional properties that are unique to the `textarea` object are discussed next.

Carriage returns inside textareas

The three classes of operating systems supported by modern browsers — Windows, Macintosh, and UNIX — do not agree about what constitutes a carriage return character in a text string. This discrepancy carries over to the `textarea` object and its contents on these platforms.

After a user enters text and uses Enter/Return on the keyboard, one or more unseen characters are inserted into the string. In the parlance of JavaScript's literal string characters, the carriage

return consists of some combination of the newline (`\n`) and return (`\r`) character. The following table shows the characters inserted into the string for each operating system category.

Operating System	Character String
Windows	`\r\n`
Macintosh	`\r`
UNIX	`\n`

This tidbit is valuable if you need to remove carriage returns from a textarea for processing in a CGI or local script. The problem is that you obviously need to perform platform-specific operations on each. For the situation in which you must preserve the carriage return locations, but your server-side database cannot accept the carriage return values, we suggest you use the `string.escape()` method to URL-encode the string. The return character is converted to `%0D`, and the newline character is converted to `%0A`. Of course these characters occupy extra character spaces in your database, so these additions must be accounted for in your database design.

As far as writing carriage returns into textareas, the situation is a bit easier. From NN3 and IE4 onward, if you specify any one of the combinations in the preceding table, all platforms know how to automatically convert the data to the form native to the operating system. Therefore, you can set the value of a `textarea` object to `1\r\n2\r\n3` in all platforms, and a columnar list of the numbers 1, 2, and 3 will appear in those fields. Or, if you URL-encoded the text for saving to a database, you can unescape that character string before setting the textarea value, and no matter what platform the visitor has, the carriage returns are rendered correctly. Upon reading those values again by script, you can see that the carriage returns are in the form of the platform (shown in the previous table).

Properties

`cols`
`rows`

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The displayed size of a `textarea` element is defined by its `cols` and `rows` attributes, which are represented in the object model by the `cols` and `rows` properties, respectively. Values for these properties are integers. For `cols`, the number represents the number of characters that can be displayed without horizontal scrolling of the textarea; for `rows`, the number is the number of lines of text that can be displayed without vertical scrolling.

Related Items: `wrap` property

wrap

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `wrap` property represents the `wrap` attribute, which, surprisingly, is not a W3C-sanctioned attribute as of HTML 4.01. In any case, IE4+ lets you adjust the property by scripting. Allowable string values are `soft`, `hard`, and `off`. The browser adds soft returns (the default in IE) to word-wrap the content, but no carriage return characters are actually inserted into the text. A setting for hard returns means that carriage return characters are added to the text (and would be submitted with the value to a server application). With wrap set to `off`, text continues to extend beyond the right edge of the textarea until the user manually presses the Enter/Return key.

Related Items: `cols` property

Methods

createTextRange()

Returns: `TextRange` object

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `createTextRange()` method for a `textarea` operates just as the `document.createTextRange()` method, except that the range consists of text inside the `textarea` element, apart from the regular body content. This version of the `TextRange` object comes in handy when you want a script to control the location of the text insertion pointer inside a `textarea` element for the user.

See the example for the `TextRange.move()` method in Chapter 33, "Body Text Objects," to see how to control the text insertion pointer inside a `textarea` element.

Related Items: `TextRange` object (Chapter 33)

CHAPTER

37

Select, Option, and FileUpload Objects

IN THIS CHAPTER

Triggering action based on a user's selection in a pop-up or select list

Modifying the contents of select objects

Using the fileUpload object

Selection lists — whether in the form of pop-up menus or scrolling lists — are space-saving form elements in HTML pages. They enable designers to present a lot of information in a comparatively small space. At the same time, users are familiar with the interface elements from working in their own operating systems' preference dialog boxes and application windows.

However, selection lists are more difficult to script, especially in older browsers, because the objects themselves are complicated entities. Scripts find all the real data associated with the form control in `option` elements that are nested inside `select` elements. As you can see throughout this chapter, backward-compatible references necessary to extract information from a `select` element object and its `option` objects can get pretty long. On the upside, the most painful backward compatibility efforts are all but unnecessary given the proliferation of modern browsers.

The other object covered in this chapter, the `fileUpload` input object, is frequently misunderstood as being more powerful than it actually is. It is, alas, not the great file transfer elixir desired by many page authors.

select Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

selectObject

(IE5+/W3C)  [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

About this object

`select` element objects are perhaps the most visually interesting user interface elements among the standard built-in objects. In one format, they appear on the page as pop-up lists; in another format, they appear as scrolling list boxes. Pop-up lists, in particular, offer efficient use of page real estate for presenting a list of choices for the user. Moreover, only the choice selected by the user shows on the page, minimizing the clutter of unneeded verbiage.

Compared with other JavaScript objects, `select` objects are difficult to script — mostly because of the complexity of data that goes into a list of items. What the user sees as a `select` element

on the page consists of both that element and option elements that contain the actual choices from which the user makes a selection. Some properties that are of value to scripters belong to the select object, whereas others belong to the nested option objects. For example, you can extract the number (index) of the currently selected option in the list — a property of the entire select object. To get the displayed text of the selected option, however, you must zero in further to extract the text property of a single option among all options defined for the object.

When you define a select object within a form, the construction of the <select>...</select> tag pair is easy to inadvertently mess up. First, most attributes that define the entire object — such as name, size, and event handlers — are attributes of the opening <select> tag. Between the end of the opening tag and the closing </select> tag are additional tags for each option to be displayed in the list. The following object definition creates a selection pop-up list containing three color choices:

```
<form>
   <select name="RGBColors" onchange="changeColor(this)">
      <option selected="selected">Red</option>
      <option>Green</option>
      <option>Blue</option>
   </select>
</form>
```

The indented formatting of the tags in the HTML document is not critical. We indent the lines of options merely for the sake of readability, which is still a worthy cause even if it isn't technically necessary.

By default, a select element is rendered as a pop-up list. To make it appear as a scrolled list, assign an integer value greater than 1 to the size attribute to specify how many options should be visible in the list without scrolling — how tall the list's box should be, measured in lines. Because scrollbars in GUI environments tend to require a fair amount of space to display a minimum set of clickable areas (including sliding "thumbs"), you should set list-box style sizes to no less than 4. If that makes the list box too tall for your page design, consider using a pop-up menu instead.

Significant differences exist in the way each GUI platform presents pop-up menus. Because each browser sometimes relies on the operating system to display its native pop-up menu style (and sometimes the browser designers go their own way), considerable differences exist among the OS and browser platforms in the size of a given pop-up menu. What fits nicely within a standard window width of one OS may not fit in the window of another OS in a different browser. In other words, you cannot rely on any select object having a precise dimension on a page (in case you're trying to align a select object with an image).

In list-box form, you can set a select object to accept multiple, noncontiguous selections. Users typically accomplish such selections by holding down a modifier key (the Shift, Ctrl, or ⌘ key, depending on the operating system) while clicking additional options. To switch on this capability for a select object, include the multiple attribute constant in the definition.

For each entry in a list, your <select> tag definition must include an <option> tag plus the text as you want it to appear in the list. If you want a pop-up list to show a default selection

when the page loads, you must attach a `selected` attribute to that item's `<option>` tag. Without this attribute, the default item may be empty or the first item, depending on the browser. (We go more in depth about this in the `option` object discussion later in this chapter.) You can also assign a string to each `option`'s `value` attribute. As with radio buttons, this value can be text other than the wording displayed in the list. In essence, your script can act on that "hidden" value rather than on the displayed text, such as letting a plain-language select listing actually refer to a complex URL. This string value is also the value sent to a CGI program (as part of the name-value pair) when the user submits the `select` object's form.

One behavioral aspect of the `select` object may influence your page design. The `onchange` event handler triggers immediately when a user makes a new selection in a pop-up list. If you prefer to delay any action until the user makes other settings in the form, omit an `onchange` event handler in the `select` object — but be sure to create a button that enables users to initiate an action governed by those user settings.

Modifying select options (NN3+, IE4+)

Script control gives you considerable flexibility in modifying the contents and selection of a `select` object. There are several techniques at your disposal when it comes to working with the `select` object, including some whose support dates back to NN3 and IE4. We quickly show you how to approach the `select` object from this backward-compatible perspective, and then move on to revealing a W3C standard approach a bit later in the chapter. Some aspects of manipulating the `select` object are rather straightforward, such as changing the `selectObj.options[i].text` property to alter the display of a single-option entry. The situation gets tricky, though, when the number of options in the `select` object changes. Your choices include:

- Removing an individual option (and thus collapsing the list)
- Reducing an existing list to a fewer number of options
- Removing all options
- Adding new options to a `select` object

To remove an option from the list, set the specific option to `null`. For example, if a list contains five items and you want to eliminate the third item altogether (reducing the list to four items), the syntax (from the `select` object reference) for doing that task is this:

```
selectObj.options[2] = null;
```

After this statement, `selectObj.options.length` equals `4`.

In another scenario, suppose that a `select` object has five options in it and you want to replace it with one having only three options. You first must hard-code the `length` property to `3`:

```
selectObj.options.length = 3;
```

Then, set individual `text` and `value` properties for index values `0` through `2`.

Perhaps you want to start building a new list of contents by completely deleting the original list (without harming the `select` object). To accomplish this, set the `length` to `0`:

```
selectObj.options.length = 0;
```

From here, you have to create new options (as you do when you want to expand a list from, say, three to seven options). The mechanism for creating a new option involves an object constructor: `new Option()`. This constructor accepts up to four parameters, which enable you to specify the equivalent of an `<option>` tag's attributes:

- Text to be displayed in the option
- Contents of the option's `value` property
- Whether the item is the `defaultSelected` option (Boolean)
- Whether the item is selected (Boolean)

You can set any (or none) of these items as part of the constructor and return to other statements to set their properties. We suggest setting the first two parameters (leave the others blank) and then setting the `selected` property separately. The following is an example of a statement that creates a new, fifth entry, in a `select` object and sets both its displayed `text` and `value` properties:

```
selectObj.options[4] = new Option("Yahoo","http://www.yahoo.com");
```

To demonstrate all of these techniques, Listing 37-1 enables you to change the text of a `select` object — first by adjusting the text properties in the same number of options and then by creating an entirely new set of options. Radio button `onclick` event handlers trigger functions for making these changes — rare examples of when radio buttons can logically initiate visible action.

               <option>yellow</option>
            </select>
         </p>
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique used in this example and throughout the chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." Several other chapters use the modern technique extensively. ■

In an effort to make this code easily maintainable, the color choice lists (one in plain language, the other in hexadecimal triplet color specifications) are established as two separate arrays. Repeat loops in both large functions can work with these arrays no matter how big they get.

The first two radio buttons (see Figure 37-1) trigger the `setLang()` function. This function's first task is to extract a reference to the `select` object to make additional references shorter (just `listObj`). Then by way of the `length` property, you find out how many items are currently displayed in the list because you just want to replace as many items as are already there. In the repeat loop, you set the `text` property of the existing `select` options to corresponding entries in either of the two array listings.

FIGURE 37-1

Radio button choices alter the contents of the select object on-the-fly.

In the second pair of radio buttons, each button stores a value indicating how many items should be displayed when the user clicks the button. This number is picked up by the `setCount()` function and is used in the repeat loop as a maximum counting point. In the meantime, the function finds the selected language radio button and zeros out the `select` object entirely. Options are rebuilt from scratch using the `new Option()` constructor for each option. The parameters are the corresponding display text entries from the arrays. Because none of these new options have other properties set (such as which one should be selected by default), the function sets that property of the first item in the list.

Notice that both functions call `history.go(0)` for legacy browsers after setting up their `select` objects. The purpose of this call is to give these earlier Navigator versions an opportunity to resize the `select` object to accommodate the contents of the list. The difference in size here is especially noticeable when you switch from the six-color, plain-language list to any other list. Without resizing, some long items are not readable. IE4+ and NN6+/Moz, on the other hand, automatically redraw the page to the newly sized form element.

Modifying select options (IE4+)

Microsoft offers another way to modify `select` element options for IE4+, but the technique involves two proprietary methods of the `options` array property of the `select` object. Because we cover all other ways of modifying the `select` element in this section, we cover the IE way of doing things here as well. Interestingly, some of the other modern browsers (Safari, Opera, and Chrome) now support this approach.

The two `options` array methods are `add()` and `remove()`. The `add()` method takes one required parameter and one optional parameter. The required parameter is a reference to an `option` element object that your script creates in another statement (using the `document.createElement()` method). If you omit the second parameter to `add()`, the new `option` element is appended to the current collection of items. But you can also specify an index value as the second parameter. The index points to the position in the `options` array where the new item is to be inserted.

Listing 37-2 shows how to modify the two main functions from Listing 37-1 using the IE approach exclusively (changes and additions appear in bold). The script assumes that only IE browsers ever load the page (in other words, there is no filtering for browser brand here, which in the "real world" is mandatory). When replacing one set of options with another, there are two approaches demonstrated. In the first (the `setLang()` function), the replacements have the same number of items, so the length of existing options provides a counter and index value for the `remove()` and `add()` methods. But when the number of items may change (as in the `setCount()` function), a tight loop removes all items before they are added back via the `add()` method without a second parameter (items are appended to the list). The approach shown in Listing 37-2 has no specific benefit over that of Listing 37-1.

LISTING 37-2

Modifying select Options (IE4+)

```
// change color language set
function setLang(which)
{
   var listObj = document.forms[0].colors;
   var newOpt;
   // filter out old IE browsers
      if (listObj.type)
      {
         // find out if it's 3 or 6 entries
         var listLength = listObj.length;
         // save selected index
         var currSelected = listObj.selectedIndex;
         // replace individual existing entries
         for (var i = 0; i < listLength; i++)
         {
            newOpt = document.createElement("option");
            newOpt.text = (which == "plain") ? plainList[i] : hardList[i];
            listObj.options.remove(i);
            listObj.options.add(newOpt, i);
         }
         listObj.selectedIndex = currSelected;
      }
}

// create entirely new options list
function setCount(choice)
{
   var listObj = document.forms[0].colors;
   var newOpt;
   // filter out old browsers
      if (listObj.type)
      {
         // get language setting
         var lang = (document.forms[0].geekLevel[0].checked) ? "plain" : "hard";
         // empty options from list
         while (listObj.options.length)
         {
            listObj.options.remove(0);
         }
         // create new option object for each entry
         for (var i = 0; i < choice.value; i++)
         {
            newOpt = document.createElement("option");
            newOpt.text = (lang == "plain") ? plainList[i] : hardList[i];
            listObj.options.add(newOpt);
         }
         listObj.options[0].selected = true;
      }
}
```

Modifying select options (W3C DOM)

Yet another approach is possible in browsers that closely adhere to the W3C DOM Level 2 standard. In NN6+, Mozilla, and Safari, for example, you can use the `add()` and `remove()` methods of the `select` element object. They work very much like the same-named methods for the `options` array in IE4+, but these are methods of the `select` element object itself. The other main difference between the two syntaxes is that the `add()` method does not use the index value as the second parameter but rather a reference to the `option` element object before which the new option is inserted. The second parameter is required, so to simply append the new item at the end of the current list, supply `null` as the parameter. Listing 37-3 shows the W3C-compatible version of the `select` element modification scripts shown in Listings 37-1 and 37-2. We highlight source code lines in bold that exhibit differences between the IE4+ and W3C DOM versions.

LISTING 37-3

Modifying select Options (W3C)

```
// change color language set
function setLang(which)
{
   var listObj = document.forms[0].colors;
   var newOpt;
   // filter out old IE browsers
      if (listObj.type)
      {
         // find out if it's 3 or 6 entries
         var listLength = listObj.length;
         // save selected index
         var currSelected = listObj.selectedIndex;
         // replace individual existing entries
         for (var i = 0; i < listLength; i++)
         {
            newOpt = document.createElement("option");
            newOpt.text = (which == "plain") ? plainList[i] : hardList[i];
            listObj.remove(i);
            listObj.add(newOpt, listObj.options[i]);
         }
         listObj.selectedIndex = currSelected;
      }
}

// create entirely new options list
function setCount(choice)
{
   var listObj = document.forms[0].colors;
   var newOpt;
   // filter out old browsers
      if (listObj.type)
      {
```

continued

LISTING 37-3 *(continued)*

```
      // get language setting
      var lang = (document.forms[0].geekLevel[0].checked) ? "plain" : "hard";
      // empty options from list
      while (listObj.options.length)
      {
         listObj.remove(0);
      }
      // create new option object for each entry
      for (var i = 0; i < choice.value; i++)
      {
         newOpt = document.createElement("option");
         newOpt.text = (lang == "plain") ? plainList[i] : hardList[i];
         listObj.add(newOpt, null);
      }
      listObj.options[0].selected = true;
   }
}
```

As with the IE4 version, the W3C version offers no specific benefit over the original, backward-compatible approach. Choose the most modern one that fits the types of browsers you need to support with your page.

Properties

`length`

Value: Integer Read/Write (see text)

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

Like all JavaScript arrays, the `options` array has a `length` property of its own. But rather than having to reference the `options` array to determine its length, the `select` object has its own `length` property that you use to find out how many items are in the list. This value is the number of options in the object. A `select` object with three choices in it has a `length` property value of `3`.

In browsers dating back to NN3 and IE4 you can adjust this value downward after the document loads. This is one way to decrease the number of options in a list. Setting the value to `0` causes the `select` object to empty but not disappear.

See Listing 37-1 for an illustration of the way you use the `length` property to help determine how often to cycle through the repeat loop in search of selected items. Because the loop counter, `i`, must start at `0`, the counting continues until the loop counter is one less than the actual length value (which starts its count with `1`).

Related Item: `options` property

multiple

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `multiple` property represents the `multiple` attribute setting for a `select` element object. If the value is `true`, the element accepts multiple selections by the user (for example, Ctrl+clicking in Windows). If you want to convert a pop-up list into a multiple `select` pick list, you must also adjust the `size` property to direct the browser to render a set number of visible choices in the list.

The following statement toggles between single and multiple selections on a `select` element object whose `size` attribute is set to a value greater than `1`:

```
document.forms[0].mySelect.multiple = !document.forms[0].mySelect.multiple;
```

Related Item: `size` property

options[*index*]

Value: Array of `option` element objects Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

You typically don't summon this property by itself. Rather, it is part of a reference to a specific option's properties (or methods in later browsers) within the entire `select` object. In other words, the `options` property is a kind of gateway to more specific properties, such as the value assigned to a single option within the list.

In modern browsers (IE4+ and W3C), you can reference individual options as separate HTML element objects. These references do not require the reference to the containing `form` or `select` element objects. If backward compatibility is a priority, however, we recommend you stick with the long references through the `select` objects.

We list the next several properties here in the `select` object discussion because they are backward-compatible with all browsers, including browsers that don't treat the `option` element as a distinct object. Be aware that all properties shown here that include `options[index]` as part of their references are also properties of the `option` element object in IE4+ and W3C browsers.

See Listings 37-1 through 37-3 for examples of how the `options` array references information about the options inside a `select` element.

Related Items: All `options[index].property` items

options[*index*].defaultSelected

Value: Boolean Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

If your `select` object definition includes one option that features the `selected` attribute, that option's `defaultSelected` property is set to `true`. The `defaultSelected` property for all other options is `false`. If you define a `select` object that allows multiple selections (and whose `size` attribute is greater than 1), however, you can define the `selected` attribute for more than one option definition. When the page loads, all items with that attribute are preselected for the user (even in noncontiguous groups).

The following statement preserves a Boolean value if the first option of the select list is the default selected item:

```
var zeroIsDefault = document.forms[0].listName.options[0].defaultSelected;
```

Related Item: `options[index].selected` property

options[*index*].index

Value: Integer Read-Only

Compatibility: WinIE3+, MacIE3+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `index` value of any single option in a `select` object is likely a redundant value in your scripting. Because you cannot access the option without knowing the index anyway (in brackets as part of the `options[index]` array reference), you have little need to extract the `index` value. The value is a property of the item just the same.

The following statement assigns the index integer of the first option of a `select` element named `listName` to a variable named `itemIndex`.

```
var itemIndex = document.forms[0].listName.options[0].index;
```

Related Item: `options` property

options[*index*].selected

Value: Boolean Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

As mentioned earlier in the discussion of this object, better ways exist for determining which option a user selects from a list than looping through all options and examining the `selected` property. An exception to that "rule" occurs when you set up a list box to enable multiple selections. In this situation, the `selectedIndex` property returns an integer of only the topmost item selected. Therefore, your script needs to look at the `true` or `false` values of the `selected` property for each option in the list and determine what to do with the text or value data.

To accumulate a list of all items selected by the user, the `seeList()` function in Listing 37-4 systematically examines the `options[index].selected` property of each item in the list. The text of each item whose `selected` property is `true` is appended to the list. We add the "`\n`" inline carriage returns and spaces to make the list in the alert dialog box look nice and indented. If you assign other values to the `value` attributes of each option, the script can extract the `options[index].value` property to collect those values instead.

LISTING 37-4

Cycling through a Multiple-Selection List

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Accessories List</title>
      <script type="text/javascript">
         function seeList(form)
         {
            var result = "";
            for (var i = 0; i < form.accList.length; i++)
            {
               if (form.accList.options[i].selected)
               {
                  result += "\n  " + form.accList.options[i].text;
               }
            }
            alert("You have selected:" + result);
         }
      </script>
   </head>
   <body>
      <form>
         <p>Control/Command-click on all accessories you use:

            </select>
         </p>
         <p><input type="button" value="View Summary..."
                  onclick="seeList(this.form)" />
         </p>
      </form>
   </body>
</html>
```

Related Items: `options[index].text`, `options[index].value`, `selectedIndex` properties

`options[`*`index`*`].text`

Value: String Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

selectObject.options[*index*].text

The `text` property of an option is the text of the item as it appears in the list. If you can pass that wording along with your script to perform appropriate tasks, this property is the one you want to extract for further processing. But if your processing requires other strings associated with each option, assign a `value` attribute in the definition and extract the `options[index].value` property (see Listing 37-6).

To demonstrate the `text` property of an option, Listing 37-5 applies the text from a selected option to the `document.bgColor` property of a document in the current window. The color names are part of the collection built into all scriptable browsers; fortunately, the values are case-insensitive so that you can capitalize the color names displayed and assign them to the property.

LISTING 37-5

Using the options[index].text Property

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Color Changer 1</title>
      <script type="text/javascript">
         function seeColor(form)
         {
            var newColor =
                (form.colorsList.options[form.colorsList.selectedIndex].text);
            document.bgColor = newColor;
         }
      </script>
   </head>
   <body>
      <form>
         <p>Choose a background color:
            <select name="colorsList">
               <option selected="selected">Gray</option>
               <option>Lime</option>
               <option>Ivory</option>
               <option>Red</option>
            </select>
         </p>
         <p><input type="button" value="Change It"
                   onclick="seeColor(this.form)" />
         </p>
      </form>
   </body>
</html>
```

Related Item: `options[index].value` property

options[*index*].value

Value: String — Read/Write

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

In many instances, the words in the options list appear in a form that is convenient for the document's users but inconvenient for the scripts behind the page. Rather than set up an elaborate lookup routine to match the `selectedIndex` or `options[index].text` values with the values your script needs, you can easily store those values in the `value` attribute of each `<option>` definition of the `select` object. You can then extract those values as needed.

You can store any string expression in the `value` attributes. That includes URLs, object properties, or even entire page descriptions that you want to send to a `parent.frames[index].document.write()` method.

Starting with IE4 and W3C browsers, the `select` element object itself has a `value` property that returns the `value` property of the selected option. But for backward compatibility, use the longer approach shown in the example in Listing 37-6.

Listing 37-6 requires the option text that the user sees to be in familiar, multiple-word form. But to set the color using the browser's built-in color palette, you must use the one-word form. Those one-word values are stored in the `value` attributes of each `<option>` definition. The function then reads the `value` property, assigning it to the `bgColor` of the current document. If you prefer to use the hexadecimal triplet form of color specifications, those values are assigned to the `value` attributes (`<option value="#e9967a">Dark Salmon</option>`).

LISTING 37-6

Using the options[index].value Property

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Color Changer 2</title>
      <script type="text/javascript">
         function seeColor(form)
         {
            var newColor =
                (form.colorsList.options[form.colorsList.selectedIndex].value);
            document.bgColor = newColor;
         }
      </script>
   </head>
```

continued

LISTING 37-6 *(continued)*

```
   <body>
      <form>
         <p>Choose a background color:
            <select name="colorsList">
               <option selected="selected" value="cornflowerblue">
                       Cornflower Blue</option>
               <option value="darksalmon">Dark Salmon</option>
               <option value="lightgoldenrodyellow">
                       Light Goldenrod Yellow</option>
               <option value="seagreen">Sea Green</option>
            </select>
         </p>
         <p><input type="button" value="Change It"
                   onclick="seeColor(this.form)" />
         </p>
      </form>
   </body>
</html>
```

Related Item: `options[index].text` property

selectedIndex

Value: Integer Read/Write

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

When a user clicks a choice in a selection list, the `selectedIndex` property changes to a zero-based number corresponding to that item in the list. The first item has a value of `0`. This information is valuable to a script that needs to extract the value or text of a selected item for further processing.

You can use this information as a shortcut to getting at a selected option's properties. To examine a `select` object's `selected` property, rather than cycling through every option in a repeat loop, use the object's `selectedIndex` property to fill in the index value for the reference to the selected item. The wording gets kind of long; but from an execution standpoint, this methodology is much more efficient. Note, however, that when the `select` object is multiple-style, the `selectedIndex` property value reflects the index of only the topmost item selected in the list.

To script the selection of a particular item, assign an integer value to the `select` element object's `selectedIndex` property, as shown in Listings 37-1 through 37-3.

In the `inspect()` function of Listing 37-7, notice that the value inside the `options` property index brackets is a reference to the object's `selectedIndex` property. Because this property always returns an integer value, it fulfills the needs of the index value for the `options` property. Therefore, if you select Green in the pop-up menu, `form.colorsList.selectedIndex` returns a value of `1`; that reduces the rest of the reference to `form.colorsList.options[1].text`, which equals "Green."

LISTING 37-7

Using the selectedIndex Property

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Select Inspector</title>
      <script type="text/javascript">
         function inspect(form)
         {
            alert(form.colorsList.options[form.colorsList.selectedIndex].text);
         }
      </script>
   </head>
   <body>
      <form>
         <p>
            <select name="colorsList">
               <option selected="selected">Red</option>
               <option value="Plants">Green</option>
               <option>Blue</option>
            </select>
         </p>
         <p><input type="button" value="Show Selection"
                  onclick="inspect(this.form)" />
         </p>
      </form>
   </body>
</html>
```

Related Item: `options` property

size

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `size` property represents the `size` attribute setting for a `select` element object. You can modify the integer value of this property to change the number of options that are visible in a pick list without having to scroll.

The following statement uses the `size` property to set the number of visible items to 5:

```
document.forms[0].mySelect.size = 5;
```

Related Item: `multiple` property

type

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Use the `type` property to help you identify a `select` object from an unknown group of form elements. The precise string returned for this property depends on whether the `select` object is defined as a single- (`select-one`) or multiple- (`select-multiple`) type.

Related Item: `form.elements` property

value

Value: String Read/Write (see text)

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The more recent browsers (and the W3C DOM) provide a `value` property for the `select` element object. This property returns the string assigned to the `value` attribute (or `value` property) of the currently selected `option` element. If you do not assign a string to the attribute or property, the `value` property returns an empty string. For these browser generations, you can use this shortcut reference to the `select` element object's `value` property instead of the longer version that requires a reference to the `selectedIndex` property and the `options` array of the element object.

The `seeColor()` function in Listing 37-6 that accesses the chosen value the long way can be simplified for newer browsers only with the following construction:

```
function seeColor(form)
{
   document.bgColor = form.colorsList.value;
}
```

Related Item: `options[index].value` property

Methods

add(*newOptionElementRef[, index]*)
add(*newOptionElementRef, optionElementRef*)
remove(*index*)

Returns: Nothing

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

These methods represent the W3C approach to adding and removing option elements from a selection. The first parameter to each of the `add()` methods is the new `option` element object to be added to the selection. The second parameters differ due to variances in IE and other W3C browsers. The first version of `add()` is the IE version, which allows you to specify an optional index position for the new option; the option is placed just before the index position,

or it is appended to the end of the selection list if no index is provided. The W3C approach is represented by the second `add()` method, which requires an `option` object reference as the second parameter. This reference is to an option already in the selection list; the new option is added just before the option, or it is appended to the end of the selection list if `null` is passed as the second parameter.

The `remove()` method requires the `index` of the option to be removed, and simply removes the option from the selection list.

options.add(*elementRef*[, *index*])
options.remove()

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera+, Chrome+

These two IE-specific methods are now supported by some of the other browsers. They belong to the `options` array property of a `select` element object. See the opening of the discussion of the `select` element object earlier in this chapter to see how to use these methods and their counterparts in other browser versions and object models.

item(*index*)
namedItem("*optionID*")

Returns: `option` element reference

Compatibility: WinIE5+, MacIE5+, NN-, Moz5+, Safari-, Opera9+, Chrome-

The `item()` and `namedItem()` methods are IE-specific convenience methods that access `option` element objects nested inside a `select` object. In a sense, they provide shortcuts to referencing nested options without having to use the `options` array property and the indexing within that array.

The parameter for the `item()` method is an index integer value. For example, the following two statements refer to the same `option` element object:

```
document.forms[0].mySelect.options[2]
document.forms[0].mySelect.item(2)
```

If your script knows the ID of an `option` element, it can use the `namedItem()` method, supplying the string version of the ID as the parameter, to return a reference to that option element.

The following statement assigns an option element reference to a variable:

```
var oneOption = document.forms[0].mySelect.namedItem("option3_2");
```

Related Item: `options` property

Event handlers

onchange

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

As a user clicks a new choice in a `select` object, the object receives a `change` event that the `onchange` event handler can capture. In examples earlier in this section (Listings 37-6 and 37-7, for example), the action is handed over to a separate button. This design may make sense in some circumstances, especially when you use multiple `select` lists or any list box. (Typically, clicking a list box item does not trigger any action that the user sees.) There are also accessibility concerns for users who do not have JavaScript enabled. Restricting action to scripted events (without a corresponding Go or similar explicit button adjacent to the `select` element) may mean that choosing an item in the list would have no effect. Therefore, consider your users carefully before implementing actions exclusively via the `change` event.

To bring a pop-up menu to life, bind an `onchange` event handler to the `<select>` definition. If the user makes the same choice as previously selected, the `onchange` event handler is not triggered. In this case, you can still trigger an action via the `onclick` event handler; but this event works for the `select` object only in modern browsers.

Listing 37-8 is a version of Listing 37-6 that invokes all action as the result of a user making a selection from the pop-up menu. The `onchange` event handler for the `<select>` tag replaces the action button. For this application — when you desire a direct response to user input — it's appropriate to have the action triggered from the pop-up menu rather than by a separate action button.

Notice two other important changes. First, the `select` element now contains a blank first option. When a user visits the page, nothing is selected yet, so you should present a blank option to encourage the user to make a selection. (The function also makes sure that the user selects one of the color-valued items before it attempts to change the background color.)

Second, the `onload` event handler invokes the `seeColor()` method, passing as a parameter a reference to the `select` element. This forces any color selection to be carried out when the page is initially loaded. As an example, this might take place if you navigate to another page and then use the browser's Back button to return to the color page. Thus, if the `select` element choice persists, the background color is adjusted accordingly after the page loads.

LISTING 37-8

Triggering a Color Change from a Pop-Up Menu

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Color Changer 2</title>
```

```
      <script type="text/javascript">
         function seeColor(list)
         {
            var newColor = (list.options[list.selectedIndex].value);
               if (newColor)
               {
                  document.bgColor = newColor;
               }
         }
      </script>
   </head>
   <body onload="seeColor(document.getElementById('colorsList'))">
      <form>
         <p>Choose a background color:
            <select name="colorsList" id="colorsList" onchange="seeColor(this)">
               <option selected="selected" value=""></option>
               <option value="cornflowerblue">Cornflower Blue</option>
               <option value="darksalmon">Dark Salmon</option>
               <option value="lightgoldenrodyellow">Light Goldenrod Yellow</option>
               <option value="seagreen">Sea Green</option>
            </select>
         </p>
      </form>
   </body>
</html>
```

option Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Syntax

Accessing `option` object properties:

```
(All)        [window.]document.formName.selectName.options[index].property |
             method([parameters])
(All)        [window.]document.formName.elements[index].options
             [index].property  | method([parameters])
(All)        [window.]document.forms[index].selectName.options[index].property
             | method([parameters])
(All)        [window.]document.forms["formName"].selectName.options[index].
             property | method([parameters])
(All)        [window.]document.forms["formName"].elements[index].options
             [index].property | method([parameters])
(IE4+)       [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)   [window.]document.getElementById("elemID").property |
             method([parameters])
(W3C)        [window.]document.forms[index].selectName.item(index).property |
             method([parameters])
(W3C)        [window.]document.forms["formName"].selectName.namedItem(elemID).
             property | method([parameters])
```

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Safari+

About this object

`option` elements are nested inside `select` elements. Each option represents an item in the list of choices presented by the `select` element. Properties of the `option` element object let scripts inspect whether a particular option is currently selected or is the default selection. Other properties enable you to get or set the hidden value associated with the option as well as the visible text. For more details about the interaction between the `select` and `option` element objects, see the discussion about the `select` object earlier in this chapter as well as the discussion of the properties and methods associated with the `options` array returned by the `select` object's `options` property.

We discuss all backward-compatible `option` object properties (`defaultSelected`, `selected`, `text`, and `value`) among the `options` property descriptions in the `select` object section. The only items listed in this section are those that are unique to the `option` element object defined in newer browsers.

In all browsers dating back to NN3 and IE4, there is a provision for creating a new `option` object via an `Option` object constructor function. The syntax is as follows:

```
var newOption = new Option("text","value");
```

Here, *text* is the string that is displayed for the item in the list, and *value* is the string assigned to the `value` property of the new option. This new `option` object is not added to a `select` object until you assign it to a slot in the `options` array of the `select` object. You can see an example of this approach to modifying options in Listing 37-1.

Properties

label

Value: String Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `label` property corresponds to the HTML 4.01 `label` attribute of an `option` element. This attribute (and property) enables you to assign alternate text for an option. In MacIE5+, any string assigned to the `label` attribute or corresponding property overrides the display of text found between the start and end tags of the `option` element. Therefore, you can assign content to both the attribute and tag, but only browsers adhering to the HTML 4.01 standard for this element display the value assigned to the label. Although the `label` property is implemented in NN6, the browser does not modify the option item's text to reflect the property's setting. This problem is resolved in Moz+ browsers.

The following statement modifies the text that appears as the selected text in a pop-up list:

```
document.forms[0].mySelect.options[3].label = "Widget 9000";
```

If this option is the currently selected one, the text on the pop-up list at rest changes to the new label.

Related Item: `text` property

optgroup Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
form†		
label		

†See ''Text Input Object'' (Chapter 36, ''Text-Related Form Objects'').

Syntax

Accessing `optgroup` object properties:

```
(IE)        [window.]document.all.elemID".property | method([parameters])
(W3C)       [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

An optgroup element in the HTML 4.01 specification enables authors to group options into subgroups within a select list. The label assigned to the optgroup element is rendered in the list as a non-selectable item, usually differentiated from the selectable items by some alternate display. In W3C browsers, optgroup items by default are shown in bold italic, whereas all option elements nested within an optgroup are indented but with normal font characteristics.

Browsers not recognizing this element ignore it. All options are presented as if the optgroup elements are not there.

Properties

label

Value: String Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The label property corresponds to the HTML 4.01 label attribute of an optgroup element. This attribute (and property) enables you to assign text to the label that encompasses a group of nested option elements in the pop-up list display.

Note

MacIE5+ exhibits a bug that prevents scripts from assigning values to the last optgroup element inside a select element. ■

Listing 37-9 demonstrates how a script can alter the text of option group labels. This page is an enhanced version of the background color setters used in other examples of this chapter. Be aware that through Opera 9 and several versions of IE prior to IE7, the browser does not alter the last optgroup element's label, and NN6+ achieves only a partial change to the text displayed in the select element. Newer Mozilla-based browsers such as Firefox 1.5+ have no problems with the task.

LISTING 37-9

Modifying optgroup Element Labels

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Color Changer 3</title>
      <script type="text/javascript">
         var regularLabels = ["Reds","Greens","Blues"];
         var naturalLabels = ["Apples","Leaves","Sea"];
         function setRegularLabels(list)
```

```
      {
         var optGrps = list.getElementsByTagName("optgroup");
         for (var i = 0; i < optGrps.length; i++)
         {
            optGrps[i].label = regularLabels[i];
         }
      }
      function setNaturalLabels(list)
      {
         var optGrps = list.getElementsByTagName("optgroup");
         for (var i = 0; i < optGrps.length; i++)
         {
            optGrps[i].label = naturalLabels[i];
         }
      }
      function seeColor(list)
      {
         var newColor = (list.options[list.selectedIndex].value);
            if (newColor)
            {
               document.bgColor = newColor;
            }
      }
   </script>
</head>
<body onload="seeColor(document.getElementById('colorsList'))">
   <form>
      <p>Choose a background color:
         <select name="colorsList" id="colorsList" onchange="seeColor(this)">
            <optgroup id="optGrp1" label="Reds">
               <option value="#ff9999">Light Red</option>
               <option value="#ff3366">Medium Red</option>
               <option value="#ff0000">Bright Red</option>
               <option value="#660000">Dark Red</option>
            </optgroup>
            <optgroup id="optGrp2" label="Greens">
               <option value="#ccff66">Light Green</option>
               <option value="#99ff33">Medium Green</option>
               <option value="#00ff00">Bright Green</option>
               <option value="#006600">Dark Green</option>
            </optgroup>
            <optgroup id="optGrp3" label="Blues">
               <option value="#ccffff">Light Blue</option>
               <option value="#66ccff">Medium Blue</option>
               <option value="#0000ff">Bright Blue</option>
               <option value="#000066">Dark Blue</option>
            </optgroup>
         </select>
      </p>
      <p><input type="radio" name="labels" checked="checked"

Syntax

Accessing `file` input element object properties:

```
(NN3+/IE4+)    [window.]document.formName.inputName.property |
               method([parameters])
(NN3+/IE4+)    [window.]document.formName.elements[index].property |
               method([parameters])
(NN3+/IE4+)    [window.]document.forms[index].inputName.property |
               method([parameters])
(NN3+/IE4+)    [window.]document.forms["formName"].inputName.property |
               method([parameters])
```

```
(NN3+/IE4+)    [window.]document.forms["formName"].elements[index].property |
               method([parameters])
(IE4+)         [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)     [window.]document.getElementById("elemID").property |
               method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

Some web sites enable you to upload files from the client to the server, typically by using a form-style submission to a CGI program on the server. The `input` element whose type is set to `"file"` (also known as a `fileUpload` object) is merely a user interface that enables users to specify which file on their PC they want to upload. Without a server process capable of receiving the file, the `file` input element does nothing. Moreover, you must also set two `form` element attributes as follows:

```
method="post"
enctype="multipart/form-data"
```

This element displays a field and a Browse button. The Browse button leads to an Open File dialog box (in the local operating system's interface vernacular) where a user can select a file. After you make a selection, the filename (or pathname, depending on the operating system) appears in the `file` input element's field. The `value` property of the object returns the filename.

You do not have to script much for this object on the client side. The `value` property, for example, is read-only in earlier browsers; in addition, a form cannot surreptitiously upload a file to the server without the user's knowledge or consent.

Listing 37-10 helps you see what the `file` input element looks like in an example page.

LISTING 37-10

file Input Element

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>FileUpload Object</title>
   </head>
   <body>
      <form method="post" action="yourCGIURL" enctype="multipart/form-data">
         File to be uploaded: <input type="file" size="40" name="fileToGo" />
         <p><input type="button" value="View Value"
                  onclick="alert(this.form.fileToGo.value)" />
```

continued

LISTING 37-10 *(continued)*

```
         </p>
      </form>
   </body>
</html>
```

In a true production environment, a Submit button and a URL to your CGI process are specified for the `action` attribute of the `<form>` tag. You would also likely use the more modern (but more code intensive) event binding approach to handle the `onclick` event, as you've seen in other examples in this chapter — here it was more concise to stick with the simple attribute assignment technique.

CHAPTER

38

Style Sheet and Style Objects

IN THIS CHAPTER

Managing style sheets by script

Changing element styles on-the-fly

Distinguishing among style, styleSheet, and style objects

Style sheets promote a concept that makes excellent sense in the fast-paced, high-volume content creation environment that is today's World Wide Web: separating content from its rendering. Textual content may come from any number of electronic sources, but it may need to be dropped into different contexts — just like an online news feed that becomes amalgamated into dozens of web portal sites, each with its own look and feel. All the content author cares about is the text and its meaning; the web page designer then decides how that content should be rendered on the page.

The style sheet concept has other advantages. Consider the large corporate web site that wants to promote its identity through a distinct style. A family of style sheets can dictate the font face, font size, the look of emphasized text, and the margin width of all body text. To apply these styles on an element-by-element basis is not only a tedious page-authoring task; it is fraught with peril. If the style is omitted from the tags of one page, the uniformity of the look is destroyed. Worse yet, if the corporate design changes to use a different font face, the task of changing every style in every tag — even with a highly powered search-and-replace operation — is risky. But if a single external style sheet file dictates the styles, then the designer need make the change only in that one file to cause the new look to ripple through the entire web site.

Learning how to create and apply style sheets is beyond the scope of this book, and this chapter assumes you are already familiar with style sheet terminology, such as a style sheet rule and a selector. If these terms are not in your vocabulary, you can find numerous tutorials on the subject both online and in books. Although IE, Firefox, Camino, Safari, and other recent browsers adhere fairly closely to W3C standards for style sheets (called Cascading Style Sheets, or CSS for short), your first learning experience should come from sources that focus on standards, rather than browser-specific features. Microsoft includes some extras in the style sheet

vocabulary that work only on IE4+ for Windows; Firefox and other Mozilla-based browsers have specially named, preliminary properties that offer future CSS capabilities in advance of the final standards. Unless you develop for a single target browser brand and client operating system, learning the common denominator of style sheet features is the right way to go. Details in this chapter cover all versions, so pay close attention to compatibility listings for each item.

Making Sense of the Object Names

The first task in this chapter is to clarify the seemingly overlapping terminology for the style sheet-related objects that you will be scripting. Some objects are more abstract than others, but they are all important. The objects in question are

- `style` element object
- `styleSheet` object (a member of the `styleSheets` array)
- `rule` or `cssRule` object (a member of the `rules` or `cssRules` array)
- `style` object

A `style` element object is the object that represents the `<style>` tag in your document. Most of its properties are inherited from the basic HTML element objects you see detailed in Chapter 26, “Generic HTML Element Objects.” By and large, you won’t be reading or writing style sheet properties via the `style` element object.

A style sheet can be embedded in a document via the `<style>` tag, or it may be linked in via a `<link>` tag. One property of the `document` object, the `styleSheets` property, returns an array (collection) of all `styleSheet` objects that are currently “visible” to the document, whether or not they are disabled. Included in the collection are style sheets defined by a `<style>` tag or linked in via a `<link>` tag. Even though the `<style>` tag, for example, contains lines of code that make up the rules for a style sheet, the `style` element object is not the path to reach the individual rules. The `styleSheet` object is. It is through the `styleSheet` object that you can enable or disable an entire sheet, access individual rules (via the `rules` or `cssRules` property array), and add or delete rules for that style sheet.

The meat of any style sheet is the set of rules that define how elements are to be rendered. At this object level, the terminology forks in IE4 and NN6/Moz. The IE4+ object model calls each style sheet rule a rule object; the W3C DOM Level 2 model (in NN6+/Moz), calls each rule a `cssRule` object. MacIE5 and Safari support both references to the same object. Despite the incompatible object names, the two objects share key property names. Assembling a reference to a rule requires array references. For example, the reference to the first rule of the first `styleSheet` object in the document is as follows for various browsers:

```
var oneRule = document.styleSheets[0].rules[0];      // IE4+, MacIE5, Safari
var oneRule = document.styleSheets[0].cssRules[0];   // NN6+/Moz, MacIE5, Safari
```

The last object in this quartet of style-related objects is the `style` object. This object is the mother lode, where actual style definitions take place. In earlier chapters, you have seen countless examples of modifying one or more `style` properties of an element. Most typically, this

modification is accomplished through the `style` property of the HTML element. For example, you would set the font color of a `span` element whose ID is "hot" as follows:

```
document.getElementById("hot").style.color = "red";
```

The `style` object is also a property of a `rule`/`cssRule` object. Thus, if you need to modify the style of elements affected by an existing style sheet rule, you approach the `style` object through a different reference path, but the `style` object is treated just as it is for elements:

```
document.styleSheets[0].rules[0].style.color = "red";    // IE4+, MacIE5, Safari
document.styleSheets[0].cssRules[0].style.color = "red"; // NN6+/Moz, MacIE5
                                                          // Safari
```

Many scripters concern themselves solely with the `style` object, and at that, a `style` object associated with a particular element object. Rare are instances that require manipulation of `styleSheet` objects beyond enabling and disabling them under script control. Therefore, if you are learning about these objects for the first time, pay closest attention to the `style` object details rather than to the other related objects.

Imported Style Sheets

Style sheets embedded in a document via the `style` element can import additional style sheets via the `@import` selector:

```
<style type="text/css">
   @import url(externalStyle.css);
   p {font-size:16pt}
</style>
```

In this example scenario, the document sees just one `styleSheet` object. But that object has a style sheet nested inside — the style sheet defined by the external file. IE4+ calls one of these imported style sheets an `import` object. An `import` object has all the properties of any `styleSheet` object, but its `parentStyle` property is a reference to the `styleSheet` that "owns" the `@import` rule. In fact, the `@import` statement does not even appear among the rules collection of the IE `styleSheet` object. Therefore, to access the first rule of the imported style sheet, the reference is as follows:

```
document.styleSheets[0].imports[0].rules[0]
```

The W3C DOM and NN6+/Moz treat `import` rule objects differently from the IE model. To the W3C DOM, even an at-rule is considered one of the `cssRules` collections of a `styleSheet` object. One of the properties of a `cssRule` object is `type`, which conveys an integer code value revealing whether the rule is a plain CSS rule or one of several other types, including an `import` rule. Of course, an imported rule object then has as one of its properties the `styleSheet` object that, in turn, contains the rules defined in the external style sheet file. The parent-child relationship exists here, as well, whereby the style sheet that contains the `@import` rule is referenced by the imported `styleSheet` object's `parentStyle` property (just as in IE4+).

Reading Style Properties

Both the IE4+ and W3C object models exhibit a behavior that at first glance may seem disconcerting. On the one hand, the W3C, and good HTML practice, encourage defining styles remotely (that is, embedded via `<style>` or `<link>` tags) rather than as values assigned to the `style` attribute of individual element tags throughout the document. This more closely adheres to the notion of separating style from content.

On the other hand, object models can be very literal beasts. Strictly speaking, if an element object presents a scriptable property that reflects an attribute for that element's tag, the first time a script tries to read that property, a value will be associated with that property *only* if the attribute is explicitly assigned in the HTML code. But if you assign style sheet settings via remote style sheets, the values are not explicitly set in the tag. Therefore, the `style` property of such an element comes up empty, even though the element is under the stylistic control of the remote style sheet. If all you want to do is assign a new value to a style property, that's not a problem, because your assignment to the element object's `style` property overrides whatever style is assigned to that property in the remote style sheet (and then that new value is subsequently readable from the `style` property). But if you want to see what the current setting is, the initial value won't be in the element's `style` object.

Microsoft (in IE5+) and the W3C DOM provide competing (and incompatible) solutions to this problem.

IE5+ provides an extra read-only property — `currentStyle` — that reveals the style sheet values that are currently being applied to the element, regardless of where the style sheet definitions are. The `currentStyle` property returns an object that is in the same format and has most of the same properties as the regular `style` property. If your audience runs browsers no earlier than IE5, you should make a habit of reading styles for an element via its `currentStyle` property. If you want a change to a `style` object's property to apply to only one element, use the element's `style` property to set that value; but if the change is to apply to all elements covered by the same remote style sheet rule, modify the `style` property of the rule object.

The W3C DOM solution is the `getComputedStyle()` method. Although the W3C DOM doesn't (yet) talk about a `window` object, it does describe an object (called the `defaultView`) which Mozilla-based browsers channel through the `window` object. The truly W3C standard way to access this method (supported by Mozilla-based and WebKit-based browsers) is via the `document.defaultView` object. To read the value of a particular style property being applied to an element, you first retrieve a *computed style* value for the element, and then read the desired CSS style property. For example, to read the `font-family` currently applied to an element whose ID is `myP`, use the following sequence:

```
var elem = document.getElementById("myP");
var computedStyle = document.defaultView.getComputedStyle(elem, "");
var fontFam = computedStyle.getPropertyValue("font-family");
```

Note that you must use the CSS property name (for example, `font-family`) and not the scripted equivalent of that property (for example, `fontFamily`).

style Element Object

See Chapter 26, "Generic HTML Element Objects," for items shared by all HTML elements.

Properties	Methods	Event Handlers
media		
type		

Syntax

Accessing `style` element object properties and methods:

```
(IE4+)        document.all.objectID.property | method([parameters])
(IE5+/W3C)    document.getElementById(objectID).property | method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

The `style` element is part of the classification of HTML directive elements (see Chapter 40, "HTML Directive Objects") in that it goes in the `head` portion of a document and does not have any of its own content rendered in the page. But the style element's contents obviously have a great amount of control over the rendering of other elements. Most of the properties, methods, and event handlers that the `style` element inherits from all HTML elements are irrelevant.

One exception is the Boolean `disabled` property. Although there are additional ways to disable a style sheet (the `disabled` property of the `styleSheet` object, for example), it may be easier to disable or enable a style sheet by way of the `style` element object. Because you can assign an ID to this element and reference it explicitly, doing so may be more convenient than trying to identify which `styleSheet` object among the document's `styleSheets` collection you intend to enable or disable.

Properties

media

Value: String — Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `media` property represents the `media` attribute of a `style` element. This attribute can define what kind of output device is governed by the style sheet. The HTML 4.0 specification has lofty goals for this attribute, but most browsers are limited to the following values: `screen`, `print`, and `all`. Thus, you can design one set of styles to apply when the page is viewed on the computer screen and a different set for when it's printed.

Other types that may eventually enter the picture with the `media` property include `braille`, `embossed`, `handheld`, `projection`, `speech`, `tty`, and `tv`. Web development tools have already begun offering support for these property values. For example, Dreamweaver 8 has a special toolbar that allows you to access all of the previously listed `media` types except for `aural`, `braille`, and `embossed`. Opera is currently the only browser to support `media` property settings beyond `screen`, `print`, and `all`. In Opera, you can also specify `projection`, `handheld`, `speech`, and `tv`.

type

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `type` property represents the `type` attribute of the `style` element. For Cascading Style Sheets, this property is always set to `text/css`. If your scripts assign some other value to this property and the browser does not support that style sheet type, the style sheet no longer functions as a Cascading Style Sheet, and any styles it controls revert to their default styles.

styleSheet Object

Properties	Methods	Event Handlers
`cssRules`	`addImport()`	
`cssText`	`addRule()`	
`disabled`	`deleteRule()`	
`href`	`insertRule()`	
`id`	`removeRule()`	
`imports`		
`media`		
`ownerNode`		
`ownerRule`		
`owningElement`		
`pages`		
`parentStyleSheet`		
`readOnly`		
`rules`		
`title`		
`type`		

Syntax

Accessing `styleSheet` object properties and methods:

```
(IE4+/W3C)    document.styleSheets[index].property | method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

If the `style` element object is the concrete incarnation of a style sheet, then the `styleSheet` object is its abstract equivalent. A `styleSheet` object exists by virtue of a style sheet definition being embedded in the current document, either by way of the `<style>` tag or linked in from an external file via the `<link>` tag. Each element that introduces a style sheet into a document creates a separate `styleSheet` object. Access to a `styleSheet` object is via the `document.styleSheets` array. If the document contains no style sheet definitions, then the array has a length of zero. Styles that are introduced into a document by way of an element's `style` attribute are not considered `styleSheet` objects.

Although both IE4+ and W3C DOM browsers present `styleSheet` objects — and the object represents the same "thing" in both browser families — the set of properties and methods diverges widely between browsers. In many cases, the object provides the same information but through differently named properties in the two families. Interestingly, on some important properties, such as the ones that return the array of style rules and a reference to the HTML element that is responsible for the style sheet's being in the document, MacIE5 and Safari provide both the Microsoft and W3C terminology. Methods for this object focus on adding rules to and deleting rules from the style sheet. For the most part, however, your use of the `styleSheet` object will be as a reference gateway to individual rules (via the `rules` or `cssRules` array).

Properties

cssRules

Value: Array of rule objects Read-Only

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari+, Opera9+, Chrome+

The `cssRules` property returns an array of style sheet rule objects. Strictly speaking, the objects are called `cssRule` objects in the W3C DOM terminology. This property is implemented in MacIE5, but not in the Windows version as of IE7. The list of rule objects is in source code order. The corresponding WinIE4+ property is `rules`.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to look at the `cssRules` property in W3C/Moz browsers or MacIE5. First, view how many rules are in the first `styleSheet` object of the page by entering the following statement into the top text box:

```
document.styleSheets[0].cssRules.length
```

Now use the array with an index value to access one of the rule objects and view the rule object's properties list. Enter the following statement into the bottom text box:

```
document.styleSheets[0].cssRules[1]
```

You use this syntax to modify the style details of an individual rule belonging to the `styleSheet` object.

Keep in mind that you can access the same information in WinIE by changing the example code to use the `rules` property instead of `cssRules`.

Related Items: `rules` property; `cssRule`, `rule` objects

cssText

Value: String Read/Write

Compatibility: WinIE5+, MacIE5, NN-, Moz-, Safari-, Opera-, Chrome-

The `cssText` property contains a string of all style sheet rules included in the `styleSheet` object. Parsing this text in search of particular strings is not wise because the text returned by this property can have carriage returns and other formatting that is not obvious from the text that is assigned to the rules in the style sheet. But you can use this property as a way to completely rewrite the rules of a style sheet in a rather brute-force manner: Assemble a string consisting of all the new rules and assign that string to the `cssText` property. The more formal way of modifying rules (by adding and removing them) is perhaps better form, but there is no penalty for using the `cssText` property if your audience is strictly IE5+.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") in WinIE to replace the style rules in one blast via the `cssText` property. Begin by examining the value returned from the property for the initially disabled style sheet by entering the following statement into the top text box:

```
document.styleSheets[0].cssText
```

Next, enable the style sheet so that its rules are applied to the document:

```
document.styleSheets[0].disabled = false
```

Finally, enter the following statement into the top text box to overwrite the style sheet with entirely new rules:

```
document.styleSheets[0].cssText = "p {color:red}"
```

Reload the page after you are finished to restore the original state.

Related Items: `addRule()`, `deleteRule()`, `insertRule()`, `removeRule()` methods

disabled

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

While the `disabled` property of the `style` element object works with that element only, the `styleSheet` object's `disabled` property works with a `styleSheet` object that comes into the document by a `link` element as well.

Enabling and disabling style sheets is one way to swap different appearance styles for a page, allowing the user to select the preferred style. The page can contain multiple style sheets that control the same selectors, but your script can enable one and disable another to change the overall style. You can even perform this action via the `onload` event handler. For example, if you have separate style sheets for Windows and Mac browsers, you can put both of them in the document, both initially disabled. An `onload` event handler determines the operating system and enables the style sheet tailored for that OS. Unless your style sheets are very extensive, there is little download performance penalty for having both style sheets in the document.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to toggle between the enabled and disabled state of the first `styleSheet` object on the page. Enter the following statement into the top text box:

```
document.styleSheets[0].disabled = (!document.styleSheets[0].disabled)
```

The inclusion of the NOT operator (`!`) forces the state to change from `true` to `false` or `false` to `true` with each click of the Evaluate button.

Related Item: `disabled` property of the `style` element object

`href`

Value: String　　　　Read/Write (See Text)

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera9+, Chrome+

When a style sheet is linked into a document via a `link` element, the `href` property of the `styleSheet` object contains a string with the URL to that file. Essentially, the `href` property of the `link` element is passed along to the `styleSheet` object that loads as a result. In WinIE4+ only, this property is read/write, allowing you to dynamically link in an external style sheet file after the page has loaded. In MacIE and NN6+/Moz, this property is read-only.

Related Item: `link` element object

`id`

Value: String　　　　Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `id` property of a `styleSheet` object inherits the `id` property of its containing element (the `style` or `link` element). This can get confusing, because it may appear as though two objects in the document have the same ID. The `id` string, however, can be used as an index to the `document.styleSheets` array in IE4+ (for example, `document.styleSheets["myStyle"]`). NN/Moz does not provide a comparable identifier associated with a `styleSheet` object.

Related Item: `id` property of all element objects

imports

Value: Array of `styleSheet` objects Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

A style sheet can contain one or more `@import` rules to import an external style sheet file into the document. Each imported `styleSheet` object is treated as an `import` object. The `imports` property is a collection of all imported `styleSheet` objects that belong to the current `styleSheet` object. Imported style sheets are not added to the `document.styleSheets` collection, so that references to an imported `styleSheet` object must be through the `document.styleSheets[i].imports[i]` array.

An `import` object is, itself, a `styleSheet` object. All properties and methods applicable to a `styleSheet` object also apply to an `import` object. Therefore, if you want to load a different external style sheet into the page, you can assign the new URL to the imported `styleSheet` object's `href` property:

```
document.styleSheets[0].imports[0].href = "alternate.css";
```

Modifications of this nature work in IE for Windows, but not in MacIE.

Related Item: `styleSheet` object

media

Value: See text Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Cascading Style Sheets can be defined to apply to specific output media, such as the video display screen, printer, and, in the future, devices such as speech synthesizers or Braille generators. A style sheet gets this direction from the `media` attribute of a `style` or `link` element. That value is represented in the `media` property of the `styleSheet` object.

In IE4+, the `media` property value is a string with one of three possible values: `screen`, `printer`, or `all`. The W3C DOM and NN6+ take this one step further by allowing for potentially multiple values being assigned to the `media` attribute. The W3C value is an array of string media names (returned in an object called a `mediaList`).

Related Item: `type` property of the `style` element object

ownerNode

Value: Node reference Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `ownerNode` property is a reference to the document node in which the `styleSheet` object is defined. For `styleSheet` objects defined inside `style` and `link` elements, the `ownerNode`

property is a reference to that element. The corresponding property in IE4+ is owningElement. Oddly, MacIE5 has an additional, misnamed property called owningNode, whose value equals that of the owningElement property.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") with NN6+/Moz, and Gecko-, WebKit-, and Presto-based browsers to inspect the ownerNode of the first styleSheet object in the document. Enter the following statement into the top text box:

```
document.styleSheets[0].ownerNode.tagName
```

The returned value is the style element tag name.

Related Items: ownerRule, owningElement properties

ownerRule

Value: cssRule object Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The ownerRule property applies to a styleSheet object that has been imported into a document via the @import rule. The property returns a reference to the @import rule responsible for loading the external style sheet. There is an interaction between the ownerRule and ownerNode properties in that an imported rule has an ownerRule, but its ownerNode property is null; conversely, a regular styleSheet has an ownerNode, but its ownerRule property is null.

Related Item: ownerNode property

owningElement

Value: Element reference Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The owningElement property is a reference to the element object in which the styleSheet object is defined. For styleSheet objects defined inside style and link elements, the owningElement property is a reference to that element. The corresponding property in W3C is ownerNode. Oddly, MacIE5 has an additional, misnamed property called owningNode, whose value equals that of the owningElement property.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") with IE4+ to inspect the owningElement of the first styleSheet object in the document. Enter the following statement into the top text box:

```
document.styleSheets[0].owningElement.tagName
```

The returned value is the style element tag name.

Related Item: `ownerNode` property

pages

Value: Array of `@page` rules Read-Only

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

An `@page` style rule defines the dimensions and margins for printed versions of a web page. The `pages` property returns a collection of `@page` rules contained by the current `styleSheet` object. If no `@page` rules are defined in the style sheet, the array has a length of zero.

While an `@page` rule has the same properties as any rule object, it has one more read-only property, the `pseudoClass` property, which returns any pseudo-class definitions in the rule. For example, the following `@page` rules define different rectangle specifications for the left and right printed pages:

```
@page :left {margin-left:4cm; margin-right:3cm;}
@page :right {margin-left:3cm; margin-right:4cm;}
```

Values for the `pseudoClass` property of these two page rules are `:left` and `:right`, respectively.

To the W3C DOM, an `@page` rule is just another rule object, but one whose `type` property returns `page`.

For more information about the paged media specification, see `http://www.w3.org/TR/CSS2/page.html`.

Related Items: None

parentStyleSheet

Value: `styleSheet` object Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera-, Chrome-

An imported style sheet is present thanks to the hosting of a `styleSheet` object created by a `style` or `link` element. That host `styleSheet` object is referenced by the `parentStyleSheet` property. For most `styleSheet` objects (that is, those not imported via the `@import` rule), the `parentStyleSheet` property is `null`. Take note of the distinction between the `parentStyleSheet` property, which points to a `styleSheet` object, and the various properties that refer to the HTML element that "owns" the `styleSheet` object.

Related Items: None

readOnly

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `readOnly` property's name is a bit misleading. Its Boolean value lets your script know whether the current style sheet was embedded in the document by way of the `style` element or

brought in from an external file via the `link` element or `@import` rule. When embedded by a `style` element, the `readOnly` property is `false`; for style sheets defined outside the page, the property is `true`. But a value of `true` doesn't mean that your scripts cannot modify the style properties. Style properties can still be modified on-the-fly, but of course the changes will not be reflected in the external file from which the initial settings came.

Related Item: `owningElement` property

rules

Value: Array of `rule` objects Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera-, Chrome+

The `rules` property returns an array of all rule objects (other than @ rules) defined in the current style sheet. The order of rule objects in the array is based on the source code order of the rules defined in the `style` element or in the external file.

Use the `rules` array as the primary way to reference an individual rule inside a style sheet. If you use a `for` loop to iterate through all rules in search of a particular rule, you will most likely be looking for a match of the rule object's `selectorText` property. This assumes, of course, that each selector is unique within the style sheet. Using unique selectors is good practice, but no restrictions prevent you from reusing a selector name in a style sheet to apply additional style information to the same selector elements.

The corresponding property name for W3C is `cssRules`. MacIE5 and WebKit-based browsers respond to both the `rules` and `cssRules` properties.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") with IE4+ to examine the `rules` property of the first `styleSheet` object in the page. First, find out how many rules are in the `styleSheet` object by entering the following statement into the top text box:

```
document.styleSheets[0].rules.length
```

Next, examine the properties of one of the rules by entering the following statement into the bottom text box:

```
document.styleSheets[0].rules[1]
```

You now see all the properties that IE4+ exposes for a rule object.

Related Items: `rule` object; `cssRules` property

title

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

If you assign a value to the `title` attribute of a `style` element, or to a `link` element that loads a style sheet, that string value filters down to the `title` property of the `styleSheet` object.

You can use the string value as a kind of identifier, but it is not usable as a true identifier as an index to the `styleSheets` array. In visible HTML elements, the `title` attribute usually sets the text that displays with the tooltip over the element. But for the unseen `style` and `link` elements, the attribute has no impact on the rendered display of the page. Therefore, you can use this attribute and corresponding property to convey any string value you want.

Related Item: `title` property of all HTML elements

type

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `type` property of a `styleSheet` object picks up the `type` attribute of the `style` or `link` element that embeds a style sheet into the page. Unless you are experimenting with some new types of style sheet language (assuming it is supported in the browser), the value of the type property is `text/css`.

Related Items: None

Methods

addImport("*URL*"[, *index*])

Returns: Integer

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `addImport()` method lets you add an `@import` rule to a `styleSheet` object. A required first parameter is the URL of the external `.css` file that contains one or more style sheet rules. If you omit the second parameter, the `@import` rule is appended to the end of the rules in the `styleSheet` object. Or, you can specify an integer as the index of the position within the rules collection where the rule should be inserted. The order of rules in a `styleSheet` object can influence the cascading order of overlapping style sheet rules (that is, multiple rules that apply to the same elements).

The value returned by the method is an integer representing the index position of the new rule within the rules collection of the `styleSheet`. If you need subsequent access to the new rule, you can preserve the value returned by the `addImport()` method and use it as the index to the `rules` collection.

Related Item: `addRule()` method

addRule("*selector*", "*styleSpec*"[, *index*])
removeRule(*index*)

Returns: Integer (for `addRule()`)

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera-, Chrome+

The addRule() method appends or inserts a style sheet rule into the current styleSheet object. The first two parameters are strings for the two components of every rule: the selector and the style specification. Any valid selector, including multiple, space-delimited selectors, is permitted. For the style specification, the string should contain the semicolon-delimited list of style attribute:value pairs, but without the curly braces that surround the specification in a regular style sheet rule.

If you omit the last parameter, the rule is appended to the end of the rules collection for the style sheet. Or, you can specify an integer index value signifying the position within the rules collection where the new rule should go. The order of rules in a styleSheet object can influence the cascading order of overlapping style sheet rules (meaning multiple rules that apply to the same elements).

The return value conveys no meaningful information.

To remove a rule from a styleSheet object's rules collection, invoke the removeRule() method. Exercise some care here, because you must have the correct index value for the rule that you want to remove. Your script can use a for loop to iterate through the rules collection, looking for a match of the selectorText property (assuming that you have unique selectors). The index for the matching rule can then be used as the parameter to removeRule(). This method returns no value.

For W3C, the corresponding methods are called insertRule() and deleteRule().

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") with IE4+ to add a style sheet rule to the first styleSheet object of the page. First, make sure the style sheet is enabled by entering the following statement into the top text box:

```
document.styleSheets[0].disabled = false
```

Next, append a style that sets the color of the textarea element:

```
document.styleSheets[0].addRule("textarea", "color:red")
```

Enter any valid object (such as document.body) into the bottom text box to see how the style has been applied to the textarea element on the page.

Now remove the style, using the index of the last item of the rules collection as the index:

```
document.styleSheets[0].removeRule(document.styleSheets[0].rules.length - 1)
```

The text in the textarea returns to its default color.

Related Items: deleteRule(), insertRule() methods

deleteRule(*index*)
insertRule("*rule*", *index*)

Returns: Integer (for `insertRule()`)

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

The `insertRule()` method appends or inserts a style sheet rule into the current `styleSheet` object. The first parameter is a string containing the style rule as it would normally appear in a style sheet, including the selector and curly braces surrounding the semicolon-delimited list of style `attribute:value` pairs.

You must supply an index location within the `cssRules` array where the new rule is to be inserted. If you want to append the rule to the end of the list, use the `length` property of the `cssRules` collection for the parameter. The order of rules in a `styleSheet` object can influence the cascading order of overlapping style sheet rules (meaning multiple rules that apply to the same elements).

The return value is an index for the position of the inserted rule.

To remove a rule from a `styleSheet` object's `cssRules` collection, invoke the `deleteRule()` method. Exercise some care here, because you must have the correct index value for the rule that you want to remove. Your script could use a `for` loop to iterate through the `cssRules` collection, looking for a match of the `selectorText` property (assuming that you have unique selectors). The index for the matching rule can then be used as the parameter to `deleteRule()`. This method returns no value.

For IE4+, the corresponding methods are called `addRule()` and `removeRule()`.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") with NN6+/Moz to add a style sheet rule to the first `styleSheet` object of the page. First, make sure the style sheet is enabled by entering the following statement into the top text box:

```
document.styleSheets[0].disabled = false
```

Next, append a style that sets the color of the `textarea` element:

```
document.styleSheets[0].insertRule("textarea {color:red}",
document.styleSheets[0].cssRules.length)
```

Enter any valid object (such as `document.body`) into the bottom text box to see how the style has been applied to the `textarea` element on the page.

Now remove the style, using the index of the last item of the rules collection as the index:

```
document.styleSheets[0].deleteRule(document.styleSheets[0].cssRules.length - 1)
```

Related Items: `addRule()`, `removeRule()` methods

cssRule and rule Objects

Properties	Methods	Event Handlers
`cssText`		
`parentStyleSheet`		
`readOnly`		
`selectorText`		
`style`		
`type`		

Syntax

Accessing `rule` or `cssRule` object properties:

```
(IE4+)          document.styleSheets[index].rules[index].property
(MacIE5/W3C)    document.styleSheets[index].cssRules[index].property
```

About these objects

The `rule` and `cssRule` objects are different object model names for the same objects. For IE4+, the object is known as a *rule* (and a collection of them, the `rules` collection); for NN6+/Moz-/Safari (and MacIE5), the object follows the W3C DOM recommendation, calling the object a *cssRule* (and a collection of them the `cssRules` collection). For the remainder of this section, they will be referred to generically as the `rule` object.

A rule object has two major components. The first is the selector text, which governs which element(s) are to be influenced by the style rule. The second component is the style definition, with its set of semicolon-delimited `attribute:value` pairs. In both the IE4+ and NN6+/Moz/W3C object models, the style definition is treated as an object: the `style` object, which has tons of properties representing the style attributes available in the browser. The `style` object that belongs to a rule object is precisely the same `style` object that is associated with every HTML element object. Accessing `style` properties of a style sheet rule requires a fairly long reference, as in

```
document.styleSheets[0].rules[0].style.color = "red";
```

but the format follows the logic of JavaScript's dot-syntax to the letter.

Properties

`cssText`

Value: String — Read/Write

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cssText` property returns the full text of the current `cssRule` object. While the text returned from this property can be parsed to locate particular strings, it is easier and more reliable to access individual style properties and their values via the `style` property of a `cssRule` object.

Related Item: `style` property

parentStyleSheet

Value: `styleSheet` object Read-Only

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

The `parentStyleSheet` property is a reference to the `styleSheet` object that contains the current `cssRule` object. The return value is a reference to a `styleSheet` object, from which scripts can read and write properties related to the entire style sheet.

Related Item: `parentRule` property

readOnly

Value: Boolean Read-Only

Compatibility: WinIE5+, MacIE5, NN-, Moz-, Safari-, Opera-, Chrome-

The `readOnly` property's name is a bit misleading. Its Boolean value lets your script know whether the current rule's `styleSheet` was embedded in the document by way of the `style` element or brought in from an external file via the `link` element or `@import` rule. When embedded by a `style` element, the `readOnly` property is false; for style sheets defined outside the page, the property is `true`. But a value of `true` doesn't mean that your scripts cannot modify the style properties. Style properties can still be modified on-the-fly, but of course the changes are not reflected in the external file from which the initial settings came.

Related Item: `styleSheet.readOnly` property

selectorText

Value: String Read-Only

Compatibility: WinIE5+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

The `selectorText` property returns only the selector portion of a style sheet rule. The value is a string, and if the selector contains multiple, space-delimited items, the `selectorText` value returns the same space-delimited string. For selectors that are applied to classes (preceded by a period) or IDs (preceded by a crosshatch), those leading characters are returned as part of the string as well.

If you want to change the selector for a rule, removing the original rule and adding a new one in its place is better. You can always preserve the `style` property of the original rule and assign the style to the new rule.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to examine the `selectorText` property of rules in the first `styleSheet` object of the page. Enter each of the following statements in the top text box:

```
document.styleSheets[0].rules[0].selectorText
document.styleSheets[0].rules[1].selectorText
```

Compare these values against the source code view for the `style` element in the page.

Related Item: `style` property

style

Value: `style` object Read/Write

Compatibility: WinIE5+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

The `style` property of a rule (or `cssRule`) is, itself, an object whose properties consist of the CSS style properties supported by the browser. Modifying a property of the `style` object requires a fairly long reference, as in

```
document.styleSheets[0].rules[0].style.color = "red";
```

Any change you make to the rule's `style` properties is reflected in the rendered style of whatever elements are denoted by the rule's selector. If you want to change the style of just one element, access the `style` property of just that element. Style values applied directly to an element override whatever style sheet style values are associated with the element.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to modify a `style` property of one of the `styleSheet` rules in the page. The syntax shown here is for IE4+, but you can substitute the `cssRules` reference for the `rules` collection reference in NN6+/Moz, MacIE5, and W3C browsers if you like.

Begin by reloading the page and making sure the style sheet is enabled. Enter the following statement into the top text box:

```
document.styleSheets[0].disabled = false
```

The first rule is for the `myP` element on the page. Change the rule's `font-size` style:

```
document.styleSheets[0].rules[0].style.fontSize = "20pt"
```

Look over the `style` object properties in the discussion of the `style` object later in this chapter, and have fun experimenting with different style properties. After you are finished, reload the page to restore the styles to their default states.

Related Item: `style` object

type

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The W3C DOM defines several classes of style sheet rules. To make it easier for a script to identify the kind of `cssRule` it is working with, the `type` property returns an integer whose value is associated with one of the known `cssRule` types. While not all of these rule types may be implemented in current browsers, the complete W3C DOM list is as follows:

Type	Description
0	Unknown type
1	Regular style rule
2	@charset rule
3	@import rule
4	@media rule
5	@font-face rule
6	@page rule

Most of the style sheet rules you work with are type 1. To learn more about these rule types, consult the W3C specification for CSS at `http://www.w3.org/TR/CSS2`.

Related Items: None

currentStyle, runtimeStyle, and style Objects

Properties	Methods	Event Handlers
See the following text.		

Syntax

Accessing `currentStyle`, `runtimeStyle`, or `style` object properties:

```
(IE4+/W3C)       elementReference.style.property
(IE4+/W3C)       document.styleSheets[index].style.property
(IE5+)           elementReference.currentStyle.property
(IE5.5+)         elementReference.runtimeStyle.property
```

About these objects

All three of these objects — `currentStyle`, `runtimeStyle`, and `style` — return an object that contains dozens of properties related to style sheet specifications associated either with a `styleSheet` object (for the `style` object only) or any rendered HTML element object. With the browser page reflow facilities of modern browsers, changes made to the properties of the `style` and IE-specific `runtimeStyle` objects are reflected immediately by the rendered content on the page.

The primary object, the `style` object, is accessed as a property of an HTML element object. It is vital to remember that style properties of an HTML element are reflected by the `style` object only if the specifications are made via the `style` attribute inside the element's tag. If your coding style requires that style sheets be applied via `style` or `link` tags, and if your scripts need to access the `style` property values as set by those style sheets, then you must read the properties of the effective style sheet through the read-only `currentStyle` property (available in IE5+) or the W3C DOM `window.getComputedStyle()` method (NN6+/Moz, and Gecko-, WebKit-, and Presto-based browsers).

IE's `currentStyle` object does not have precisely the same properties as its `style` object. Missing from the `currentStyle` object are the properties that contain combination values, such as `border` or `borderBottom`. On the other hand, `currentStyle` provides separate properties for each of the sides of a clipping rectangle (`clipTop`, `clipRight`, `clipBottom`, and `clipLeft`), which the `clip` property does not provide.

Microsoft introduced one more flavor of style object — the `runtimeStyle` object — in IE5.5. This object lets scripts override any style property that is set in a style sheet or via the `style` attribute. In other words, the `runtimeStyle` object is like a read/write version of `currentStyle`, except that assigning a new value to one of its properties does not modify the style sheet definition or the value assigned in a `style` attribute. By and large, however, your scripts will modify the `style` property of an element to make changes, unless you modify styles by enabling and disabling style sheets (or changing the `className` property of an element so that it is under the control of a different selector).

Style properties

If you add up all the `style` object properties available in browsers starting with IE4 and NN6/Moz, you have a list approximately 180 properties long. A sizable percentage are in common among all browsers and are scriptable versions of W3C Cascading Style Sheet properties. The actual CSS property names are frequently script-unfriendly in that multiple-word properties have hyphens in them, such as `font-size`. JavaScript identifiers do not allow hyphens, so multiple-word properties are converted to camelCase versions, such as `fontSize`.

Not all style properties are supported by all browsers that have the `style` object in their object models. Microsoft, in particular, has added many properties that are sometimes unique to IE, and sometimes unique to just IE for Windows. On the Mozilla side, you find some properties that appear to be supported by the `style` object, but the browser doesn't genuinely support the attributes. For example, the CSS specification defines several attributes that enhance the

delivery of content rendered through a speech synthesizer. Although Firefox doesn't qualify, the Gecko browser engine at its core could be adapted to such a browser. Therefore, if you see a property in the following listings that doesn't make sense to you, test it out in the compatible browsers to verify that it works as you need it. You will also find some properties that are proprietary to Mozilla-based browsers — properties that begin with `moz`. These properties are preliminary implementations of as yet unreleased CSS Level 3 properties. The `moz` prefix lets you use these properties today without conflicting with future, sanctioned implementations of the properties (which won't have the `moz` prefix). When specifying these properties in CSS syntax for your style sheets, the properties begin with the special prefix `-moz-`, as in `-moz-opacity` (and the scripted equivalent, `mozOpacity`).

Some browsers also expose advanced `style` object properties to scripters, when, in fact, they are not genuinely supported in the browser. For example, an inspection of the `style` object for MacIE5 and NN6+/Moz shows a `quotes` property, which matches the `quotes` style property in the W3C CSS2 specification. But in truth, the `quotes` style property cannot be set by script in these browsers. When you see that a property is supported by MacIE5 and NN6+/Moz but not others, testing out the `style` property (and the style sheet attribute as well) in The Evaluator is a good idea before attempting to employ the property in your application.

With so many properties associated with an object, it may be difficult to locate the specific property you need for a particular style effect. To help you locate properties, the listings that follow are divided into functional categories, ordered by popularity:

Category	Description
Text & Fonts	Font specifications, text rendering, text alignment
Inline Display & Layout	Element flow, alignment, and display
Positioning	Explicit positioning of ''layers''
Background	Background images and colors
Borders & Edges	Borders, padding, and margins around elements
Lists	Details for `ul` and `ol` elements
Scroll bars	Scroll bar colors (WinIE5.5+ only)
Tables	Details for `table` elements and components
Printing	Page breaks and alignment for printed pages
Miscellaneous	Odds and ends
Aural	For rendering via speech-synthesis

Property values

All `style` object property values are strings. Moreover, many groups of style properties share the same format for their values. Knowing the formats for the frequently used values is helpful.

The purpose of this chapter is not to teach you about style sheets but to show you how to script them. Therefore, if you see unfamiliar terminology here, consult online or print instructional material about Cascading Style Sheets.

Length

Values for length cover a wide range, but they all define an amount of physical space in the document. Because content can be displayed on a video monitor or printed on a sheet of paper, any kind of length value should include a unit of measure as well as a quantity. One group of units (`px`, `em`, `ex`) are considered *relative* units, because the precise size depends on factors beyond the control of the style sheet (for example, the pixel density of the display) or units set by elements with more global scope (for example, a `p` element's margin `em` length is dependent upon the `body` element's font-size setting). *Absolute* units (`in`, `cm`, `mm`, `pi`, `pt`) are more appropriate for printed output. Length units are referenced in script according to the following table:

Unit	Script Version	Example
Pixel	`px`	`14px`
Em	`em`	`1.5em`
Ex	`ex`	`1.5ex`
Inch	`in`	`3.0in`
Centimeter	`cm`	`4.0cm`
Millimeter	`mm`	`40mm`
Pica	`pi`	`72pi`
Point	`pt`	`14pt`

A length value can also be represented by a percentage as a string. For example, the `lineHeight` style for a paragraph would be set to `120%` of the font size established for the paragraph by the following statement:

```
document.getElementById("myP").style.lineHeight = "120%";
```

Style inheritance — an important CSS concept — often has significant impact on style properties whose values are lengths.

Color

Values for colors can be one of three types:

- RGB values (in a few different formats)
- plain-language versions of the color names
- plain-language names of system user interface items

RGB values can be expressed as hexadecimal values. The most common way is with a crosshatch character followed by six hex numbers, as in `#ff00ff` (letters can be uppercase or lowercase). A special shortcut is also available to let you specify three numbers with the assumption that they will be expanded to pairs of numbers. For example, a color of `#f0f` is expanded internally to be `#ff00ff`.

An alternative RGB expression is with the `rgb()` prefix and three numbers (from 0 to 255) or percentages corresponding to the red, green, and blue components of the color. Here are a couple of examples:

```
document.styleSheets[0].rules[0].style.color = "rgb(0, 255, 0)";
document.styleSheets[0].rules[0].style.color = "rgb(0%, 100%, 0%)";
```

Browsers also respond to a long list of plain-language color names originally adopted from the X Window System palette by Netscape, and now known as X11 colors. You can see the list with sample colors at `http://en.wikipedia.org/wiki/X11_color_names`. Not all of those colors are necessarily part of what are known as "web safe" colors. For a demonstration of web safe colors, visit `http://www.lynda.com/hexh.html`. Of course, it's worth noting that "web safe" colors only enter the picture when a user is limited to an 8-bit (256) color display, which is rare these days.

The last category of color values references user interface pieces, many of which are determined by the user's control panel for video display. The string values correspond to recognizable UI components (also called system colors), as follows:

```
activeborder
activecaption
appworkspace
background
buttonface
buttonhighlight
buttonshadow
buttontext
captiontext
graytext
highlight
highlighttext
inactiveborder
inactivecaption
inactivecaptiontext
infobackground
infotext
menu
menutext
scrollbar
threeddarkshadow
threedface
threedhighlight
```

```
threedlightshadow
threedshadow
window
windowframe
windowtext
```

Using these color settings may be risky for public sites, because you are at the mercy of the color settings the user has chosen. For a corporate environment where system installations and preferences are strictly controlled, these values could help define a safe color scheme for your pages.

Rectangle sides

Many style properties control the look of sides of rectangles (for example, thickness of a border around a block element). In most cases, the style values can be applied to individual sides or combinations of sides, depending on the number of values supplied to the property. The number of values affects the four sides of the rectangle according to the following matrix:

Number of Values	Impact
1	All four sides set to the one value
2	Top and bottom sides set to first value; left and right sides set to second value
3	Top side set to first value; left and right sides set to second value; bottom side set to third value
4	Top, right, bottom, and left sides set to individual values in that order

For example, to set the border color of an element so that all sides are red, the syntax is

```
elementRef.style.borderColor = "red";
```

To set the top and bottom to red but the left and right to green, the syntax is

```
elementRef.style.borderColor = "red green";
```

Properties that accept these multiple values cover a wide range of styles. Values may be colors, lengths, or selections from a fixed list of possible values.

Combination values

Another category of style values includes properties that act as shortcuts for several related properties. For example, the `border` property encompasses the `borderWidth`, `borderStyle`, and `borderColor` properties. This is possible because very different classes of values represent the three component properties: `borderWidth` is a length; `borderStyle` is based on a fixed list of values; and `borderColor` is a color value. Therefore, you can specify one or more of these property values (in any order), and the browser knows how to apply the values to the detailed

subproperty. Only one value is permitted for any one of these subproperties, which means that if the property is one of the four-sided styles described in the previous section, the value is applied to all four sides equally.

For example, setting the `border` property to a single value, as in

```
elementRef.style.border = "blue";
```

is the same as setting the border color:

```
elementRef.style.borderColor = "blue";
```

But if you set multiple items, as in

```
elementRef.style.border = "groove blue 3px";
```

then you have set the equivalent of the following three statements:

```
elementRef.style.borderStyle = "groove";
elementRef.style.borderColor = "blue";
elementRef.style.borderWidth = "3px";
```

In the property descriptions that follow, these combination values are denoted by their scripted property names and the OR (||) operator, as in

```
border = "borderStyle || borderColor || borderWidth";
```

URLs

Unlike other property values containing URLs, a `style` property requires a slightly different format. This format includes the `url()` prefix, with the actual URL (relative or absolute) located inside the parentheses. The URL itself is not quoted, but the entire property value is, as in

```
elementRef.style.backgroundImage = "url(chainlink.jpg)";
```

URLs should not have any spaces in them, but if they do, use the URL-encoded version for the file specification: convert spaces to `%20`. This format distinguishes a URL value from some other string value for shortcut properties.

Text and font properties

`color`

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Foreground color of an element, primarily used to assign color to text. May also affect edges and highlights of other elements in some browsers.

Value: Color specification

Example: `elementRef.style.color = "rgb(#22FF00)";`

font

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Up to six font-related style properties.

Value: Combination values: `fontStyle` || `fontVariant` || `fontWeight` || `fontSize` || `lineHeight` || `fontFamily`. See individual properties for their value formats

Example: `elementRef.style.font = "bold sans-serif 16px";`

fontFamily

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Font family to be applied to an element in order of priority.

Value: Comma-delimited list of font families to be applied to element, starting with the most preferred font family name. You can also use one of several generic family names that rely on the browser to choose the optimal font to match the class: `serif` | `sans-serif` | `cursive` | `fantasy` | `monospace`. Not all browsers support all constants, but `serif`, `sans-serif`, and `monospace` are commonly implemented.

Example: `elementRef.style.fontFamily = "Bauhaus 93, Arial, monospace";`

fontSize

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Size of the characters of the current font family.

Value: Lengths (generally px or pt values); relative size constants: `larger` | `smaller`; absolute size constants: `xx-small` | `x-small` | `small` | `medium` | `large` | `x-large` | `xx-large`

Examples: `elementRef.style.fontSize = "16px"; elementRef.style.fontSize = "small";`

fontSizeAdjust

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari-, Opera-, Chrome-

Controls: Aspect value of a secondary font family so that it maintains a similar character height as the primary font family.

Value: Number (including floating-point value) or `none`

Example: `elementRef.style.fontSizeAdjust = "1.05";`

fontStretch

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari-, Opera-, Chrome-

Controls: Rendered width of a font's characters.

Value: Constant: `ultra-condensed` | `extra-condensed` | `condensed` | `semi-condensed` | `semi-expanded` | `expanded` | `extra-expanded` | `ultra-expanded`; or: `wider` | `narrower` | `inherit` | `normal`

Example: `elementRef.style.fontStretch = "expanded";`

fontStyle

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Italic style of characters.

Value: Constant: `normal` | `italic` | `oblique` | `inherit`

Example: `elementRef.style.fontStyle = "italic";`

fontVariant

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari1.3+, Opera+, Chrome+

Controls: Rendering characters as small caps.

Value: Constant: `normal` | `small-caps` | `inherit`

Example: `elementRef.style.fontVariant = "small-caps";`

fontWeight

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Rendering characters in bold or light weights. Fonts that support numbered gradations can be controlled by those numbers. Normal = `400`; bold = `700`.

Value: Constant: `bold` | `bolder` | `lighter` | `normal` | `100` | `200` | `300` | `400` | `500` | `600` | `700` | `800` | `inherit`

Example: `elementRef.style.fontWeight = "bold";`

letterSpacing

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Spacing between characters. Used to override a font family's own characteristics.

Value: Length (usually em units, relative to current font size); Constant: `normal` | `inherit`

Example: `elementRef.style.letterSpacing = "1.2em";`

lineBreak

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Line-break rules for Japanese text content.

Value: Constant: `normal` | `strict`

Example: `elementRef.style.lineBreak = "strict";`

lineHeight

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Height of the rectangular space that holds a line of text characters.

Value: Length (usually em units, relative to current font size); number (a multiplier on the inherited line height); percentage (relative to inherited line height); constant: `normal | inherit`

Example: `elementRef.style.lineHeight = "1.1";`

quotes

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari-, Opera+, Chrome-

Controls: Characters to be used for quotation marks.

Value: Space-delimited pairs of open and close quotation symbols; Constant: `none | inherit`

Example: `elementRef.style.quotes = "« »"`

rubyAlign

Compatibility: WinIE5+, MacIE5, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Alignment of ruby text within a `ruby` element.

Value: Constant: `auto | left | center | right | distribute-letter | distribute-space | line-edge`

Example: `RUBYelementRef.style.rubyAlign = "distribute=letter";`

rubyOverhang

Compatibility: WinIE5+, MacIE5, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Overhang of ruby text within a `ruby` element.

Value: Constant: `auto | whitespace | none`

Example: `RUBYelementRef.style.rubyOverhang = "whitespace";`

rubyPosition

Compatibility: WinIE5+, MacIE5, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Placement of ruby text with respect to the `ruby` element's base text.

Value: Constant: `above | inline`

Example: `RUBYelementRef.style.rubyPosition = "inline";`

textAlign

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Horizontal alignment of text with respect to its containing element.

Value: Constant: `center | justify | left | right`

Example: `elementRef.style.textAlign = "center";`

textAlignLast

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Horizontal alignment of last line of text in a paragraph.

Value: Constant: `auto | center | justify | left | right`

Example: `elementRef.style.textAlignLast = "justify";`

textAutospace

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Extra spacing between ideographic and non-ideographic text.

Value: Constant: `none | ideograph-alpha | ideograph-numeric | ideograph-parenthesis | ideograph-space`

Example: `elementRef.style.textAutospace = "ideograph=alpha";`

textDecoration

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Display of underline, overline, or line-through with text.

Value: Constant: `none | blink | line-through | overline | underline`

Example: `elementRef.style.textDecoration = "underline";`

textDecorationBlink
textDecorationLineThrough
textDecorationNone
textDecorationOverline
textDecorationUnderline

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Individual text decoration characteristics for text, allowing for multiple decorations to be applied to the same text.

Value: Boolean (not strings): `true | false`

Example: `elementRef.style.textDecorationUnderline = true;`

textIndent

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Amount of indentation for the first line of a block text element (for example, `p`).

Value: Length (negative values for outdenting); percentage (relative to inherited value)

Example: `elementRef.style.textIndent = "2.5em";`

textJustify

Compatibility: WinIE5+, MacIE5, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Additional detailed specifications for an element whose `textAlign` property is set to `justify`.

Value: Constant: `auto` | `distribute` | `distribute-all-lines` | `distribute-center-last` | `inter-cluster` | `inter-ideograph` | `inter-word` | `kashida` | `newspaper`

Example: `elementRef.style.textJustify = "distribute";`

textJustifyTrim

Compatibility: WinIE5+, MacIE5, NN-, Moz-, Safari-, Opera-, Chrome-

Reserved for future use.

textKashidaSpace

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Ratio of kashida expansion to white space expansion for Arabic writing systems.

Value: Percentage

Example: `elementRef.style.textKashidaSpace = "90%";`

textOverflow

Compatibility: WinIE6+, MacIE-, NN-, Moz-, Safari1.3+, Opera-, Chrome+

Controls: Whether an ellipsis (...) is displayed at the end of a line of overflowed text to indicate that more text is available.

Value: Constant: `clip` | `ellipsis`

textShadow

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari1.2+, Opera+, Chrome+

Controls: Shadow rendering around text characters. Note: The `style` attribute for this property is not implemented in MacIE5 or NN6+/Moz, but the property is listed as valid for the `style` object.

Value: Each shadow specification consists of an optional color and three space-delimited length values (horizontal shadow offset, vertical shadow offset, blur radius length). Multiple shadow specifications are comma-delimited.

textTransform

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Case rendering of the text (without altering the case of the original text).

Value: Constant: `none` | `capitalize` | `lowercase` | `uppercase`

Example: `elementRef.style.textTransform = "uppercase";`

textUnderlinePosition

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Whether an underline text decoration is displayed above or below the text. Seems redundant with `textDecorationUnderline` and `textDecorationOverline`.

Value: Constant: `above | below`

Example: `elementRef.style.textUnderlinePosition = "above";`

unicodeBidi

Compatibility: WinIE5+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Within bidirectional text (for example, English and Arabic), to what extent an alternate direction text block is embedded within the outer element.

Value: Constant: `normal | embed | bidi-override`

Example: `elementRef.style.unicodeBidi = "embed";`

whiteSpace

Compatibility: WinIE5.5+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Treatment of white space characters within an element's source code.

Value: Constant: `normal | nowrap | pre`

Example: `elementRef.style.whiteSpace = "nowrap";`

wordBreak

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari+, Opera-, Chrome+

Controls: Word breaking characteristics, primarily for Asian-language text or text containing a mixture of Asian and Latin characters.

Value: Constant: `normal | break-all | keep-all`

Example: `elementRef.style.wordBreak = "break-all";`

wordSpacing

Compatibility: WinIE6+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Spacing between words.

Value: Length (usually in em units); Constant: `normal`

Example: `elementRef.style.wordSpacing = "1em";`

wordWrap

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari1.3+, Opera-, Chrome+

Controls: Word wrapping characteristics of text in a block element, explicitly-sized inline element, or positioned element.

Value: Constant: `normal` | `break-word`

Example: `elementRef.style.wordWrap = "break-word";`

writingMode

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Direction of content flow (left-to-right/top-to-bottom or top-to-bottom/right-to-left, as in some Asian languages).

Value: Constant: `lr-tb` | `tb-rl`

Example: `elementRef.style.writingMode = "tb-rl";`

Inline display and layout properties

clear

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Layout orientation of an element with respect to a neighboring floating element.

Value: Constant: `both` | `left` | `none` | `right`

Example: `elementRef.style.clear = "right";`

clip

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: The clipping rectangle of an element (that is, the position of the rectangle through which the user sees an element's content).

Value: `rect(topLength, rightLength, bottomLength, leftLength)` | `auto`

Example: `elementRef.style.clip = "rect(10px, 300px, 200px, 0px)";`

clipBottom
clipLeft
clipRight
clipTop

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Individual edges of the clipping rectangle of an element. These properties are read-only properties of the `currentStyle` object.

Value: Length | `auto`

Example: var leftEdge = *elementRef*.currentStyle.clipLeft;

content

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari1.3+, Opera+, Chrome+

Controls: The content rendered in addition to the element, usually to be applied with a `:before` or `:after` pseudo-class. This feature will become more useful when CSS counters are implemented in browsers. They'll provide automatic section or paragraph numbering. While the CSS equivalent is implemented in NN7/Moz and Gecko-, WebKit-, and Presto-based browsers, changes to the scripted property are not rendered.

Value: See `http://www.w3.org/TR/CSS2/generate.html#propdef-content`

counterIncrement

Compatibility: WinIE-, MacIE5, NN6+, Moz1.8+, Safari+, Opera+, Chrome+

Controls: The jumps in counter values to be displayed via the `content` style property.

Value: One or more pairs of counter identifier and integers

counterReset

Compatibility: WinIE-, MacIE5, NN6+, Moz1.8+, Safari+, Opera9+, Chrome+

Controls: Resets a named counter for content to be displayed via the `content` style property.

Value: One or more pairs of counter identifiers and integers.

cssFloat

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Horizontal alignment of an element that allows other content to wrap around the element (usually text wrapping around an image). Corresponds to the CSS `float` style attribute. See also the `styleFloat` property, later in this chapter. Floating (non-positioned) elements follow a long sequence of rules for their behavior, detailed at `http://www.w3.org/TR/CSS2/visuren.html#propdef-float`.

Value: Constant: `left | right | none`

Example: `elementRef.style.cssFloat = "right";`

cursor

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari1.3+, Opera+, Chrome+

Controls: The icon used for the cursor on the screen from a library of system-generated cursors. The CSS2 specification defines syntax for downloadable cursors, but this feature is not implemented in NN6+/Moz. You can change this style property only if a `:hover` pseudo-class is initially defined for the element.

Value: Constant: `auto | crosshair | default | e-resize | help | move | n-resize | ne-resize | nw-resize | pointer | s-resize | se-resize | sw-resize | text | w-resize | wait`. New values for IE6 are: `all-scroll | col-resize | no-drop | not-allowed | progress | row-resize | url | vertical-text`. Mozilla-based browsers include: `alias | cell | context-menu | copy | count-down | count-up | count-up-down | grab | grabbing | spinning`.

Example: `elementRef.style.cursor = "hand";`

`direction`

Compatibility: WinIE5+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Layout direction (left-to-right or right-to-left) of inline text (same as `dir` attribute of an element).

Value: Constant: `ltr | rtl`

Example: `elementRef.style.direction = "rtl";`

`display`

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Whether an element is displayed on the page and in which display mode. Content surrounding an undisplayed element cinches up to occupy the undisplayed element's space — as if the element didn't exist for rendering purposes (see the `visibility` property for a different approach). Commonly used to hide or show segments of a graphical tree structure. Also used to direct the browser to display an element as an inline or block-level element. Some special-purpose values are associated with specific element types (for example, lists, table cells, and so on).

Value: Constant: `block | compact | inline | inline-table | list-item | none | run-in | table | table-caption | table-cell | table-column-group | table-footer-group | table-header-group | table-row | table-row-group`

Example: `elementRef.style.display = "none"; // removes element from page`

`filter`

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Rendering effects on static content and on transitions between hiding and showing elements. Microsoft made a massive overhaul of the `filter` stylesheet syntax in WinIE5.5 (using the `DXImageTransform` ActiveX control). Scripting transitions require several steps to load the transition and actions before playing the transition. Use `style.filter` to read or write the entire filter specification string; use the `elem.styles[i]` object to access individual filter properties. See the discussion of the `filter` object later in this chapter.

Value: Filter specification as string

Example: `var filterSpec = elementRef.style.filter = "alpha(opacity=50) flipH()";`

`layoutGrid`

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Page grid properties (primarily for Asian-language pages).

Value: Combination values: `layoutGridMode || layoutGridType || layoutGridLine || layoutGridChar`. See individual properties for their value formats.

Example: `elementRef.style.layoutGrid = "2em fixed";`

layoutGridChar

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Size of the character grid (Asian languages).

Value: Length; Percentage; Constant: `none` | `auto`

Example: `elementRef.style.layoutGridChar = "2em";`

layoutGridLine

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Line height of the grid (Asian languages).

Value: Length; Percentage; Constant: `none` | `auto`

Example: `elementRef.style.layoutGridLine = "110%";`

layoutGridMode

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: One- or two-dimensional grid (Asian languages).

Value: Constant: `both` | `none` | `line` | `char`

Example: `elementRef.style.layoutGridMode = "both";`

layoutGridType

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Type of grid for text content (Asian languages).

Value: Constant: `loose` | `strict` | `fixed`

Example: `elementRef.style.layoutGridType = "strict";`

markerOffset

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera-, Chrome-

Controls: Distance between the edges of a marker box (content whose display is of a marker type) and a block-level element's box. Note: The CSS property is not implemented in MacIE5 or NN6+/Moz, but the property is listed as valid for a `style` object.

Value: Length; Constant: `auto`

Example: `elementRef.style.markerOffset = "2em";`

marks

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari-, Opera-, Chrome-

Controls: Rendering of crop marks and the like on the printed page. Note: The CSS property is not implemented in MacIE5 or NN6+/Moz, but the property is listed as valid for a `style` object.

Value: Constant: `crop` || `cross` | `none`

Example: `elementRef.style.marks = "crop";`

maxHeight
maxWidth
minHeight
minWidth

Compatibility: WinIE (see text), MacIE-, NN6+, Moz+, Safari1+, Opera+, Chrome+

Controls: Maximum or minimum height or width of an element. Microsoft supports `maxHeight` only starting with IE7.

Value: Length; Percentage; Constant (for max properties only): `none`

Example: `elementRef.style.maxWidth = "300px";`

mozOpacity

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari-, Opera-, Chrome-

Controls: The level of opacity (transparency) of the element as a percentage; the lower the value, the more transparent the element becomes (`0%` or `0.0` is completely transparent, while `100%` or `1.0` is completely opaque).

Value: Percentage, or numeric value between `0.0` and `1.0`

Example: `elementRef.style.mozOpacity = "75%";`

opacity

Compatibility: WinIE-, MacIE-, NN-, Moz1.7.2+, Safari1.2+, Opera+, Chrome+

Controls: The level of opacity (transparency) of the element as a percentage; the lower the value, the more transparent the element becomes (`0%` or `0.0` is completely transparent, while `100%` or `1.0` is completely opaque). Unlike `mozOpacity`, which is unique to Mozilla, `opacity` is the official W3C standard for opacity.

Value: Percentage, or numeric value between `0.0` and `1.0`

Example: `elementRef.style.opacity = "25%";`

overflow

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: The rendering of a block-level element's content when its native rectangle exceeds that of its next outermost rectangular space. A `hidden` overflow clips the block-level content; a `scrolled` overflow forces the outermost rectangle to display scroll bars so that users can scroll around the block-level element's content; a `visible` overflow causes the block-level element to extend beyond the outermost container's rectangle (indeed, "overflowing" the container).

Value: Constant: `auto` | `hidden` | `scroll` | `visible`

Example: `elementRef.style.overflow = "scroll";`

overflowX
overflowY

Compatibility: WinIE5+, MacIE-, NN-, Moz1.8+, Safari1.2, Opera+, Chrome+

Controls: The rendering of a block-level element's content when its native rectangle exceeds the width (`overflowX`) or height (`overflowY`) of its next outermost rectangular space. A hidden overflow clips the block-level content; a scrolled overflow forces the outermost rectangle to display scroll bars so that users can scroll around the block-level element's content; a visible overflow causes the block-level element to extend beyond the outermost container's rectangle (indeed, "overflowing" the container).

Value: Constant: `auto` | `hidden` | `scroll` | `visible`

Example: `elementRef.style.overflowX = "scroll";`

styleFloat

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera+, Chrome-

Controls: Horizontal alignment of an element that allows other content to wrap around the element (usually text wrapping around an image). Corresponds to the CSS `float` style attribute. See also the `cssFloat` property, earlier in the chapter. Floating (non-positioned) elements follow a long sequence of rules for their behavior, detailed at `http://www.w3.org/TR/CSS2/visuren.html#propdef-float`.

Value: Constant: `left` | `right` | `none`

Example: `elementRef.style.styleFloat = "right";`

verticalAlign

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari1.2+, Opera+, Chrome+

Controls: How inline and table cell content aligns vertically with surrounding content. Not all constant values are supported by all browsers.

Value: Constant: `baseline` | `bottom` | `middle` | `sub` | `super` | `text-bottom` | `text-top` | `top`; Length; Percentage

Example: `elementRef.style.verticalAlign = "baseline";`

visibility

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Whether an element is displayed on the page. The element's spot is preserved as empty space when the element is hidden. To cinch up surrounding content, see the `display` property. This property is used frequently for hiding and showing positioned elements under script control.

Value: Constant: `collapse` | `hidden` | `visible`

Example: `elementRef.style.visibility = "hidden";`

width

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Horizontal dimension of a block-level element. Earlier browsers exhibit unexpected behavior when nesting elements that have their `width` style properties set.

Value: Length; Percentage; Constant: `auto`

Example: `elementRef.style.width = "200px";`

zoom

Compatibility: WinIE5.5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Magnification factor of a rendered element.

Value: Constant: `normal`; Percentage (where `100%` is normal); floating-point number (scale multiplier, where 1.0 is normal)

Example: `elementRef.style.zoom = ".9";`

Positioning properties

See Chapter 43, "Positioned Objects", on the CD-ROM for coding examples of positioned elements and their `style` properties.

bottom
right

Compatibility: WinIE5+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: The offset measure of a positioned element from its containing rectangle's bottom and right edges, respectively. In practice, you should adjust the size of a positioned element via the style's `height` and `width` properties.

Value: Length; Percentage; Constant: `auto`

Example: `elementRef.style.bottom = "20px";`

left
top

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: The offset measure of a positioned element from its containing rectangle's left and top edges, respectively. In practice, use these properties to position an element under script control. To position an absolute-positioned element atop an inline element, calculate the position of the inline element via the `offsetTop` and `offsetLeft` properties with some browser-specific adjustments, as shown in Chapter 43, "Positioned Objects."

Value: Length; Percentage; Constant: `auto`

Example: `elementRef.style.top = "250px";`

***elementRefObject*.style.height**

height
width

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Height and width of a block-level element's box. Used most commonly to adjust the dimensions of a positioned element (Chapter 43, "Positioned Objects").

Value: Length; Percentage; Constant: `auto`

Example: `elementRef.style.height = "300px";`

pixelBottom
pixelHeight
pixelLeft
pixelRight
pixelTop
pixelWidth

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera+, Chrome+

Controls: Integer pixel values for (primarily positioned) elements. Because the non-pixel versions of these properties return strings that also contain the unit measure (for example, `30px`), these properties let you work exclusively in integers for pixel units. The same can be done cross-platform by using `parseInt()` on the non-pixel versions of these properties. The `pixelBottom` and `pixelRight` properties are not supported by MacIE4.

Value: Integer

Example: `elementRef.style.pixelTop = elementRef.style.pixelTop + 20;`

posBottom
posHeight
posLeft
posRight
posTop
posWidth

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari+, Opera+, Chrome+

Controls: Numeric values for (primarily positioned) elements in whatever unit was specified by the corresponding `style` attribute. Because the non-pos versions of these properties return strings that also contain the unit measure (for example, `1.2em`), these properties let you work exclusively in numeric values of the same units in which the style was originally defined. The same can be done cross-platform by using `parseFloat()` on the non-pixel versions of these properties.

Value: Integer

Example: `elementRef.style.posTop = elementRef.style.posTop + 0.5;`

position

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: The type of positioning to be applied to the element. An element that is not explicitly positioned is said to be *static*. A relative-positioned element appears in its normal page flow location but can be explicitly positioned relative to that location. An absolute-positioned element must have its `top` and `left` style attributes assigned to give the element a set of coordinates for its location. MacIE5 and NN6+/Moz, and Gecko-, WebKit-, and Presto-based browsers also allow for a fixed positioned element, which remains at its designated position in the browser window, even if the page scrolls (for example, for a watermark effect). You cannot use scripts to change between positioned and non-positioned style settings. See Chapter 43 for more information on positioned elements.

Value: Constant: `absolute` | `fixed` | `relative` | `static`

Example: `elementRef.style.position = "absolute";`

zIndex

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Front-to-back layering of positioned elements. Multiple items with the same `zIndex` value are layered in source code order (earliest item at the bottom). The higher the value, the closer to the user's eye the element is.

Value: Integer number; Constant: `auto`

Example: `elementRef.style.zIndex = "3";`

Background properties

background

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Up to five background style properties for an element.

Value: Combination values: `backgroundAttachment` || `backgroundColor` || `backgroundImage` || `backgroundPosition` || `backgroundRepeat`

Example: `elementRef.style.background = "scroll url(bricks.jpg) repeat-x";`

backgroundAttachment

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari1.2+, Opera+, Chrome+

Controls: Whether the background image remains fixed or scrolls with the content. Default is `scroll`.

Value: Constant: `fixed` | `scroll`

Example: `elementRef.style.backgroundAttachment = "fixed";`

backgroundColor

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Solid opaque color for the background, or completely transparent. If you assign a background image, the color is layered behind the image so that any transparent spots of the image show the background color.

Value: Color value; Constant: `transparent`

Example: `elementRef.style.backgroundColor = "salmon";`

backgroundImage

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: The URL (if any) of an image to be used for the background for the element.

Value: URL value; Constant: `none`

Example: `elementRef.style.backgroundImage = "url(bricks.jpg)";`

backgroundPosition

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: The left-top location of the background image. Any offset from the left-top corner (default value `"0% 0%"`) allows background color to show through along the left and top edges of the element.

Value: Length values; Percentages; Constant: `left | center | right || top | center | bottom`. While single values are accepted, their behavior may not be as expected. Providing space-delimited pairs of values is more reliable

Example: `elementRef.style.backgroundPosition = "left top";`

backgroundPositionX
backgroundPositionY

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari1.3+, Opera-, Chrome+

Controls: The left (`backgroundPositionX`) and top (`backgroundPositionY`) locations of the background image. Any offset from the left-top corner (default value "0%") allows background color to show through along the left and top edges of the element.

Value: Length value; Percentage; Constant: `left | center | right` (for `backgroundPositionX`); Constant: `top | center | bottom` (for `backgroundPositionY`)

Example: `elementRef.style.backgroundPositionX = "5px";`

backgroundRepeat

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Image repetition characteristics of a background image. You can force the image to repeat along a single axis, if you want.

Value: Constant: `repeat` | `repeat-x` | `repeat-y` | `no-repeat`

Example: `elementRef.style.backgroundRepeat = "repeat-y";`

Border and edge properties

border

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Up to three border characteristics (color, style, and width) for all four edges of an element.

Value: Combination values: `borderColor` || `borderStyle` || `borderWidth`

Example: `elementRef.style.border = "green groove 2px";`

borderBottom
borderLeft
borderRight
borderTop

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Up to three border characteristics (color, style, and width) for a single edge of an element.

Value: Combination values: (for `borderBottom`) `borderBottomColor` || `borderBottomStyle` || `borderBottomWidth` (for `borderLeft`) `borderLeftColor` || `borderLeftStyle` || `border-LeftWidth` (for `borderRight`) `borderRightColor` || `borderRightStyle` || `border-RightWidth` (for `borderTop`) `borderTopColor` || `borderTopStyle` || `borderTopWidth`

Example: `elementRef.style.borderLeft = "#3300ff solid 2px";`

borderBottomColor
borderLeftColor
borderRightColor
borderTopColor

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Color for a single border edge of an element.

Value: Color values; Constant: `transparent`

Example: `elementRef.style.borderTopColor = "rgb(30%, 50%, 0%)";`

borderBottomStyle
borderLeftStyle
borderRightStyle
borderTopStyle

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Rendered style for a border edge of an element.

Value: Constant: `none` | `hidden` | `dotted` | `dashed` | `solid` | `double` | `groove` | `ridge` | `inset` | `outset`. WinIE versions prior to IE5.5 do not respond to the `dotted` or `dashed` types; MacIE does not respond to the `hidden` type

Example: `elementRef.style.borderRightStyle = "double";`

borderBottomWidth
borderLeftWidth
borderRightWidth
borderTopWidth

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Thickness of a border edge of an element.

Value: Length value; Constant: `thin` | `medium` | `thick` (precise measure is at browser's discretion)

Example: `elementRef.style.borderBottomWidth = "5px";`

borderColor

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Rendered color for one to four sides of an element.

Value: Color values for one to four rectangle sides

Example: `elementRef.style.borderColor = "green black";`

borderStyle

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Rendered style for one to four sides of an element.

Value: One to four rectangle side constants: `none` | `hidden` | `dotted` | `dashed` | `solid` | `double` | `groove` | `ridge` | `inset` | `outset`. WinIE versions prior to IE5.5 do not respond to the `dotted` or `dashed` types; MacIE does not respond to the `hidden` type

Example: `elementRef.style.borderStyle = "ridge";`

borderWidth

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Thickness of border for one to four sides of an element.

Value: One to four rectangle side length values or constants: `thin` | `medium` | `thick` (precise dimension is at browser's discretion)

Example: `elementRef.style.borderWidth = "5px 4px 5px 3px";`

margin

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Thickness of transparent margin space outside the element's borders for one to four edges.

Value: One to four rectangle side length values

Example: `elementRef.style.margin = "10px 5px";`

marginBottom
marginLeft
marginRight
marginTop

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Thickness of transparent margin space outside the element's borders for a single border edge.

Value: Length value

Example: `elementRef.style.marginBottom = "50px";`

mozBorderRadius
mozBorderRadiusBottomLeft
mozBorderRadiusBottomRight
mozBorderRadiusTopLeft
mozBorderRadiusTopRight

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari-, Opera-, Chrome-

Controls: Radius of the border around the element. You can specify each radius corner as a series of values in the `mozBorderRadius` style (one value for all four corners; two values for top-left/bottom-right and top-right/bottom-left; three values for top-left, top-right/bottom-left, and bottom-right; four values for top-left, top-right, bottom-right, and bottom-left), or set each corner radius individually with its own property.

Value: Radius length value

Example: `elementRef.style.mozBorderRadius = "20px 10px 20px 10px";`

outline

Compatibility: WinIE-, MacIE5, NN-, Moz1.8.1+, Safari1.2+, Opera+, Chrome+

Controls: Up to three characteristics of an outline surrounding an element (similar to a border, but not shifting the location of internal content).

Value: Combination values: `outlineColor` || `outlineStyle` || `outlineWidth`

Example: `elementRef.style.outline = "red groove 2px";`

outlineColor

Compatibility: WinIE-, MacIE5, NN-, Moz1.8.1+, Safari1.2+, Opera+, Chrome+

Controls: Color of all four edges of an outline.

Value: Color values; Constant: `invert`

Example: `elementRef.style.outlineColor = "cornflowerblue";`

outlineOffset

Compatibility: WinIE-, MacIE5, NN-, Moz1.8.1+, Safari1.2+, Opera+, Chrome+

Controls: The space between an outline surrounding an element and the border of the element.

Value: Length value

Example: `elementRef.style.outlineOffset = "3px";`

outlineStyle

Compatibility: WinIE-, MacIE5, NN-, Moz1.8.1+, Safari1.2+, Opera+, Chrome+

Controls: Rendered style for all four sides of an element outline.

Value: Constant: `none` | `hidden` | `dotted` | `dashed` | `solid` | `double` | `groove` | `ridge` | `inset` | `outset`

Example: `elementRef.style.outlineStyle = "ridge";`

outlineWidth

Compatibility: WinIE-, MacIE5, NN-, Moz1.8.1+, Safari1.2+, Opera+, Chrome+

Controls: Thickness of all four sides of an element outline.

Value: Length value or constant: `thin` | `medium` | `thick` (precise dimension is at browser's discretion)

Example: `elementRef.style.outlineWidth = "4px";`

padding

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Thickness of space between an element's content and its borders for one to four edges.

Value: One to four rectangle side length values.

Example: `elementRef.style.padding = "5px";`

paddingBottom
paddingLeft
paddingRight
paddingTop

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Thickness of space between an element's content and its borders for a single edge.

Value: Length value

Example: `elementRef.style.paddingBottom = "20px";`

List properties

listStyle

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Up to three characteristics of a list (`ol` or `ul`) presentation. Also applies to `dd`, `dt`, and `li` elements.

Value: Combination values: `listStyleImage` || `listStylePosition` || `listStyleType`

Example: `elementRef.style.listStyle = "none inside lower-alpha";`

listStyleImage

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: URL of the image to be used as a marker for a list item.

Value: URL value; Constant: `none`

Example: `elementRef.style.listStyleImage = "url(custombullet.jpg)";`

listStylePosition

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Whether the marker should be formatted inside the wrapped text of its content or dangle outside the wrapped text (default).

Value: Constant: `inside` | `outside`

Example: `elementRef.style.listStylePosition = "inside";`

listStyleType

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Which of the standard marker sets should be used for items in the list. A change to this property for a single `li` element causes succeeding items to be in the same style.

Value: For `ul` elements, constant: `circle` | `disc` | `square`

For `ol` elements, constant: `decimal` | `decimal-leading-zero` | `lower-alpha` | `lower-greek` | `lower-latin` | `lower-roman` | `upper-alpha` | `upper-greek` | `upper-latin` | `upper-roman`, and non-Roman formats when supported by the operating system (as in Mozilla for MacOS X): `armenian` | `georgian` | `hebrew` | `cjk-ideographic` | `hiragana` | `hiragana-iroha` | `katakana` | `katakana-iroha`

Example: `elementRef.style.listStyleType = "upper-roman";`

Scroll bar properties

scrollbar3dLightColor
scrollbarArrowColor
scrollbarBaseColor
scrollbarDarkShadowColor
scrollbarFaceColor
scrollbarHighlightColor
scrollbarShadowColor
scrollbarTrackColor

Compatibility: WinIE5.5, Mac-, NN-, Moz-, Safari-, Opera+, Chrome-

Controls: Colors of individual components of scroll bars when they are displayed for `applet`, `body`, `div`, `embed`, `object`, or `textarea` elements. To experiment with how different colors can affect the individual components, visit `http://msdn.microsoft.com/en-us/library/ms533055%28VS.85%29.aspx`.

Value: Color values; Constant: `none`

Example: `elementRef.style.scrollbarTrackColor = "hotpink";`

Table properties

borderCollapse

Compatibility: WinIE5+, MacIE5, NN6+, Moz+, Safari1.3+, Opera+, Chrome+

Controls: Whether a `table` element adheres to the CSS2 separated borders model or the collapsed borders model. Style is not fully supported in MacIE5.

Value: Constant: `collapse | separate`

Example: `elementRef.style.borderCollapse = "separate";`

borderSpacing

Compatibility: WinIE5+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: For a table following the separated borders model, the thickness of the spacing between cell rectangles (akin to the `cellspacing` attribute of `table` elements). Style is not fully supported in MacIE5.

Value: One length value (for horizontal and vertical spacing) or comma-delimited list of two length values (the first for horizontal; the second for vertical)

Example: `elementRef.style.borderSpacing = "10px";`

captionSide

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Position of the `caption` element inside a `table` element. Style is not implemented in MacIE5 and is only partially implemented in Safari.

Value: Constant: `top` | `right` | `bottom` | `left`

Example: `elementRef.style.captionSide = "bottom";`

emptyCells

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari1.3+, Opera+, Chrome+

Controls: Rendering of cells and their borders when the cells have no content. Default behavior is to not render borders around empty cells. Style is not implemented in MacIE5.

Value: Constant: `show` | `hide`

Example: `elementRef.style.emptyCells = "show";`

tableLayout

Compatibility: WinIE5+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Whether table is rendered progressively based on fixed width settings of the first row of cells, or is rendered after the widths of all row content can be determined. Modifying this property after a table loads has no effect on the table.

Value: Constant `auto` | `fixed`

Example: `elementRef.style.tableLayout = "auto";`

Page and printing properties

orphans
widows

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari-, Opera+, Chrome-

Controls: The minimum number of lines of a paragraph to be displayed at the bottom of a page (orphans) or top of a page (widows) when a page break occurs.

Value: Integer

Example: `elementRef.style.orphans = "4";`

page

Compatibility: WinIE-, MacIE5, NN6+, Moz+, Safari-, Opera-, Chrome-

Controls: The page (defined in an `@page` rule) with which the current element should be associated for printing.

Value: Identifier assigned to an existing `@page` rule

Example: `elementRef.style.page = "landscape";`

pageBreakAfter
pageBreakBefore

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari1.3+, Opera+, Chrome+

Controls: Whether a printed page break should be before or after the current element and the page break type.

Value: Constant: `auto | always | avoid | left | right`

Example: `elementRef.style.pageBreakBefore = "always";`

pageBreakInside

Compatibility: WinIE8+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

Controls: Whether a printed page break is allowed inside an element.

Value: Constant: `auto | avoid`

Example: `elementRef.style.pageBreakInside = "avoid";`

size

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera+, Chrome-

Controls: The size or orientation of the page box (linked to the style rule via the page property) used to determine printed pages.

Value: One (same value for width and height) or two (width and height) space-delimited length values; constant: `auto | portrait | landscape`

Example: `elementRef.style.size = "portrait";`

Miscellaneous properties

accelerator

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: Whether an accelerator key is defined for an element.

Value: Boolean

Example: `elementRef.style.accelerator = "true";`

behavior

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Controls: The external behavior to be applied to the current element.

Value: Space-delimited list of URL values. URLs can be a file location, an `object` element ID, or one of the built-in (default) behaviors.

Example: `elementRef.style.behavior = "url(#default#anchorClick)";`

cssText

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari1.3+, Opera+, Chrome+

Controls: Actual CSS rule text (read-only). This property exists by virtue of the browser's object model and is not part of the CSS specification. There is no corresponding CSS attribute.

Value: String

Example: `var cssRuleText = elementRef.style.cssText;`

imeMode

Compatibility: WinIE5+, MacIE-, NN-, Moz-, FF+, Safari-, Opera-, Chrome-

Controls: Whether text is entered into a text `input` or `textarea` element through the Input Method Editor (for languages, such as Chinese, Japanese, or Korean).

Value: Constant: `auto` | `active` | `inactive` | `disabled`

Example: `elementRef.style.imeMode = "active";`

Aural properties

Although these properties are defined in the CSS2 specification and placeholders exist for them in Mozilla-based browsers, the styles are not implemented in any browser other than Opera, and that support is experimental. The script equivalent properties are listed here for the sake of completeness only.

azimuth
cue
cueAfter
cueBefore
elevation
pause
pauseAfter
pauseBefore
pitch
pitchRange
playDuring
richness
speak
speakHeader
speakNumeral
speakPunctuation
speechRate
stress
voiceFamily
volume

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera+, Chrome-

Controls: A variety of styles primarily for browsers that support speech synthesis output.

Value: Consult `http://www.w3.org/TR/CSS2/aural.html` for details on aural stylesheets

filter Object

Properties	Methods	Event Handlers
See text		

Syntax

Accessing `filter` object properties and methods:

```
(IE4+)    document.all.objectID.filters[i].property | method([parameters])
(IE5.5+)  document.all.objectID.filters[filterName].property |
          method([parameters])
```

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

About this object

Earlier in this chapter, the `style.filter` property was shown to allow reading and writing of the string value that is assigned to an element's `style.filter` property. Filters are available in WinIE only, even though MacIE5 returns the `style.filter` property value. The purpose of this section is not to teach you how to use filters, but rather, how to script them.

Multiple filters are merely part of the space-delimited list of filters. Some filter types have additional specifications. For example, the `glow()` filter has three properties that more clearly define how the element should be rendered with a glow effect. The style sheet rule for an element whose ID is `glower` looks like the following:

```
#glower {filter:glow(color=yellow, strength=5, enabled=true)}
```

Accessing the `currentStyle.filter` property for that element yields the string value:

```
glow(color=yellow, strength=5, enabled=true)
```

Attempting to modify a single subproperty of the `glow()` filter by way of string parsing would be cumbersome and hazardous at best. For example, imagine trying to increment the glow filter's `strength` property by 5.

Reading and writing subproperties

A cleaner way to work with individual properties of a filter is to access the filter as an object belonging to the element affected by the filter. Each type of filter object has as its properties the individual sub-properties that you set in the style sheet. Continuing with the `glow()` filter example, you could access just the `color` property of the filter as follows:

```
var currColor = document.all.glower.filters["glow"].color;
```

To modify the color, assign a new value to the `filter` object's property:

```
document.all.glower.filters["glow"].color = "green";
```

To increment a numeric value, such as increasing the `glow()` filter's `strength` property by 5, use a construction such as the following (long-winded though it may be):

```
document.all.glower.filters["glow"].strength =
document.all.glower.filters["glow"].strength + 5;
```

Table 38-1 lists the filter object names that work all the way back to IE4, and the properties associated with each filter type.

In addition to the static filter types, which are applied to content and sit there unless modified by script, the IE4+ `filter` object also provides types for blends and reveals, for transitions between visible and invisible elements. Scripting transitions that occur when a script hides or shows an element requires a few lines of code, including calls to some of the `filter` object's methods. First, Table 38-2 shows the IE4+ syntax for transition filters.

TABLE 38-1

IE4-Compatible Static Filter Types

Filter Name	Description and Properties		
`alpha()`	Transparency level		
	Properties:	`opacity`	(0 to 100)
		`finishopacity`	(0 to 100)
		`style`	(gradient shape 0 to 3)
		`startX`	(coordinate integer)
		`startY`	(coordinate integer)
		`finishX`	(coordinate integer)
		`finishY`	(coordinate integer)
`blur()`	Simulate blurred motion		
	Properties:	`add`	(1 or 0)
		`direction`	(0, 45, 90, 135, 180, 225, 270, 315)
		`strength`	(pixel count)
`chroma()`	Color transparency		
	Properties:	`color`	(color value)
`dropShadow()`	Shadow effect		
	Properties:	`color`	(color value)
		`offx`	(horizontal offset in pixels)

continued

TABLE 38-1 *(continued)*

Filter Name	Description and Properties		
		`offy`	(vertical offset in pixels)
		`positive`	(1 or 0)
`flipH()`	Horizontally mirrored image		
	Properties:	None	
`flipV()`	Vertically mirrored image		
	Properties:	None	
`glow()`	Outer edge radiance		
	Properties:	`color`	(color value)
		`strength`	(intensity 1 to 255)
`gray()`	Eliminate color		
	Properties:	None	
`invert()`	Opposite hue, saturation, brightness levels		
	Properties:	None	
`light()`	Add light source (controlled by methods)		
	Properties:	None	
`mask()`	Overlay transparent mask		
	Properties:	`color`	(color value)
`shadow()`	Render as silhouette		
	Properties:	`color`	(color value)
		`direction`	(0, 45, 90, 135, 180, 225, 270, 315)
`wave()`	Add sine-wave distortion		
	Properties:	`add`	(1 or 0)
		`freq`	(integer number of waves)
		`light`	(strength 0 to 100)
		`phase`	(percentage offset 0 to 100)
		`strength`	(intensity 0 to 255)
`xRay()`	Render edges only		
	Properties:	None	

TABLE 38-2

IE4+ Transition Filters

Filter Name	Description and Properties			
`blendTrans()`	Fade out old element, fade in new element			
	Properties:	`duration`	(floating-point number of seconds)	
	Methods:	`apply()`	(freezes current display)	
		`play()`	(plays transition)	
		`stop()`	(stops transition mid-stream)	
`revealTrans()`	Reveal element to be shown through an effect			
	Properties:	`duration`	(floating-point number of seconds)	
		`transition`	(code number for effect)	
			`0`	Box in
			`1`	Box out
			`2`	Circle in
			`3`	Circle out
			`4`	Wipe up
			`5`	Wipe down
			`6`	Wipe right
			`7`	Wipe left
			`8`	Vertical blinds
			`9`	Horizontal blinds
			`10`	Checkerboard across
			`11`	Checkerboard down
			`12`	Random dissolve
			`13`	Split vertical in

continued

TABLE 38-2 *(continued)*

Filter Name	Description and Properties			
			14	Split vertical out
			15	Split horizontal in
			16	Split horizontal out
			17	Strips left down
			18	Strips left up
			19	Strips right down
			20	Strips right up
			21	Random bars horizontally
			22	Random bars vertically
			23	Random effect
	Methods:	`apply()`	(freezes current display)	
		`play()`	(plays transition)	
		`stop()`	(stops transition mid-stream)	

To make a transition work under script control, a filter must be applied to the element that you want the transition to work on. That can be done by script or by assigning a filter style to the element. As for the scripting, you begin by invoking the `apply()` method of the desired `filter` object. Next, script the change, such as assigning a new URL to the `src` property of an `img` element. While you do this, the `apply()` method freezes the image until you invoke the `play()` method on the filter. Listing 38-1 effects a checkerboard transition between two images after you click the image.

LISTING 38-1

A Reveal Transition Between Images

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>IE Transition</title>
      <style type="text/css">
         img {filter:revealTrans(transition=10)}
```

```
      </style>
      <script type="text/javascript">
         function doReveal()
         {
            document.getElementById("myIMG").filters["revealTrans"].apply();
               if (document.getElementById("myIMG").src.indexOf("desk1") != -1)
               {
                  document.getElementById("myIMG").src = "desk3.gif";
               }
               else
               {
                  document.getElementById("myIMG").src = "desk1.gif";
               }
            document.getElementById("myIMG").filters["revealTrans"].play();
         }
      </script>
   </head>
   <body>
      <h1>IE Transition</h1>
      <hr />
      <p>Click on the image to cause a reveal transition.</p>
      <img id="myIMG" alt="image" src="desk1.gif" height="90" width="120"
           onclick="doReveal()" />
   </body>
</html>
```

Note

The property assignment event handling technique used in this example, and the next, is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." ■

Building on the example in Listing 38-1, the next example in Listing 38-2 demonstrates how a script can also modify a `filter` object's property, including a transition filter. Before the transition filter has its `apply()` method invoked, the script sets the transition type based on a user choice in a `select` list.

LISTING 38-2

Choosing Reveal Transitions Between Images

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>IE Transition and Choices</title>
      <style type="text/css">
         img {filter:revealTrans(transition=10)}
```

continued

LISTING 38-2 *(continued)*

```
   </style>
   <script type="text/javascript">
      function doReveal()
      {
         document.getElementById("myIMG").filters
           ["revealTrans"].transition = document.forms[0].transChoice.value;
         document.getElementById("myIMG").filters["revealTrans"].apply();
            if (document.getElementById("myIMG").src.indexOf("desk1") != -1)
            {
               document.getElementById("myIMG").src = "desk3.gif";
            }
            else
            {
               document.getElementById("myIMG").src = "desk1.gif";
            }
         document.getElementById("myIMG").filters["revealTrans"].play();
      }
   </script>
</head>
<body>
   <h1>IE Transition and Choices</h1>
   <hr />
   <form>
      <p>Choose the desired transition type:
         <select name="transChoice">
            <option value="0">Box in</option>
            <option value="1">Box out</option>
            <option value="2">Circle in</option>
            <option value="3">Circle out</option>
            <option value="4">Wipe up</option>
            <option value="5">Wipe down</option>
            <option value="6">Wipe right</option>
            <option value="7">Wipe left</option>
            <option value="8">Vertical blinds</option>
            <option value="9">Horizontal blinds</option>
            <option value="10">Checkerboard across</option>
            <option value="11">Checkerboard down</option>
            <option value="12">Random dissolve</option>
            <option value="13">Split vertical in</option>
            <option value="14">Split vertical out</option>
            <option value="15">Split horizontal in</option>
            <option value="16">Split horizontal out</option>
            <option value="17">Strips left down</option>
            <option value="18">Strips left up</option>
            <option value="19">Strips right down</option>
            <option value="20">Strips right up</option>
            <option value="21">Random bars horizontally</option>
            <option value="22">Random bars vertically</option>
            <option value="23">Random effect</option>

      </form>
      <p>Click on the image to cause a reveal transition.</p>
      <img alt="image" id="myIMG" src="desk1.gif" height="90" width="120"
           onclick="doReveal()" />
   </body>
</html>
```

WinIE5.5+ filter syntax changes

While WinIE5.5+ still supports the original IE4 way of controlling filters, the browser also implements a new filter component, which Microsoft strongly encourages authors to use (as evidenced by the difficulty in finding documentation for the IE4 syntax at its developer web site). In the process of implementing this new filter component, the names of many filters change, as do their individual properties. Moreover, the way the filter component is invoked in the style sheet is also quite different from the original component.

The style sheet syntax requires a reference to the new component as well as to the filter name. Here is the old way:

```
#glower {filter:glow(color=yellow, strength=5, enabled=true)}
```

And here is the new way:

```
#glower {filter:progid:DXImageTransform.Microsoft.Glow(color=yellow,
   strength=5, enabled=true)}
```

Don't overlook the extra `progid:` pointer in the reference. This program identifier becomes part of the name that your scripts use to reference the filter:

```
document.getElementById("glower").filters[
   "DXImageTransform.Microsoft.Glow"].color = "green";
```

While some of the filter names and properties stay the same (except for the long prefix), several older properties are subsumed by new filters whose properties help identify the specific effect. The former `revealTrans()` filter is now divided among several new filters dedicated to transition effects. Table 38-3 shows the IE5.5+ syntax.

Note

Using the filter syntax introduced in IE5.5+ can cause frequent crashes of the browser (at least in early released versions), especially when it's used for transition filters. If you implement the new syntax, be sure to torture-test your pages extensively. Ideally, you should encourage users of these pages to run IE6+. ■

TABLE 38-3

IE5.5 DXImageTransform.Microsoft Filter Names

Filter Name	Description and Properties		
Alpha()	Transparency level		
	Properties:	opacity	(0 to 100)
		finishopacity	(0 to 100)
		style	(gradient shape 0 to 3)
		startX	(coordinate integer)
		startY	(coordinate integer)
		finishX	(coordinate integer)
		finishY	(coordinate integer)
Barn()	Barn-door style transition		
	Properties:	duration	(floating-point number of seconds)
		motion	(in or out)
		orientation	(horizontal or vertical)
		percent	(0 to 100)
		status	0 (stopped), 1 (applied), 2 (playing)
	Methods:	apply()	(freezes current display)
		play()	(plays transition)
		stop()	(stops transition mid-stream)
BasicImage()	Element rotation, flip, color effects, and opacity		
	Properties:	grayScale	(1 or 0)
		invert	(1 or 0)
		mask	(1 or 0)
		maskColor	(color value)
		mirror	(1 or 0)
		opacity	(0.0 to 1.0)

Filter Name	Description and Properties		
		rotation	0 (no rotation), 1 (90°), 2 (180°), 3 (270°)
		xRay	(1 or 0)
Blinds()	Action transition with Venetian blind effect		
	Properties:	direction	(up, down, right, left)
		squaresX	(integer column count)
		squaresY	(integer row count)
		status	0 (stopped), 1 (applied), 2 (playing)
	Methods:	apply()	(freezes current display)
		play()	(plays transition)
		stop()	(stops transition mid-stream)
Checkerboard()	Action transition with checkerboard effect		
	Properties:	bands	(1 to 100)
		direction	(up, down, right, left)
		duration	(floating-point number of seconds)
		percent	(0 to 100)
		slideStyle	(HIDE, PUSH, SWAP)
		status	0 (stopped), 1 (applied), 2 (playing)
	Methods:	apply()	(freezes current display)
		play()	(plays transition)
		stop()	(stops transition mid-stream)
Chroma()	Color transparency		
	Properties:	color	(color value)
DropShadow()	Shadow effect		
	Properties:	color	(color value)

continued

TABLE 38-3 *(continued)*

Filter Name	Description and Properties		
		offx	(horizontal offset pixels)
		offy	(vertical offset pixels)
		positive	(1 or 0)
Fade()	Blend transition		
	Properties:	duration	(floating-point number of seconds)
		overlap	(0.0 to 1.0 seconds)
		percent	(0 to 100)
		status	0 (stopped), 1 (applied), 2 (playing)
	Methods:	apply()	(freezes current display)
		play()	(plays transition)
		stop()	(stops transition mid-stream)
Glow()	Outer edge radiance		
	Properties:	color	(color value)
		strength	(intensity 1 to 255)
Iris()	Action transition with zoom effect		
	Properties:	duration	(floating-point number of seconds)
		irisStyle	(CIRCLE, CROSS, DIAMOND, PLUS, SQUARE, STAR)
		motion	(in or out)
		percent	(0 to 100)
		status	0 (stopped), 1 (applied), 2 (playing)
	Methods:	apply()	(freezes current display)
		play()	(plays transition)
		stop()	(stops transition mid-stream)
Light()	Add light source (controlled by methods)		
	Properties:	None	

Filter Name	Description and Properties		
	Methods:	addAmbient (red, green, blue, strength)	
		addCone (sourceLeft, sourceTop, sourceZAxis, targetLeft, targetTop, red, green, blue, strength, spreadAngle)	
		addPoint (sourceLeft, sourceTop, sourceZAxis, red, green, blue, strength)	
		changeColor (lightID, red, green, blue, absoluteColorFlag)	
		changeStrength (lightID, strength, absoluteIntensityFlag)	
		clear()	
		moveLight (lightID, sourceLeft, sourceTop, sourceZAxis, absoluteMovementFlag)	
MaskFilter()	Overlay transparent mask		
	Properties:	color	(color value)
MotionBlur()	Simulate blurred motion		
	Properties:	add	(1 or 0)
		direction	(0, 45, 90, 135, 180, 225, 270, 315)
		strength	(pixel count)
RandomDissolve()	Pixelated dissolve transition		
	Properties:	duration	(floating-point number of seconds)

continued

		play()	(plays transition)
		stop()	(stops transition mid-stream)
RandomBars()	Bar style transition		
	Properties:	duration	(floating-point number of seconds)
		orientation	(horizontal or vertical)
		percent	(0 to 100)
		status	0 (stopped), 1 (applied), 2 (playing)
	Methods:	apply()	(freezes current display)
		play()	(plays transition)
		stop()	(stops transition mid-stream)
Shadow()	Render as silhouette		
	Properties:	color	(color value)
		direction	(0, 45, 90, 135, 180, 225, 270, 315)
Stripes()	Striped style transition		
	Properties:	duration	(floating-point number of seconds)
		motion	(in or out)
		percent	(0 to 100)
		status	0 (stopped), 1 (applied), 2 (playing)
	Methods:	apply()	(freezes current display)
		play()	(plays transition)
		stop()	(stops transition mid-stream)

Filter Name	Description and Properties		
`Wave()`	Add sine-wave distortion		
	Properties:	`add`	(1 or 0)
		`freq`	(integer number of waves)
		`light`	(strength 0 to 100)
		`phase`	(percentage offset 0 to 100)
		`strength`	(intensity 0 to 255)
`xRay()`	Render edges only		
	Properties:	None	

For more details on deploying filters in IE for Windows, visit `http://msdn.microsoft.com/library/default.asp?url=/workshop/author/filter/filters.asp`. Because most of the live examples at that page require WinIE5.5+, be sure to use that version for the best experience.

CHAPTER 39

Ajax, E4X, and XML

IN THIS CHAPTER

Treating XML elements as objects

Creating XML data islands

Accessing XML element attributes

Using the XMLHttpRequest object

Using E4X to create dynamic XML objects

XML (eXtensible Markup Language) is an undeniably hot topic in the Internet world, and has been for the past few years. Not only has the W3C organization formed multiple working groups and recommendations for XML and its offshoots, but the W3C DOM recommendation also has XML in mind when it comes to defining how elements, attributes, and data of any kind — not just the HTML vocabulary — are exposed to browsers as an object model. Most of the arcana of the W3C DOM Core specification — especially the structure based on the node — are in direct response to the XML possibilities of documents that are beginning to travel the Internet.

ECMAScript for XML (E4X) is a standardized programming language extension that provides native XML support to ECMAScript as a primitive type, at the same level as strings, numbers, and Booleans. It has been supported since FireFox 1.5, but is not supported as of Safari 4.0.4, Google Chrome 4.1.249.1045, Opera 10.51, or IE 8.

During its early explorations into XML and browsers, Microsoft devised a custom HTML element — the `<xml>` tag — that allowed authors to embed XML data into an HTML document. These tags created what were called XML *data islands*. A more practical solution came slightly later with the creation of an ActiveX control that could retrieve XML data (from either a static `.xml` file or a web service that returns XML-structured data) into a web page without disturbing the HTML portion. Scripts could then use W3C DOM methods and properties to read the node tree as needed. Mozilla, Opera, and Safari browsers emulate the behavior of this `XMLHttpRequest` control in a native object so that modern web applications can load external XML data into a page for script inspection and manipulation. In an unusual turn of events, Microsoft has also now implemented the native `XMLHttpRequest` object in IE7 to match the implementation of other browsers.

The functionality made possible by the `XMLHttpRequest` object encapsulates the much-hyped buzzword Ajax, which stands for Asynchronous JavaScript And XML. This chapter covers both WinIE XML data islands and the client-side aspects of Ajax (the `XMLHttpRequest` object). Out of necessity, this book assumes that you are already familiar with XML such that your server-based applications serve up XML data exclusively, embed XML islands into HTML documents, or convert database data into XML. The focus of this chapter, and the application examples in Chapter 55, "Application: Outline-Style Table of Contents," and Chapter 60, "Application: Transforming XML Data" (on the CD-ROM), is how to access XML data and apply that data to rendered HTML content.

Elements and Nodes

When you leave the specialized DOM vocabulary of HTML elements, the world can appear rather primitive — a highly granular world of node hierarchies, elements, element attributes, and node data. This granularity is a necessity in an environment in which the elements are far from generic, and the structure of data in a document does not have to follow a format handed down from above. One web application can describe an individual's contact information with one set of elements, whereas another application uses a completely different approach to element names, element nesting, and their sequence.

Fortunately, most, if not all, scripting you do on XML data is on data served up by your own applications. Therefore, you know what the structure of the data is — or you know enough of it to let your scripts access the data.

The discussion of the W3C DOM in Chapter 25, "Document Object Model Essentials," should serve as a good introduction to the way you need to think about elements and their content. All relevant properties and methods are listed among the items shared by all elements in Chapter 26, "Generic HTML Element Objects."

XML data, whether delivered raw or embedded in a WinIE HTML document as a *data island* is a hierarchy of nodes. Typically, the outermost nodes are elements. Some elements have attributes, each of which is a typical name/value pair. Some elements have data that goes between the start and end tags of the element (such data is a text node nested inside the element node). And some elements can have both attributes and data. When an XML data collection contains the equivalent of multiple database records, an element container whose tag name is the same as each of the other records surrounds each record. Thus, the `getElementsByTagName()` method frequently accesses a collection of like-named elements.

When you have a reference to an element node, you can reference that element's attributes as properties; however, a more formal access route is through the `getAttribute()` method of the element. If the element has text data between its start and end tags, you can access that data from the element's reference by calling the `firstChild.nodeValue` property (although you may want to verify that the element has a child node of the text type before committing to retrieving the data).

Of course, your specific approach to `xml` elements and their data varies with what you intend to script with the data. For example, you may wish to do nothing more with scripting than enable

a different style sheet for the data based on a user choice. The XSL (eXtensible Stylesheet Language) standard is a kind of (non-JavaScript) scripting language for transforming raw `xml` data into a variety of presentations. But you can still use JavaScript to connect user-interface elements that control which of several style sheets renders the data. Or, as demonstrated in Chapters 55 and 60, you may want to use JavaScript for more explicit control over the data and its rendering, taking advantage of JavaScript sorting and data manipulation facilities along the way.

Table 39-1 summarizes the W3C DOM Core objects, properties, and methods that you are most likely to use in extracting data from `xml` elements. You can find details about all these items in Chapter 26.

TABLE 39-1

Properties and Methods for XML Element Reading

Property or Method	Description
`Node.nodeValue`	Data of a text node
`Node.nodeType`	Which node type
`Node.parentNode`	Reference to parent node
`Node.childNodes`	Array of child nodes
`Node.firstChild`	First of all child nodes
`Node.lastChild`	Last of all child nodes
`Node.previousSibling`	Previous node at same level
`Node.nextSibling`	Next node at same level
`Element.parentNode`	Reference to parent node
`Element.childNodes`	Array of child nodes
`Element.firstChild`	First of all child nodes
`Element.lastChild`	Last of all child nodes
`Element.previousSibling`	Previous node at same level
`Element.nextSibling`	Next node at same level
`Element.tagName`	Tag name
`Element.getAttribute(name)`	Retrieves attribute (`Attr`) object
`Element.getElementsByTagName(name)`	Array of nested, named elements
`Attr.name`	Name part of attribute object's name/value pair
`Attr.value`	Value part of attribute object's name/value pair

xml Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
`src`		
`XMLDocument`		

Syntax

Accessing `xml` element object properties or methods:

```
(IE5+)    [window.]document.all.elementID.property | method([parameters])
```

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

About this object

The `xml` element object is the primary container of an `xml` data island within an HTML page. If your scripts intend to traverse the node hierarchy within the element, or simply access properties of nested elements, you should assign an identifier to the `id` attribute of the XML element. For example, if the XML data contains results from a database query for music recordings that match some user-entered criteria, each returned record might be denoted as a `recording` element as follows:

```
<xml id="results">
   <searchresults>
      <recording>
         ...elements with details...
      </recording>
      <recording>
         ...elements with details...
      </recording>
      <recording>
         ...elements with details...
      </recording>
   </searchresults>
</xml>
```

Your script can now obtain an array of references to `recording` elements as follows:

```
var recs =
   document.getElementById("results").getElementsByTagName("recording");
```

Although it is also true that there is no known HTML element with the tag name `recording` (which enables you to use `document.getElementsByTagName("recording")`), the

unpredictability of `xml` data element names is reason enough to limit the scope of the `getElementsByTagName()` method to the `xml` data island.

The W3C DOM Level 2 does not define an `xml` element object within the HTML section. However, you can embed an XML document inside an HTML document in Mozilla even though the standards clearly indicate that a document can be one or the other, but not both. Of course, the browser understandably gets confused when custom elements have tag names that already belong to the HTML DTD. Therefore, we do not recommend attempting to embed custom elements into an HTML document for NN6+/Moz unless you are very careful to use entirely unique tag names that don't clash in any way with HTML or you know how to use XML namespaces within an XHTML document.

Properties

src

Value: String Read/Write

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `src` property represents the `src` attribute of the `xml` element. The attribute points to the URL of an external `xml` document whose data is embedded within the current HTML document.

XMLDocument

Value: Object reference Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `XMLDocument` property returns a reference to Microsoft's proprietary XML `document` object and the object model associated with it (the so-called XML DOM). A lot of this object model is patterned after the W3C DOM model, but access to these properties is through a rather roundabout way. For more details, visit `http://msdn.microsoft.com/en-us/library/ms535918.aspx`.

XMLHttpRequest Object

Properties	Methods	Event Handlers
readyState	abort()	onreadystatechange†
responseText	getAllResponseHeaders()	
responseXML	getResponseHeader()	
status	open()	
statusText	send()	
	setRequestHeader()	

†See Chapter 26, "Generic HTML Element Objects."

Syntax

Accessing `XMLHttpRequest` object properties or methods:

```
(IE5+/Moz)     XMLHttpRequestObjectRef.property | method([parameters])
```

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

About this object

The `XMLHttpRequest` object is an abstract object that lets your scripts retrieve XML data from, or send XML data to, any URL designed for that purpose. All the action occurs invisibly to the user, and it is the responsibility of your scripts to make the connection with the server and process the XML data, either after retrieval or prior to submission. This object was originally designed by Microsoft as part of its XML Core Services (MSXML), as first released as part of Internet Explorer 5 for Windows. Mozilla engineers implemented much of the same functionality in Mozilla browsers, with almost identical syntax. Similar functionality entered the Safari equation in Safari 1.2, not to mention the Opera browser in Opera 8. These latter implementations adhere very closely to the Mozilla `XMLHttpRequest` implementation.

Where the IE and Mozilla variations differ is how you create the object to begin with. Because the IE version is an ActiveX control, you create the object using the `ActiveXObject` constructor function. At least that's the case with versions of IE prior to version 7. In IE7, Microsoft finally got around to supporting the Mozilla object creation approach, which involves using a constructor for the `XMLHttpRequest` object. If you plan on using the `XMLHttpRequest` object in versions of IE prior to version 7, which is likely, you must equalize the creation of the two object versions in a single document and branch your code accordingly. Use object detection to handle the branching most effectively:

```
var req = null;
// branch for native XMLHttpRequest object
if (window.XMLHttpRequest)
   {
      try
      {
         req = new XMLHttpRequest();
      }
      catch(e)
      {
         req = null;
      }
   // branch for IE/Windows ActiveX version
   } else if (window.ActiveXObject)
   {
      try
      {
         req = new ActiveXObject("Msxml2.XMLHTTP");
      }
      catch(e)
```

```
        {
           try
           {
              req = new ActiveXObject("Microsoft.XMLHTTP");
           }
           catch(e)
           {
              req = null;
           }
        }
     }
```

Notice in the code how there are actually two different ActiveX objects that support the `XMLHttpRequest` functionality in IE. The first ActiveX object, `Microsoft.XMLHTTP`, represents the first incarnation of `XMLHttpRequest` as found in IE5. IE5.5 supplanted this ActiveX object with a newer one called `Msxml2.XMLHTTP`, which continued to be the IE-preferred means of accessing `XMLHttpRequest` through IE6. IE7 added support for the Mozilla-style approach of instantiating an actual `XMLHttpRequest` object without ActiveX. The example code, therefore, demonstrates how to gracefully create an `XMLHttpRequest` object while taking into consideration the various browser inconsistencies dating back to IE5/NN6/Moz1/Safari1.2/Opera8.

After the object is created, the basic syntax for opening a connection, sending the request, and retrieving the response data is the same for both WinIE and other browsers. To retrieve an XML document (node tree) from a URL source, the basic conceptual sequence is as follows:

1. Open the request object, specifying the request type and URL.
2. Bind an event handler function to the request object; this function is called when the request finishes.
3. Send the request.
4. Process the results of the request.

Let's take a look at each of these steps and the JavaScript code involved. Following is the code required to open the request object:

```
req.open("GET", "sourceURL", true);
```

This line of code opens the request object by passing along the `GET` request type, the URL of the data source, and whether the request is synchronous or asynchronous. The last argument is undoubtedly the most important because it directly controls whether the request is allowed to place in the background (asynchronously) or if the script should wait on the request (synchronously). Seeing as how the word *asynchronous* is in the acronym Ajax, it stands to reason that all Ajax requests pass `true` as the third parameter to the `open()` method. The asynchronous nature of Ajax is what gives Ajax applications such a unique feel, in that work can be carried out on the server and dynamically reflected on the client as it finishes.

The event handler binding in Step 2 of the previous list involves setting a function reference to the `onreadystatechange` property:

```
req.onreadystatechange = processRequest;
```

The function you assign here is called when the status of the request changes. You will typically only be concerned with the status changing to "complete."

An intermediate step that isn't strictly required involves setting the content type of the request header. The `XMLHttpRequest` object isn't limited to opening XML documents. Because of this, you may want to explicitly set the header type to `text/xml`, just to make sure there is no confusion when you are opening XML data; some browsers act very strict with respect to the content type of the header. Following is the code that sets the header's content type:

```
req.setRequestHeader("Content-Type", "text/xml");
```

Step 3, sending the request, is perhaps the simplest step in performing an Ajax request:

```
req.send("");
```

At this point, the request has been issued, and you can begin to check and see if it has completed. Control has returned to the browser thanks to the asynchronous nature of the request. The job of checking the status of the request and processing any results falls to the `processRequest()` handler function that was set a moment ago.

The request handler function is automatically called when a change occurs in the state of the request. It is possible for the request to cycle through any of the following states:

- Uninitialized (0)
- Loading (1)
- Loaded (2)
- Interactive (3)
- Complete (4)

The number beside each of the states corresponds to possible values for the `readyState` property of the request object. This is the property you use to find out if the request has finished and is ready for processing. There is one other property, however, that is important to look at before charging into the XML processing. We're referring to the `status` property, which really has only one value of concern to you, `200` — which means the request was successful.

Pulling this information together enables you to assemble a skeletal request event handling function:

```
function processRequest(req) {
   if (req.readyState == 4 && req.status == 200)
   {
      var xmlDoc = req.responseXML;
      // further processing of document here
   }
}
```

At this point, scripts can inspect the contents of the `xmlDoc` value by way of W3C DOM node properties and methods.

Note

The `XMLHttpRequest` object in some browsers must reference pages served from a web server, and not a local file. You can experiment successfully from a personal web server running on your PC, but not with files accessed through the `file:` protocol. If the xml file is accessed through the `file:` protocol, the `status` property will return a `0`. ■

Listing 39-1 shows a utility script that retrieves XML content from a URL (passed as a parameter to the `loadXML()` function) in a cross-browser manner. Additional error checking verifies that the retrieval is successful before moving forward. Notice that this code is more of an Ajax template than a functioning example. You have to plug in your own code inside the `processRequest()` function once the `xmlDoc` variable is set.

LISTING 39-1

Utility XML Data Reading Script

```
var req = null;

// retrieve XML document as document object
function loadXMLDoc(url)
{
   // branch for native XMLHttpRequest object
   if (window.XMLHttpRequest)
   {
      try
      {
         req = new XMLHttpRequest();
      }
      catch(e)
      {
         req = null;
      }
   // branch for IE/Windows ActiveX version
   } else if (window.ActiveXObject)
   {
      try
      {
         req = new ActiveXObject("Msxml2.XMLHTTP");
      }
      catch(e)
      {
         try
         {
            req = new ActiveXObject("Microsoft.XMLHTTP");
         }
         catch(e)
         {
            req = null;
         }
      }
   }
```

```
    if (req)
    {
       req.open("GET", url, true);
       req.onreadystatechange = processRequest;
       req.setRequestHeader("Content-Type", "text/xml");
       req.send("");
    }
}

function processRequest()
{
    if (req.readyState == 4 && req.status == 200)
    {
       var xmlDoc = req.responseXML;
          if (xmlDoc)
          {
             // get busy processing XML
          }
    }
}
```

Properties and methods described in this chapter are those that the object has in common for both WinIE and Mozilla browsers, as well as WebKit-based browsers and Opera. You can see examples of this object, and the template in Listing 39-1, within the applications of Chapters 55 and 60.

Properties

readyState

Value: Integer Read-Only

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

Your scripts can read the value of the `readyState` property to determine the state of the `XMLHttpRequest` object, particularly while it is operating during its initialization or data transfer. Values are the same as for other objects that offer this property. See the bulleted list earlier in this chapter, as well as Table 26-6, for integer values and their meanings. When carrying out asynchronous (Ajax) requests, you assign an `onreadystatechange` event handler to the `XMLHttpRequest` object; the event function then inspects the `readyState` property for further processing.

Related Item: `status` property

responseText

Value: String Read-Only

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

After the `send()` method executes, and if the server returns any data (as it will with a `GET` operation), you can access a string version of the returned data through the `responseText` property. If the returned data is an XML document, this property provides a string-only version of the entire content.

Related Item: `responseXML` property

responseXML

Value: XML document object — Read-Only

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

After the `send()` method executes, and if the server returns any data (as it will with a `GET` operation), you can access the returned W3C DOM–compliant document object through the `responseXML` property. The object to which this property points is a genuine document node (with a `nodeType` of 9), which gives your scripts the power to walk the node tree, and retrieve tags, attributes, and text nodes inside elements, as you would with any DOM document.

As the examples in Chapters 55 and 60 demonstrate, you can use the data from the XML document to build HTML that displays the XML content in the format of your choice (using JavaScript as a more flexible alternative to XSL). If your page is interactive to the extent that users can modify the content, you may then modify the document tree stored in your script variable, and send the revised XML back to the server by opening a new `XMLHttpRequest` connection pointing to the URL that accepts the posted data.

Related Items: `responseText` property; `open()` method

status

Value: Integer — Read-Only

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

After the `send()` method executes, you can read the status of the transaction through the `status` property. The value is an integer corresponding to the response issued by the server at the end of the transaction. A successful transaction value is 200 (corresponding to the OK `statusText` property value). Perhaps the other most common status value is 404, which occurs if the URL you supply to the `open()` method points to a file or source not found on the server. As shown in Listing 39-1, you can use the 200 value as the key to determining if the transaction is a success. You might consider reporting any other value to the user (although inexperienced users may not understand the meaning of the status text).

A complete list of status values and related descriptions (status text) is shown in Table 39-2. Keep in mind that the vast majority of the time you will be concerned only with whether or not the status code is 200 (OK).

Related Item: `statusText` property

TABLE 39-2

HTTP Status Codes for the status Property

Status Code	Status Text
100	Continue
101	Switching Protocols
200	OK
201	Created
202	Accepted
203	Non-Authoritative Information
204	No Content
205	Reset Content
206	Partial Content
300	Multiple Choices
301	Moved Permanently
302	Found
303	See Other
304	Not Modified
305	Use Proxy
307	Temporary Redirect
400	Bad Request
401	Unauthorized
402	Payment Required
403	Forbidden
404	Not Found
405	Method Not Allowed
406	Not Acceptable
407	Proxy Authentication Required
408	Request Timeout
409	Conflict
410	Gone
411	Length Required

Status Code	Status Text
412	Precondition Failed
413	Request Entity Too Large
414	Request-URI Too Long
415	Unsupported Media Type
416	Requested Range Not Suitable
417	Expectation Failed
500	Internal Server Error
501	Not Implemented
502	Bad Gateway
503	Service Unavailable
504	Gateway Timeout
505	HTTP Version Not Supported

`statusText`

Value: String Read-Only

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

After the `send()` method executes, you can read the plain-language status of the transaction through the `statusText` property. The value is a string corresponding to the response integer by the server at the end of the transaction. A successful transaction value is OK (corresponding to the 200 `status` property value). Use the `status` property for testing the results in your script, and the `statusText` property to report errors to users. Table 39-2 contains a list of the possible status text values that may be stored in the `statusText` property. For an example using the `status` property, see Listing 39-1.

Related Item: `status` property

Methods

`abort()`

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

The `abort()` method stops any transaction currently in progress. This method is the scripted equivalent of clicking a browser's Stop button while it retrieves the contents of a web page.

Related Items: `readyState` property; `send()` method

getAllResponseHeaders()
getResponseHeader("*headerName*")

Returns: String

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

For each transaction, the server transmits a series of name/value pairs as a header to the actual data. The `getAllResponseHeaders()` method returns the complete set as received by the `XMLHttpRequest` object. Such a header set may look like the following:

```
Date: Mon, 12 Feb 2007 03:12:59 GMT
Server: Apache/1.3.27 (Darwin)
Last-Modified: Sun, 28 Jan 2007 22:13:04 GMT
Etag: "12babe-3a2-3f809770"
Accept-Ranges: bytes
Content-Length: 930
Keep-Alive: timeout=15, max=100
Connection: Keep-Alive
Content-Type: text/xml
```

If you want to retrieve the value of just one of the headers, use the `getResponseHeader()` method, and pass as a parameter a string with only the name portion of one of the headers. For example:

```
var size = req.getResponseHeader("Content-Length");
```

The parameter is not case-sensitive, but the spelling (along with any hyphen in the name) is critical.

Related Items: `readyState` property; `send()` method

open("*method*", "URL"[, *asyncFlag*[, "*userName*"[, "*password*"]]])

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

Use the `open()` method to specify the transaction type and URL of the destination of the request. The *method* parameter may be either `GET` (for retrieving data from a server) or `POST` (for sending XML to a server). The *URL* may be either relative to the current page, or a complete `http:` URL.

Three additional parameters are optional. The first is a Boolean value for whether the request should be asynchronous. If `true` (the default), the `XMLHttpRequest` object does not wait for a response (after the `send()` method) before continuing with script processing. By setting this parameter to `false`, you ensure that processing continues only after the transaction has completed or timed out. Of course, this also ensures that the user can't do anything while waiting for the server to process your request, and may feel as though the browser has frozen. The preferred approach is to set the parameter to `true` and carry out all requests asynchronously. All

the `XMLHttpRequest` examples in this book (Chapters 55 and 60, primarily) utilize this latter asynchronous (Ajax) approach.

The other optional parameters are strings for a username and password, if authentication is needed to access the URL.

Note that the `open()` method merely fills various properties of the request, and that the request does not occur until the `send()` method is invoked.

Related Item: `send()` method

send(*content*)

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

After setting the characteristics of the request through the `open()` method and its parameters, invoke the `send()` method to trigger the actual request over the network. For a GET operation, specify `""` or `null` as the parameter. But for a POST operation, the parameter should be a reference to a DOM document that has been assembled in script. You may also specify a string as the value being posted to the request's URL.

Related Item: `open()` method

setRequestHeader("*name*", "value")

Returns: Nothing

Compatibility: WinIE5+, MacIE-, NN7+, Moz+, Safari1.2+, Opera+, Chrome+

The `setRequestHeader()` method enables you to specify a name/value pair for the header being sent with the HTTP request. For this method to succeed, it must be called only when `readyState` is set to 1 (Loading); see Table 26-6 for more details. In practical coding terms, this equates to setting the request header after the call to `open()` but before the call to `send()`.

Related Item: `readyState` property

ECMAScript for XML (E4X)

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
	`toXMLString()`	

Prior to E4X, the only way to access XML documents with JavaScript was through the DOM at the object level. With the advent of E4X, XML is treated as a primitive type, at the same level as strings, numbers, and Booleans. What does this mean for us? The short version is that

XML access is now simpler for us as web developers, and faster for the end user. An `XML` object created with the XML primitive is not part of the DOM; neither is it a DOM representation of XML. Because it is a primitive, you use it in ways similar to how you use strings, numbers and Booleans. The sample code in this section is in listing `jsb-02.html` on the CD-ROM.

While you can use the standard MIME type with E4X

```
<script type="text/javascript">
```

you could end up with inexplicable syntax errors. This usually occurs for one of two reasons: you are using HTML comments to hide script from older browsers, or you are putting your scripts into XML CDATA sections. If either of these is the case, then you can add the E4X argument to the standard MIME type:

```
<script type="text/javascript; e4x=1">
```

With E4X, you declare an `XML` object, in much the same way that you declare a string or numeric or Boolean object, with the `XML` constructor:

```
var copyrightData1 = new XML();
```

You can then assign XML text to the object:

```
copyrightData1 = <copyright>
                    <date>2010</date>
                    <author>Danny Goodman</author>
                 </copyright>;
```

You can also pass a string to the `XML` constructor:

```
var copyrightText = "<copyright>"
                  + "<date>2010</date>"
                  + "<author>Danny Goodman</author>"
                  + "</copyright>";
var copyrightData2 = new XML(copyrightText);
```

Either way, you create an `XML` object. The XML elements within the object are properties, which means you can use the standard `object.property` notation that you've been using all along in JavaScript. At the very least, you can take your very simple XML document and write it to the current web page:

```
document.write("Copyright by " +
               copyrightData1.author);
```

E4X becomes really exciting when you want the `XML` object to dynamically interact with JavaScript expressions. You do this with curly braces:

```
copyrightDate = new Date();
copyrightData1 = <copyright>
                    <date>{copyrightDate.getFullYear()}</date>
                    <author>Danny Goodman</author>
                 </copyright>;
```

Just as in XML documents, the elements in your `XML` objects can have attributes. Those attribute values can be set dynamically with curly brace notation as well. Notice that you can extract the value of an element's attribute by using dot notation, with the @ operator in front of the attribute name:

```
copyrightData1 = <copyright date={copyrightDate.getFullYear()}>
                    <author>Danny Goodman</author>
                 </copyright>;
document.write("<br />The value of the date attribute" +
               " of the copyright element is " +
               copyrightData1.@date +
               ".");
```

Most XML documents contain repeating sets of elements. You can also create such sets in your `XML` object:

```
copyrightData1 = <copyright date={copyrightDate.getFullYear()}>
                    <author>Danny Goodman</author>
                    <withAuthor>Michael Morrison</withAuthor>
                    <withAuthor>Paul Novitski</withAuthor>
                    <withAuthor>Cynthia Gustaff Rayl</withAuthor>
                 </copyright>;
```

When you access the repeating set, you get back an `XMLList` object. It can be processed almost like an array. There are two primary differences: `length()` is a method and not a property; also, other `Array` object methods are not supported by `XMLList`.

```
document.write("<br >The number of repeating 'with' elements is " +
              copyrightData1.withAuthor.length() +
              ".");
var message = "<br />The JavaScript Bible was written by " +
              copyrightData1.author +
              " with";
for each (i in copyrightData1.withAuthor)
{
   message += "<br />" + i;
}
document.write(message);
```

Methods

toXMLString()

Returns: String

Compatibility: WinIE5-, MacIE-, NN-, FF1.5+, Safari-, Opera-, Chrome-

The `toXMLString()` method returns a string that is the concatenated text of all the text nodes of the XML object.

Related Item: `toString()` method (see Chapter 26)

CHAPTER

HTML Directive Objects

IN THIS CHAPTER

Accessing non-displayed element objects

Linking operating system–specific style sheet definitions

HTML, head, link, title, meta, base, and script elements

Thanks to the modern browser's desire to expose all HTML elements to the document object model, we can now access a variety of objects that represent HTML elements that are normally invisible to the human viewer of a page. These elements are called *directive elements* because they predominantly contain instructions for the browser — instructions that direct the browser to locate associated content on the page, link in external specifications, treat content as executable script statements, and more.

As you browse through the objects of this chapter, you may wonder why they have so many properties that normally indicate that the elements occupy space on the rendered page. After all, how can a `meta` element have dimension or position on the page when it has no renderable content? The reason is that modern browsers internally employ some form of object-oriented behavior that lets all HTML elements — rendered or not — inherit the same set of properties, methods, and event handlers that any generic element has (see Chapter 26, "Generic HTML Element Objects"). The logical flaw is that unrendered elements can have properties and methods that don't genuinely apply to them. In such cases, their property values may be zero, an empty string, or an empty array. Yet the properties and methods exist in the objects just the same. Therefore, despite the large number of objects covered in this chapter, there are relatively few properties and methods that are not shared with all HTML elements (as covered in Chapter 26).

HTML Element Object

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
version		

Syntax

Accessing `html` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE4+)     [window.]document.body.parentElement.property | method([parameters])
(IE5+/W3C) [window.]document.body.parentNode.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
                     method([parameters])
```

About this object

The `html` element is the big wrapper around all other elements of the page. In the object tree, the `html` element sits between the all-encompassing `document` object and the element's most common children, the `head` and `body` elements. Other than one deprecated property (`version`), the `html` element object offers nothing of importance to the scripter — with one possible exception. When your script needs to use methods on the child nodes of the `html` element, you must invoke most of those methods from the point of view of the `html` element. Therefore, you should know how to create a reference to the `html` element object (shown in the preceding "Syntax" section), just in case you need it.

Property

version

Value: String Read-Only

Compatibility: WinIE6+, MacIE5+, NN6+, Moz1+, Safari1+, Opera+, Chrome+s

The `version` property is an artifact of an "ancient" way that an HTML document specified the HTML version of its content. These days, the preferred way to declare the HTML version for a document is through a Document Type Declaration (DTD) statement that precedes the `<html>` tag. An example of a modern DTD statement that accommodates HTML 4, plus deprecated elements and attributes, as well as frameset support is

```
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.0 Frameset//EN"
   "http://www.w3.org/TR/REC-html40/frameset.dtd">
```

If you're looking to create pages that adhere to a somewhat stricter standard, then the XHTML 1.0 Transitional DTD might be a better option:

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
   "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
```

See `http://www.w3.org/TR/REC-html40/struct/global.html#h-7.2` for several other possibilities. A DTD statement does not affect the `version` property of an html element object.

head Element Object

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
`profile`		

Syntax

Accessing `head` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
                     method([parameters])
```

About this object

The purpose of the `head` element is primarily to act as a container for most of the other HTML directive elements. Other than as a reference point to the child elements nested within, the `head` element object rarely comes into play when scripting a document.

Property

`profile`

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `profile` property is the script version of the optional `profile` attribute of a `head` element. Although the attribute and property are supported in modern browsers, they are not used in practice yet. You can find details about the attribute at `http://www.w3.org/TR/REC-html40/struct/global.html#profiles`.

Related Items: `meta` element object

base Element Object

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
href		
target		

Syntax

Accessing `base` element object properties or methods:

```
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
                  method([parameters])
```

About this object

The `base` element enables the page author to specify a default server directory and/or link target for the entire page. If you omit the `base` element from the HTML, which is often the case, browsers use the current page's path as the base URL and the current window or frame as the default target. Occasionally, a page generated entirely by way of `document.write()` has difficulty establishing the same `base` URL as the document that generates the content, particularly if the primary page is written out by a server script (in Perl or another language). Including a `<base>` tag in the dynamically-written new page solves the problem; the new page can fetch images or other external elements via relative URLs within the page.

The two distinctive properties of the `base` element object are rarely, if ever, scripted.

Properties

href

Value: URL string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `href` property is generally an absolute URL to the directory you wish to declare as the default directory for the page. Even though browsers automatically set the `base href` to the document's own directory, this object and property do not have any values unless you explicitly set them in a `<base>` tag. In IE, changing this property after a page loads causes the page to re-resolve all relative URLs on the page to the new `base href`. Therefore, if images have relative URLs assigned to their `src` properties (either by way of the tag attribute or script), a change to the `base` element's `href` property forces the browser to look for those same relative URLs in the new directory. If the files aren't there, the images show up broken on the page.

target

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `target` property governs the default window or frame that is to receive any content coming from a server in response to a click on a link or any other element that has its own `target` attribute. Valid values include the name of any frame (as assigned to the `name` attribute of the `<frame>` tag) or window (as defined by the second attribute of the `window.open()` method). You can also assign standard HTML targets (`_blank`, `_parent`, `_self`, and `_top`) to this property as strings.

link Element Object

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
charset		Onload
disabled		
href		
hreflang		
media		
rel		
rev		
sheet		
styleSheet		
target		
type		

Syntax

Accessing `link` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
                method([parameters])
```

About this object

The `link` element (not to be confused with the `a` element that is often referred to as a "link" element when it contains an `href` attribute pointing to another document) has many potential uses in pointing to external documents that relate to the current document. Its most common usage today is for linking an external style sheet specification to the document. In fact, it's not

uncommon for sophisticated site designs to use `document.write()` to generate the `<link>` tag so that operating system–specific style sheets are applied to the page. In the following code fragment (which goes inside a document's `head` element), the page loads a Macintosh-specific style sheet when the page is running on a Macintosh; otherwise, it loads a Windows-specific style sheet:

```
<script type="text/javascript">
var isMac = navigator.userAgent.indexOf("Mac") != -1;
var linkTagStart = "<link rel='stylesheet' type='text/css' href='";
var linkTagEnd = ".css'>";
   if (isMac)
   {
       document.write(linkTagStart + "mac" + linkTagEnd;
   }
   else
   {
       document.write(linkTagStart + "windows" + linkTagEnd;
   }
</script>
```

Although it may appear that the `link` element can load a variety of content into a page, do not use it for multimedia (for which you should use the `object` element) or external HTML (for which you should use an `iframe` element).

Many of the properties of the `link` element object are script representations of HTML 4.0 attributes for the element. However, browsers don't take full advantage of the possibilities available from the `link` element yet, at least not without an add-on browser extension. (For example, a browser can provide arrows to the previous and next documents in a series, as specified by the `rev` and `rel` attributes. But so far, no browser implements this by default.) Properties unique to this object offer scripted access (in various browser versions) to attribute values of the `link` element. Therefore, this chapter does not spend a lot of time on properties that are not in current use.

Properties

`charset`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `charset` property advises the browser about the character encoding of the content that will arrive from the external document (assuming you also have the `href` attribute set). Values for this property must match the encoding naming conventions defined in an industry standard registry (`http://www.iana.org/assignments/character-sets`).

`disabled`

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

By changing the `disabled` property (the default is `false`), you can turn externally linked content on and off. For example, you can define two different style sheet links in a document that has two `<link>` tags with the `disabled` attribute of one of them set. You can switch between the two style sheets by setting the `disabled` property of one to `true` and the other to `false`.

href

Value: String See Text

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

Another way to swap style sheets is to modify the value of a single `link` element object's `href` property. The property's value is a URL string.

hrefLang

Value: String Read/Write

Compatibility: WinIE6+, MacIE6+, NN6+, Moz1+, Safari1+, Opera+ Chrome+

The `hrefLang` property is an advisory for the browser (if the browser takes advantage of it) about the written language used for the content to which the `link` element's `href` attribute points. Values for this property must be in the form of the standard language codes (for example, `en-us` for U.S. English). For a complete list of language codes, visit `http://www.devguru.com/technologies/vbscript/QuickRef/LCIDchart.html`.

media

Value: String Read/Write

Compatibility: WinIE4+, MacIE-, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `media` property is an advisory for the browser about the target output device intended for the content to which the `link` element's `href` attribute points. This is an outgrowth of HTML 4.0 efforts to make way for future browsers and content that can be optimized for devices such as printers, handheld computers, and audio digitizers. The W3C specifies a preliminary set of constant string values for this property's equivalent attribute. So far, browsers recognize (at most) `all` (default), `print`, and `screen`. The notable exception is Opera, which also supports `handheld` as an acceptable value for the `media` property.

rel
rev

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `rel` and `rev` properties are intended to define relationships in the forward and backward directions with respect to the current document. Browsers have yet to exploit most of the potential of these attributes and properties without an add-on of some sort. For the most part, the attributes solely direct the browser to treat the external content as a style sheet definition file.

A long list of values is predefined for these properties, based on the corresponding attribute values specified in HTML 4.0. If the browser does not respond to a particular value, the value is

simply ignored. You can string together multiple values in a space-delimited list inside a single string. Accepted values are as follows:

alternate	contents	index	start
appendix	copyright	next	stylesheet
bookmark	glossary	prev	subsection
chapter	help	section	

sheet

Value: Object Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz1+, Safari-, Opera-, Chrome-

When a `link` element loads an external style sheet, the W3C DOM `sheet` property of the `link` element object provides scripted access to the style sheet rules that belong to that external file. Use properties of the `sheet` object to access specifics about the imported rules.

styleSheet

Value: Object Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

When a `link` element loads an external style sheet, the IE-specific `styleSheet` property of the `link` element object provides scripted access to the style sheet rules that belong to that external file. Use properties of the `styleSheet` object (see Chapter 38, "Style Sheet and Style Objects") to access specifics about the imported rules.

target

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

In the context of using `link` elements to point to other content associated with the current document (for example, the next and previous documents within a series), the `target` property can advise the browser which frame or window to use to display that content. For example, a suitably equipped browser can display a glossary in a separate window. No browsers currently implement these extended features of the `link` element, so the property is provided in browsers only for compatibility with the W3C standards. If the property were truly functional, it would accept values in the form of a string name for a frame or one of the window constants (`_blank`, `_parent`, `_self`, or `_top`).

type

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `type` property specifies the `mime` type for the content that will arrive from the external document to which the element's `href` attribute points. `link` elements are used primarily for Cascading Style Sheets, so the property value is `text/css`.

Event handlers

onload

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `onload` event handler fires when the external content pointed to by the `link` element's `href` attribute completes loading. WinIE5 fires this event handler even if the loading does not succeed, so use this event handler with care.

meta Element Object

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
charset		
content		
httpEquiv		
name		
url		

Syntax

Accessing `meta` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
                     method([parameters])
```

About this object

In computer terminology, *metadata* usually consists of extra information about the primary data of a document or information collection. In HTML documents, metadata can be additional hidden information about the document, such as the name of the author and keywords. If the browser is suitably equipped, metadata can also include some instructions, such as when to reload the page by itself. `meta` elements add all of this metadata to HTML documents. Both fact

and folklore surround the application of `meta` elements within pages. One fact is that Internet search engine robots used to scour pages for certain kinds of keyword meta tags to help place your page within relevant categories when Web surfers are looking for specific content. (But thanks to keyword loading by unscrupulous web sites, search engines now rarely consider `meta` keywords.) Folklore holds that browsers always respond to `meta` element wording that prevents browsers from copying pages into the cache — when in fact, this behavior is not universal among browsers.

Complete details about `meta` element usage is beyond the scope of this JavaScript book, but you should be aware of one widely accepted composition that enables you to set a page to reload itself (or another page) at a fixed time interval. This is especially useful if your page retrieves very timely information from a database. The format is

```
<meta http-equiv="refresh" content="n,url=url" />
```

`n` is the number of seconds to delay before reloading the page, and `url` is the complete URL of the page to be reloaded. Note that you can specify any page you like. This allows for a kind of slide show to be sequenced in a freestanding kiosk, for example, because each page's `meta` element points to the next page in the series after a fixed amount of time.

Unique properties for the `meta` element object mimic the HTML attributes for the `<meta>` tag. Browsers read most attributes only at load time, which means that scripted changes to values after the page loads have no effect. These properties are rarely, if ever, accessed from a script, so we mention them here only briefly.

Properties

charset

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `charset` property advises the browser about the character encoding of the content for the page. Values for this property must match the encoding naming conventions defined in an industry standard registry (`http://www.iana.org/assignments/character-sets`).

content

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

For many applications of the `meta` element, the `content` property contains the primary value associated with the element. For example, search engines used to look for (and some still do) a `meta` element whose `name` attribute is `"keywords"`. The value of the `content` attribute is a comma-delimited string of keywords that the search engine reads and indexes in its own database. The `content` property simply represents the `content` attribute string. Changing the values by script obviously does nothing to alter the tag values of the page on the server.

`httpEquiv`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

A `meta` element can simulate and extend the transmission of server instructions to the browser — instructions that normally arrive in the form of HTTP headers. These header supplements are supplied in `meta` elements via the `http-equiv` attribute, which is represented in the object model by the `httpEquiv` property. Common values include `refresh` and `expires`. Each of these also requires a `content` attribute that provides necessary details for carrying out the instructions. If you assign a string value to the `httpEquiv` property, be sure the `content` property has a suitable string assigned to it.

`name`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

A `meta` element that includes genuine metadata about the page (for example, author or keywords) usually has a `name` attribute that identifies what the metadata is (analogous to the name of a name-value pair). The `name` and `content` properties go hand in hand because the content string usually must be in a particular form for an external process, such as a search engine, to read the data successfully. Values for the `name` attribute are rarely case-sensitive.

`url`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

If a `meta` element needs to point to a document on the Internet for any reason, the URL of that document is assigned to the `url` attribute of the element. You can modify the value via the `url` property of a `meta` element object. We recommend a complete URL string for the `url` property value.

script Element Object

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
`defer`		
`event`		
`htmlFor`		
`src`		
`text`		
`type`		

Syntax

Accessing `script` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
                    method([parameters])
```

About this object

The `<script>` tag is well known to scripters, and modern browsers treat the `script` element as an object that, itself, can be scripted. The circularity of this description isn't as far-fetched as it sounds. Although scripting an existing script is a rarity in practice, it is not out of the question to generate a new `script` element after the page loads. If you use W3C DOM syntax to create a new `script` element, you then need to assign values to the properties that are normally set via the tag's attributes. Thus, scripting a script does make sense.

Unless you have experience with IE's option of binding event handlers to `<script>` tags (see Chapter 25, "Document Object Model Essentials"), some of the properties described next will be foreign to you. Even so, these properties are now a part of the W3C DOM specification.

Properties

`defer`

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6-, Moz-, Safari-, Opera-, Chrome-

The default process of loading a page that contains scripts is to wait for any immediate script execution to complete before the rest of the page loads. But, if you include a `defer` attribute in the tag, modern browsers continue to load the rest of the page without waiting for immediate scripts to run. The `defer` property enables you to inspect or set that property; its default value is `false`. Once a page loads, any change you make to an existing `script` element's `defer` property has no effect. Although the property is available in modern browsers, only IE responds to setting the property to `true`.

`event`
`htmlFor`

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6-, Moz-, Safari-, Opera-, Chrome-

Internet Explorer enables you to bind events to script statements when you specify both a `for` and `event` attribute in the `<script>` tag. Statements inside the tag execute only when the

object named by the `for` attribute receives the event named by the `event` attribute. You can examine the `event` attribute by way of the `script` element object's `event` property, and you can view the `for` attribute through the `htmlFor` property. Both properties simply mimic whatever values are assigned to their respective attributes, such as `onclick()` and `myDIV`. Only IE responds to the corresponding attributes of a `<script>` tag.

src

Value: String — See Text

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `src` property is a string of the URL of an external `.js` script file to be linked into a page. You can change this property in IE after you load the external script, but the old script does not go away from the page. If the new script defines the same variable and function names, the new versions overwrite the old. Other browsers may not load a new external script.

text

Value: String — Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The full text of a `script` element is available for reading through the `text` property. Although IE5+ may give the impression that you can modify this property, the script that loads with the page is the script that's stored in the browser's memory. Thus, the original script statements continue to work even though the object's property is different.

type

Value: String — Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `type` attribute was added to the `<script>` tag in HTML 4.0 to help resolve the conflict that the deprecated `language` attribute created for all HTML elements. The value of the attribute (and thus the `type` property) is a `mime` type string. For JavaScript, that value is `text/javascript`.

title Element Object

For HTML element properties, methods, and event handlers, see Chapter 26.

Properties	Methods	Event Handlers
`text`		

Syntax

Accessing `title` element object properties or methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
                    method([parameters])
```

About this object

Before the `title` element was accessible to scripting as an object, the prescribed way to get to the content of the page's `<title>` tag was through the `document.title` property. Although that property is still available for backward compatibility, modern scripts should access the `text` property of the `title` element object. As a useful exercise, you can modify Listing 29-15 (loaded via Listing 29-14) to use the W3C DOM syntax to retrieve and display the document's title.

Property

text

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `text` property represents the text between the start and end tags of the `title` element object. This is simply a convenience property because the text can be referenced by other ways in the IE4+ (`innerText` property), NN6+ (`innerHTML`), and W3C DOM (`firstChild.nodeValue`) syntaxes, with the latter being the preferred approach. For backward compatibility with earlier browsers, you can, alternatively, use the `document.title` property.

CHAPTER

Table and List Objects

IN THIS CHAPTER

Modifying table cell content

Adding and deleting table rows

table, caption, tbody, tfoot, thead, col, colgroup, th, tr, and td element objects

ol, ul, li, and dl list element objects

Tables are incredibly popular HTML constructions. When you consider that a lot of server applications search SQL databases and display data gathered from SQL tables, it's not unusual to find the table concept carried over from data storage to data display. Spreadsheet programs certainly put the notion of tabular display into the minds of most computer users.

One of the truly beneficial properties of tables in HTML is that they pack a lot of page organization and alignment punch in just a few tags and attributes. Even if you're not a graphic designer or a dedicated HTML jockey, you can get rows and columns of text and images to line up perfectly on the page. This behavior also lures many page designers to sculpt elaborately detailed pages out of what appear to be positioned elements. Earlier browsers didn't offer positioning facilities, so borderless tables were torqued into performing all kinds of placement tricks with the help of precisely-sized, transparent images, creating the illusion of white space between carefully placed elements.

Using tables to specify design and page layout is rapidly giving way to CSS techniques that achieve a similar look with less code. This trend is driven by web standards goals of using HTML markup to denote context rather than layout. In fact, it is now considered an antiquated practice to use tables purely for the purpose of laying out pages. Even so, many web pages need to display genuinely columnar data — a purpose for which HTML tables are still ideally suited. The first part of this chapter focuses on the scriptable aspects of `table` element objects and the shopping list of elements that support tables. Later in the chapter, we discuss element objects that create formatted lists in pages.

The Table Object Family Hierarchy

Although most of this discussion of table markup is best left to HTML texts, the structure of a full-fledged table and the relationships among the elements — particularly the parent-child relationships — may affect your scripting and event handling.

You are probably very familiar with the most basic table structure that has been around since the early days of HTML. Such a table (in a 2×2 layout) can have the following form:

```
<table>
   <tr>
      <td></td>
      <td></td>
   </tr>
   <tr>
      <td></td>
      <td></td>
   </tr>
</table>
```

If you want to place a row of cells at the top of each column such that the contents of the cells act as headers for each column, add a row as follows:

```
<table>
   <tr>
      <th></th>
      <th></th>
   </tr>
   <tr>
      <td></td>
      <td></td>
   </tr>
   <tr>
      <td></td>
      <td></td>
   </tr>
</table>
```

You can also include a caption associated with the table. Its tag goes immediately after the `table` element's start tag:

```
<table>
   <caption></caption>
   <tr>
      <th></th>
      <th></th>
   </tr>
   <tr>
      <td></td>
      <td></td>
```

```
    </tr>
    <tr>
       <td></td>
       <td></td>
    </tr>
 </table>
```

In line with its emphasis on providing contextual tags, HTML 4.0 added three tags that enable you to define groups of table rows according to whether they are the header, body, or footer of the table (`thead`, `tbody`, and `tfoot` elements, respectively). A table footer, for example, can display column totals. The only seemingly illogical rule about these elements is that you should define the `tfoot` element and its row contents before the `tbody` element(s) in the table. Even with this source code placement, the `tfoot` row appears at the bottom of the table.

Some browsers produce visual dividers between these sections (WinIE5+ does a nice job of this). Moreover, you can have multiple `tbody` sections within a table. Some browsers render dividers between these `tbody` sections (again, WinIE5+ does it well). Regardless of the built-in divider support, these contextual groupings also enable you to assign style sheets to HTML tag selectors, so that you don't have to dream up a scheme of class and `id` names tied to style sheet rules. Building upon the skeletal table shown thus far, you add the `thead` and `tbody` elements like this:

```
<table>
   <caption></caption>
   <thead>
      <tr>
         <th></th>
         <th></th>
      </tr>
   </thead>
   <tbody>
      <tr>
         <td></td>
         <td></td>
      </tr>
      <tr>
         <td></td>
         <td></td>
      </tr>
   </tbody>
</table>
```

That's the extent of table-oriented HTML containers. The remaining two elements, `colgroup` and `col`, provide a different "slice" of the table for style sheets and other visual groupings. One of the most obvious purposes of these two elements is to assign a width or other style to all cells in a particular column or group of columns. You can also use these elements to group adjacent columns so that dividers are drawn between groups of columns — if the browser (such as WinIE5+) supports dividers between column groups — without specifying global table borders. You can see an example of the HTML for a complex table in the HTML 4.0 specification (`http://www.w3.org/tr/REC-html40/struct/tables.html#h-11.5`). Elsewhere on

that same page, you can find the formal specification for all table-related tags and attributes as defined by the W3C.

Populating table cells

Source material for a table's content can come from many different places. Most of the tables you see on the Web are hard-coded in the HTML. That is, the content of the table is fixed inside a static HTML file on the server.

But tables may also convey content from live databases or content that changes more frequently than content that's manually updated by the web site's author. The source and your web development infrastructure (not to mention your technical skills) dictate other avenues for populating tables.

After hard-coded HTML files, the next most common way to generate tables is through server-based CGI programs. These programs (written in Perl, C, and many other languages, including server-side JavaScript on those few servers that support it) generally compose a query for the database and then repackage the data returned from the database into HTML-formatted pages.

A more client-side–oriented approach is to let JavaScript apply the `document.write()` method to compose the table's tags as the page loads. Data for the cells can come from JavaScript arrays defined at the beginning of the document or from arrays defined in external `.js` library files that are linked in as the page loads. In the newest browsers, the data may come from blocks of XML-formatted data stuffed into the document. These solutions can work in situations where you need to update the table data periodically, but the table delivered to the client does not reflect the instantaneous state of a database. For example, a daily batch program on a server can capture the day's sales totals and write out a `.js` text file to a known place on the server. The file consists entirely of JavaScript array definitions. When the HTML page loads, the current `.js` file is automatically loaded into the page, and `document.write()` statements compose the table's HTML from the data supplied in the arrays. Although the script that assembles the HTML for the tables might appear formidable to a nonscripter, a nonscripter can also manually update the array data by following a template format supplied by the programmer.

Finally, if your page visitors run IE4+, you can take advantage of a Microsoft-specific technology called *data binding*. Data binding invokes the powers of one or more ActiveX controls that come with the IE browser (simulated in MacIE). These objects (collectively called Data Source Objects) let HTML pages access ODBC databases and structured text files (MacIE works only with text files). As the page loads, the table fills with data pulled live from the database. You can see an example of data binding in Chapter 26, "Generic HTML Element Objects," under the description of the data binding property: `dataFld`. The HTML file carries tags for only one row of cells, but data binding fills in the rest of the rows and cells.

Modifying table cell content

You can modify the HTML content of a table cell directly, in modern browsers, through the `td` element's `innerHTML` property (a Microsoft invention that is not sanctioned by the W3C DOM

Level 2, but is supported elsewhere as a de facto standard). Even if the content is simply text that is to inherit the style format of the surrounding td element, you can still use the innerHTML property. If the size of the new content affects the dimensions of the cell's column width or row height, the browser reflows the rest of the table content around it.

Even better than the innerHTML property is the W3C DOM form of modifying an element's content, which enables you to generate the new content via the document.createElement() or document.createTextNode() sequence and assign that new content to the cell by way of the td element's replaceChild() method.

Listing 41-1 shows a synthesis of different techniques to effect cell content replacement, including script code branches that emulate the appearance of replacement in NN4. The table represents only one line of what might be an order form for several products. As the user makes a selection of the quantity, the extended total is displayed in the rightmost column.

Although the page shown in Listing 41-1 consists of only one row of data, the scripts and naming conventions are intended to be carried out among multiple rows. The product name appears in several object names and ids in each row, and the scripts count on the convention being followed throughout. In fact, the regularity of the namings can allow the content for a table's row to form a script function that is invoked for each table row. The product code name can be passed as the parameter, and all object names and ids can be assembled in that function. The regularity of table content often lends itself to script-generated construction.

LISTING 41-1

Replacing Table Cell Content

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Modifying Table Cell Content</title>
      <style type="text/css">
         .absoluteWrap {position:absolute;}
         .relativeWrap {position:relative;}
         .total {color:red;}
      </style>
      <script type="text/javascript">
         // calculate and display a row's total
         function showTotal(qtyList)
         {
            var qty = qtyList.options[qtyList.selectedIndex].value;
            var prodID = qtyList.name;
            var total = "US$" + (qty * parseFloat(qtyList.form.elements[prodID +
                 "Price"].value));
            var newCellHTML = "<span class='total'>" + total + "</span>";

            var prodElem = document.getElementById(prodID + "Total");
            while (prodElem.firstChild)
```

continued

LISTING 41-1 *(continued)*

```
            {
               prodElem.removeChild(prodElem.firstChild);
            }
            var totalElem = document.createElement("span");
            totalElem.appendChild(document.createTextNode(total));
            totalElem.style.color = "red";
            prodElem.appendChild(totalElem);
         }

         // display content for all products (e.g., in case of Back navigation)
         function showAllTotals(form)
         {
            for (var i = 0; i < form.elements.length; i++)
            {
               if (form.elements[i].type == "select-one")
               {
                  showTotal(form.elements[i]);
               }
            }
         }
      </script>
   </head>
   <body onload="showAllTotals(document.orderForm)">

            <tr>
               <td>Wonder Widget 9000</td>
               <td>US$125.00</td>
               <td>
                  <select name="ww9000" onchange="showTotal(this)">
                     <option value="0">0</option>
                     <option value="1">1</option>
                     <option value="2">2</option>
                     <option value="3">3</option>
                  </select>
                  <input type="hidden" name="ww9000Price" value="125.00" />
               </td>
```

```
            <td>
               <script type="text/javascript">
                  document.write("<span id='ww9000Total' ↩
                    class='relativeWrap'><p> <\/p><\/span>");
               </script>
            </td>
         </tr>
      </table>
   </form>
</body>
</html>
```

Modifying table rows

In modern browsers, all table-related elements are full-fledged objects within the browser's object model. This means that you are free to use your choice of DOM element modification techniques on the row and column makeup of a table. But due to the frequent complexity of tables and all of their nested elements, the code required to manage a table can balloon in size. To the rescue, come some methods that enable you to add and remove rows and cells from a table. Despite minor differences in the implementations of these methods across DOMs, the syntax exhibits sufficient unanimity to allow one set of code to work on both browsers — especially for adding elements to a table.

Table 41-1 provides a quick summary of the key methods used to add or remove elements within a `table`, a table section (`thead`, `tbody`, or `tfoot`), and a row (`tr`). For simple tables (in other words, those that do not define `thead` or `tfoot` segments), you can work exclusively with the row modification methods of the `table` element object (and then the cell modification methods of the rows within the `table` element). The reason for the duplication of the row methods in the table section objects is that instead of having to worry about row index numbers lining up among the combined total of head, body, and foot rows, you can treat each segment as a distinct unit. For example, if you want to add a row just to the beginning of the `tfoot` section, you don't have to count up the `tr` elements and perform arithmetic to arrive at the desired row number. Instead, simply use the `insertRow()` method on the `tfoot` element object and supply the method with parameters that ensure the row is inserted as the first row of the element.

Note

IE5 for the Macintosh offers unpredictable results when inserting rows of a table via these methods. The browser does behave when modifying the HTML elements by accumulating the HTML for a row as a string, and then adding the row to the table via IE DOM methods such as `insertAdjacentHTML()`. If your pages must modify the composition of tables after the page loads — and your audience includes MacIE5 users — use the element and node insertion techniques rather than the methods shown in Table 41-1 and the techniques described next. ■

TABLE 41-1

IE4+ and NN6+/W3C Table Modification Methods

table	thead, tbody, tfoot	tr
insertRow()	insertRow()	insertCell()
deleteRow()	deleteRow()	deleteCell()
createTHead()		
deleteTHead()		
createTFoot()		
deleteTFoot()		
createCaption()		
deleteCaption()		

The basic sequence for inserting a row into a table entails the following steps:

1. Invoke `insertRow()` and capture the returned reference to the new, unpopulated row.
2. Use the reference to the row to invoke `insertCell()` for each cell in the row, capturing the returned reference to each new, unpopulated cell.
3. Assign values to properties of the cell, including its content.

The following code fragment appends a new row to a table (`myTABLE`) and supplies information for the two cells in that row:

```
// parameter of -1 appends to table
// (you can use document.all.myTABLE.insertRow(-1) for IE4+ only)
   var newRow = document.getElementById("myTABLE").insertRow(-1);
// parameter of 0 inserts at first cell position
   var newCell = newRow.insertCell(0);
   newCell.innerHTML = "Mighty Widget 2000";
// parameter of 1 inserts at second cell position
   newCell = newRow.insertCell(1);
   newCell.innerHTML = "Release Date TBA";
```

Note

Although we encourage you to use the DOM approach (`removeChild()/appendChild()`) to modifying the content within a node, as is used in all of the complete code listings in this chapter, in this particular example the table-specific code is easier to read using the Microsoft-specific `innerHTML` approach. ■

A key point to note about this sequence is that the `insertRow()` and `insertCell()` methods do their jobs before any content is handed over to the table. In other words, you first create the HTML space for the content and then add the content.

Listing 41-2 presents a living environment that adds and removes `thead`, `tr`, and `tfoot` elements to an empty table in the HTML. The only subelement inside the `table` element is a `tbody` element, which directs the insertion of table rows so as not to disturb any existing `thead` or `tfoot` elements. You can also see how to add or remove a caption from a table via caption-specific methods.

Each table row consists of the hours, minutes, seconds, and milliseconds of a time stamp generated when you add the row. The color of any freshly added row in the `tbody` is a darker color than the normal `tbody` rows. This is so you can see what happens when you specify an index value to the `insertRow()` method. Some of the code here concerns itself with enabling and disabling form controls and updating `select` elements, so don't be deterred by the length of Listing 41-2.

LISTING 41-2

Inserting/Removing Row Elements

</html>
```

Note

The property assignment event handling technique used in the examples throughout this chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects."** ■

Modifying table columns

Unlike the table row-oriented elements, such as `tbody`, the `col` and `colgroup` elements are not containers of cells. Instead, these elements serve as directives for the rendering of columns within a table. But through scripting, you can add or remove one or more columns from a table on the fly. There is no magic to it; you simply insert or delete the same-indexed cell from every row of the table.

Listing 41-3 demonstrates adding and removing a left-hand column of a table. The table presents the four longest rivers in Africa, and the new column provides the numeric ranking. Thanks to the regularity of this table, the values for the rankings can be calculated dynamically. Note, too, that the `className` property of each new table cell is set to a class that has a style sheet rule defined for it. Instead of inheriting the style of the table, the cells obey the more specific background color and font weight rules defined for the cells.

W3C DOM table object classes

If you ever read the W3C DOM Level 2 specification, notice that the objects defined for tables do not align themselves fully with the actual elements defined in the HTML 4.0 specification. That's not to say the DOM scoffs at the HTML spec; rather, the needs of a DOM with respect to tables differ a bit. For example, as far as the W3C DOM is concerned, the `thead`, `tbody`, and `tfoot` are all regarded as table sections and are thus known as `HTMLTableSectionElement` objects. In other words, in the W3C DOM, there is no particular distinction among the types of table section elements. They're all lumped together, and they bear the same properties and methods. With their strong adherence to the W3C DOM, Mozilla-based browsers and Safari stick to the W3C DOM object constructions.

When you work in both the IE and W3C DOMs at the same time, it's helpful to know the relationships between the object naming conventions used in each. Table 41-2 provides a quick cross-reference between the object types in both DOMs. None of the terminology in Table 41-2 affects the way scripts construct references to elements or the way elements are nested within one another. The containment hierarchy is driven by the HTML element containment — and that remains the same regardless of DOM exposure.

TABLE 41-2

Table Object Classifications

W3C DOM (NN6+/Mozilla/WebKit browsers)	IE4+ and HTML
`HTMLTableElement`	`table`
`HTMLTableCaptionElement`	`caption`
`HTMLTableColElement`	`col, colgroup`
`HTMLTableSectionElement`	`tbody, tfoot, thead`
`HTMLTableRowElement`	`tr`
`HTMLTableCellElement`	`td, th`

Although the following object-specific discussions list the objects according to their HTML tag names, we group these objects according to the W3C DOM classifications because element objects that share a classification also share the same properties, methods, and event handlers.

table Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
align	createCaption()	onscroll†
background	createTFoot()	
bgColor	createTHead()	
border	deleteCaption()	
borderColor	deleteRow()	
borderColorDark	deleteTFoot()	
borderColorLight	deleteTHead()	
caption	firstPage()	
cellPadding	insertRow()	
cells	lastPage()	
cellSpacing	moveRow()	
cols	nextPage()	
datePageSize	previousPage()	
frame	refresh()	
height

rules		
summary		
tbodies		
tfoot		
thead		
width		

†See Chapter 29, "Document and Body Objects."

Syntax

Accessing `table` element object properties and methods:

```
(IE4+)        [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C)    [window.]document.getElementById("elemID").property |
              method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

The `table` element object is the outermost container of table-related information. The HTML element has a large number of attributes, most of which are echoed by their counterpart properties in the object model. You will rarely modify these properties if the values are set in the tag's attributes. However, if you construct a new `table` element object for insertion into the page, use these properties to assign values to the equivalents of the element's attributes.

A number of additional properties return collections of cell, row, and row section objects; still more properties return references to other, singular objects within the table (such as the `caption` element object). For example, if your script needs to iterate through all rows within just the `tbody` elements (in other words, without affecting the rows in the `thead` element), your script can perform a nested `for` loop to access each row:

```
var oneTBody, oneRow;
for (var i = 0; i < tableRef.tBodies.length; i++)
{
   oneTBody = tableRef.tBodies[i];
   for (var j = 0; j < oneTBody.rows.length; j++)
   {
      oneRow = oneTBody.rows[j];
      // more stuff working on each row
   }
}
```

For a simple table that does not define table row sections, you can iterate through the `rows` collection property of a `table` element object. You can even access cells directly; but it may be easier to keep track of cells in a loop by going through them row by row (via the `cells` property of each `tr` element object).

A large number of methods enable you to modify the structure of a table (as described earlier in this chapter), but they primarily work with rows. Column modifications require a different approach, as also demonstrated earlier.

Properties

`align`

Value: String (`center`, `left`, `right`) Read/Write

Compatibility: WinIE5+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `align` property controls the horizontal alignment of the table with respect to the next outermost container that provides positioning context. Most typically, the next outermost positioning container is the `body` element. Modifications to this property on an existing table cause the surrounding content to reflow on the page. Be sure you test the consequences of any modification with a variety of browser window sizes.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see the `align` property at work. The default value (`left`) is in force when the page loads. But you can shift the table to right-align with the body by entering the following statement into the top text box:

```
document.getElementById("myTable").align = "right"
```

Related Item: `style.align` property

`background`

Value: URL string Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

Only IE4+ makes a provision for assigning a background image to a table, and the `background` property controls that value. You can swap out an image by assigning a new URL to the `background` property. The image appears in front of any background color assigned to the table. Thus, you can assign attributes for both characteristics so that there is at least a background color (and an image for IE users).

Example

Treat the `background` property of a table like you do the `src` property of an `img` element object. If you pre-cache an image, you can assign the `src` property of the pre-cached `image` object to the `background` property of the table for quick image changing. Such an assignment statement looks like the following:

```
document.all.myTable.background = imgArray["myTableAlternate"].src;
```

Related Item: `IMG.src` property

`bgColor`

Value: Color value string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `bgColor` attribute controls the background color of a table (the `bgcolor` attribute). Colors assigned to the entire table are overridden if colors are assigned to row, row groups, or cells within the table. If you set the `bgColor` property, the `backgroundColor` style property is not affected. Assign values in any acceptable color string format, such as hexadecimal triplets (for example, `"#FCFC00"`) or the generally recognized plain-language names (for example, `"cornflowerblue"`).

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to assign a color to the table. After looking at the table to see its initial state, enter the following statement into the top text box:

```
document.getElementById("myTable").bgColor = "lightgreen"
```

When you look at the table again, you see that only some of the cells turned green. This is because colors also are assigned to table elements nested inside the outermost table element, and the color specification closest to the actual element wins the contest. Opera currently does not support the HTML `bgcolor` attribute on the `table` element, so you'll see the entire table turn to green.

Related Item: `style.backgroundColor` property

`border`

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `border` property controls the thickness of the table's borders. Values indicate the number of pixels thick the border should be. A value of zero removes all visible borders surrounding the table. Different browsers render table cell borders differently, depending on background colors and other visual attributes of tables and table elements. Be sure to verify the appearance on as many browsers and operating systems as possible.

Example

To remove all traces of an outside border of a table (and, in some combinations of attributes of other table elements, borders between cells), use the following statement:

```
document.getElementById("myTable").border = 0;
```

Related Item: `borderColor` property

`borderColor`
`borderColorDark`
`borderColorLight`

Value: Color value string Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

IE4+ provides attributes and corresponding properties to control the border colors of a table. When table borders have enough thickness to display a three-dimensional raised look, the appearance is created by generating two dark and two light edges (simulating a light source coming from the upper-left or lower-right corner). If you want to do a better job of specifying the color combinations for the light and dark edges, you can control them individually via the `borderColorLight` and `borderColorDark` properties, respectively. You can assign colors in any valid color value (hexadecimal triplet or plain-language name); but when you read the property, the value is returned as a hexadecimal triplet (for example, `"#008000"`).

Example

Assuming that you have set the initial light and dark color attributes of a table, the following function swaps the light and dark colors to shift the light source to the opposite corner:

```
function swapColors(tableRef)
{
   var oldLight = tableRef.borderColorLight;
   tableRef.borderColorLight = tableRef.borderColorDark;
   tableRef.borderColorDark = oldLight;
}
```

Although you can easily invoke this function over and over by ending it with a `setTimeout()` method that calls this function after a fraction of a second, the results are very distracting to the person trying to read your page. Please don't do it.

Related Item: `td.borderColor` property

`caption`

Value: `caption` element object reference   Read/Write (see text)

Compatibility: WinIE4+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `caption` property returns a reference to the `caption` element object that is nested inside the current table. If there is no `caption` element, the value is `null`. You can use this property as a shortcut reference to the `caption` element if you need to read or modify that element's properties. The property is read/write, provided that you create a valid `caption` element object and assign that new object to the `caption` property.

Example

The following example, for use with The Evaluator (Chapter 4, "JavaScript Essentials"), demonstrates the sequence of assigning a new `caption` element object to a table. Although the table in The Evaluator already has a `caption` element, the following statements replace it with an entirely new one. Enter each of the following statements into the top text box, starting with the one that saves a long reference into a variable for multiple use at the end:

```
t = document.getElementById("myTable")
a = document.createElement("caption")
b = document.createTextNode("A Brand New Caption")
a.appendChild(b)
t.replaceChild(a, t.caption)
```

A view of the table shows that the new caption has replaced the old one because a table can have only one `caption` element.

Related Item: `caption` element object

cellPadding
cellSpacing

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cellPadding` property is a table-wide specification for the blank space inserted between the edge of a table cell and the content of the cell. One value affects the padding on all four sides. The effect of cell padding is especially apparent when there are borders between cells; in this case, the padding provides welcome breathing space between the border and content. The `cellSpacing` property influences the thickness of borders between cells. If no visible borders are present between cells in a table, you can usually set either `cellpadding` or `cellspacing` to provide the desired blank space between cells.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to adjust the `cellPadding` and `cellSpacing` properties of the demonstrator table. First, adjust the padding:

```
document.getElementById("myTable").cellPadding = 50
```

Now, adjust the cell spacing:

```
document.getElementById("myTable").cellSpacing = 15
```

Notice how `cellSpacing` affects the thickness of inter-cell borders.

Related Item: `border` property

cells

Value: Array Read-Only

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `cells` property returns an array (collection) of all `td` and `th` element objects within the entire table. From the perspective of the `table` element object, this "view" encompasses all cells — whether they are inside a table row segment (for example, a `thead`) or in a freestanding row. In the W3C DOM, the `cells` collection is accessible only as a property of a `tr` object. However, a `rows` collection is available from all table container elements, thus enabling you to iterate through all cells of all rows.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") with WinIE5+ to have JavaScript calculate the number of columns in the demonstrator table with the help of the `cells` and `rows` properties. Enter the following statement into the top text box:

```
document.all.myTable.cells.length/document.all.myTable.rows.length
```

The result is the number of columns in the table.

Related Items: `rows`, `tr.cells` properties

cols

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `cols` property represents the IE-specific `cols` attribute for `table` elements. Specifying this attribute should speed table rendering. If you don't specify the attribute explicitly in your HTML, the property has a value of zero — the property does not tell you the size of your table dynamically. Although this property is read/write, you cannot use this property to add or remove columns from a table. Instead, use the table modification methods discussed later in this section.

Related Item: `rows` property

dataPageSize

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

When using IE4+ data binding to obtain table data from a data source, there may be more rows or data (records) than you wish to display in one table. If so, you can define the number of rows (records) that constitutes a "page" of data within the table. With this limit installed for the table, you can then use the `firstPage()`, `previousPage()`, `nextPage()`, and `lastPage()` methods to access another page relative to the currently-viewed page. Although you usually establish this value via the `datapagesize` attribute of the `table` element, you can adjust it later via the `dataPageSize` property to show more or fewer records per "page" in the table.

Example

If you wanted to change the number of visible rows of linked data in the table to 15, you'd use the following statement:

```
document.all.myTable.dataPageSize = 15;
```

Or, you could use the more standardized W3C approach:

```
document.getElementById("myTable").dataPageSize = 15;
```

Related Items: `dataSrc`, `dataFld` properties; `firstPage()`, `lastPage()`, `nextPage()`, `previousPage()` methods

frame

Value: String constant Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `frame` property enables you to control which side or sides of the table's border should be displayed. Values for this property can be any of a fixed set of string constants. Table 41-3 lists the acceptable values. Hiding or showing table border edges under script control can have an effect on the layout and placement of both the table and surrounding elements. Note that Safari versions 1.3 and earlier do not change the border rendering when you change this property value.

TABLE 41-3

Table frame Property Values

Value	Description
`above`	Top edge only
`below`	Bottom edge only
`border`	All four sides (same as box)
`box`	All four sides (same as border)
`hsides`	Horizontal (top and bottom) edges only
`lhs`	Left-hand side, edge only
`rhs`	Right-hand side, edge only
`void`	No borders
`vsides`	Vertical (left and right) edges only

Example

Listing 41-4 presents a page that cycles through all possible settings for the `frame` property. The `frame` property value is displayed in the table's caption.

LISTING 41-4

Cycling Through Table frame Property Values

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>table.frame Property</title>
      <script type="text/javascript">
         var timeoutID;
         var frameValues = ["box", "above", "rhs", "below", "lhs", "hsides",
             "vsides", "border", "void"];
         function rotateBorder(i)
         {
            document.getElementById("myTABLE").frame = frameValues[i];
            var captionElem = document.getElementById("myCAPTION");
            while(captionElem.firstChild)
            {
               captionElem.removeChild(captionElem.firstChild);
            }
            captionElem.appendChild(document.createTextNode(frameValues[i]));
            i = (++i == frameValues.length) ? 0 : i;
```

continued

LISTING 41-4 *(continued)*

```
            timeoutID = setTimeout("rotateBorder(" + i + ")", 2000);
         }
         function stopRotate()
         {
            clearTimeout(timeoutID);
            document.getElementById("myTABLE").frame = "box";
            var captionElem = document.getElementById("myCAPTION");
            while(captionElem.firstChild)
            {
               captionElem.removeChild(captionElem.firstChild);
            }
            captionElem.appendChild(document.createTextNode("box"));
         }
      </script>
   </head>
   <body>
      <h1>table.frame Property</h1>
      <hr />
      <form name="controls">
         <fieldset>
            <legend>Cycle Table Edge Visibility</legend>
            <table width="100%" cellspacing="20">
               <tr>
                  <td>
                     <input type="button" value="Cycle"
                            onclick="rotateBorder(0)" />
                  </td>
                  <td>
                     <input type="button" value="Stop"
                            onclick="stopRotate()" />
                  </td>
               </tr>
            </table>
         </fieldset>
      </form>
      <hr />
      <table id="myTABLE" cellpadding="5" border="3" align="center">
         <caption id="myCAPTION">
            Default
         </caption>
         <thead id="myTHEAD">
            <tr>
               <th>River</th>
               <th>Outflow</th>
               <th>Miles</th>
               <th>Kilometers</th>
            </tr>
         </thead>
```

```
      <tbody>
         <tr>
            <td>Nile</td>
            <td>Mediterranean</td>
            <td>4160</td>
            <td>6700</td>
         </tr>
         <tr>
            <td>Congo</td>
            <td>Atlantic Ocean</td>
            <td>2900</td>
            <td>4670</td>
         </tr>
         <tr>
            <td>Niger</td>
            <td>Atlantic Ocean</td>
            <td>2600</td>
            <td>4180</td>
         </tr>
         <tr>
            <td>Zambezi</td>
            <td>Indian Ocean</td>
            <td>1700</td>
            <td>2740</td>
         </tr>
      </tbody>
   </table>
  </body>
</html>
```

Related Items: `border`, `borderColor`, `rules` properties

height
width

Value: Integer or length string — Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `height` (IE4+) and `width` (IE4+/W3C) properties represent the `height` and `width` attributes assigned to the `table` element. If no values are assigned to the element in the tag, the properties do not reveal the rendered size of the table (use the `offsetHeight` and `offsetWidth` properties for that information). Values for these properties can be integers representing pixel dimensions or strings containing percentage values, just like the attribute values. Scripts can shrink the dimensions of a table to no smaller than the minimum space required to render the cell content. Notice that only the `width` property is W3C DOM-sanctioned (as well as the corresponding property in the HTML 4.0 specification).

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to adjust the width of the demonstrator table. Begin by increasing the width to the full width of the page:

```
document.getElementById("myTable").width = "100%"
```

To restore the table to its minimum width, assign a very small value to the property:

```
document.getElementById("myTable").width = 50
```

At this point the `width` property will remain 50, even though the table has been sized larger to the minimum size required to accommodate the cell content. To see the actual table width, enter this:

```
document.getElementById("myTable").offsetWidth
```

If you have IE4+, you can perform similar experiments with the `height` and `offsetHeight` properties of the table.

Related Items: `offsetHeight`, `offsetWidth` properties

rows

Value: Array of row objects Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `rows` property returns an array (collection) of `tr` element objects in the current table. This array includes rows in the `thead`, `tbody`, and `tfoot` row sections, if the table is segmented. You can use the `rows` property to create a cross-browser script that accesses each cell of a table. Such a nested `for` loop looks like the following:

```
var oneCell;
for (var i = 0; i < tableRef.rows.length; i++)
{
   for (var j = 0; j < tableRef.rows[i].cells.length; j++)
   {
      oneCell = tableRef.rows[i].cells[j];
      // more statements working with the cell
   }
}
```

If you want to limit the scope of the `rows` property to rows within a row segment (for example, just in the `tbody`), you can access this property for any of the three types of row segment objects.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to examine the number of rows in the demonstrator table. Enter the following statement into the top text box:

```
document.getElementById("myTable").rows.length
```

In contrast, notice how the `rows` property sees only the rows within the demonstrator table's `tbody` element in IE:

```
document.getElementById("myTbody").rows.length
```

Related Items: `tbody.rows`, `tfoot.rows`, `thead.rows` properties

rules

Value: String constant Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

In contrast to the `frame` property, the `rules` property governs the display of borders between cells. Values for this property can be any of a fixed set of string constants. Table 41-4 lists the acceptable values. Hiding or showing table cell border edges under script control can have an effect on the layout and placement of both the table and surrounding elements. Note that WebKit-based browsers and Opera partially implement the rules rendering when you change this property value.

TABLE 41-4

Table rules Property Values

Value	Description
`all`	Borders around every cell
`cols`	Vertical borders between columns
`groups`	Vertical borders between column groups; horizontal borders between row groups
`none`	No borders between cells
`rows`	Horizontal borders between row groups

Example

Listing 41-5 presents a page that cycles through all possible settings for the `rules` property. The `rules` property value is displayed in the table's caption. When you run this script, notice the nice border display for this table's combination of `colgroup` and table row segment elements.

LISTING 41-5

Cycling Through Table rules Property Values

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
```

continued

***tableObject*.rules**

LISTING 41-5 *(continued)*

```
    <title>table.rules Property</title>
    <script type="text/javascript">
       var timeoutID;
       var rulesValues = ["all", "cols", "groups", "none", "rows"];
       function rotateBorder(i)
       {
          document.getElementById("myTABLE").rules = rulesValues[i];
          var captionElem = document.getElementById("myCAPTION");
          while(captionElem.firstChild)
          {
             captionElem.removeChild(captionElem.firstChild);
          }
          captionElem.appendChild(document.createTextNode(rulesValues[i]));
          i = (++i == rulesValues.length) ? 0 : i;
          timeoutID = setTimeout("rotateBorder(" + i + ")", 2000);
       }
       function stopRotate()
       {
          clearTimeout(timeoutID);
          document.getElementById("myTABLE").rules = "all";
          var captionElem = document.getElementById("myCAPTION");
          while(captionElem.firstChild)
          {
             captionElem.removeChild(captionElem.firstChild);
          }
          captionElem.appendChild(document.createTextNode("all"));
       }
    </script>
 </head>
 <body>
    <h1>table.rules Property</h1>
    <hr />
    <form name="controls">

         <colgroup span="1">
         </colgroup>
         <colgroup span="3">
         </colgroup>
         <thead id="myTHEAD">
            <tr>
               <th>River</th>
               <th>Outflow</th>
               <th>Miles</th>
               <th>Kilometers</th>
            </tr>
         </thead>
         <tbody>
            <tr>
               <td>Nile</td>
               <td>Mediterranean</td>
               <td>4160</td>
               <td>6700</td>
            </tr>
            <tr>
               <td>Congo</td>
               <td>Atlantic Ocean</td>
               <td>2900</td>
               <td>4670</td>
            </tr>
            <tr>
               <td>Niger</td>
               <td>Atlantic Ocean</td>
               <td>2600</td>
               <td>4180</td>
            </tr>
            <tr>
               <td>Zambezi</td>
               <td>Indian Ocean</td>
               <td>1700</td>
               <td>2740</td>
            </tr>
         </tbody>
      </table>
   </body>
</html>
```

Related Items: `border`, `borderColor`, `frame` properties

`summary`

Value: String Read/Write

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `summary` property represents the HTML 4.0 `summary` attribute. The text assigned to this attribute is intended for use by browsers that present a page's content through nonvisual means. For example, a browser equipped to use speech synthesis to read the page aloud can use the text of the summary to describe the table for the user.

Related Item: `caption` property

tBodies

Value: Array of `tbody` element objects Read-Only

Compatibility: WinIE4+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `tBodies` property returns an array of all `tbody` elements in the table. Even if you don't specify a `tbody` element, every table contains an implied `tbody` element. Thus, to access a batch of rows, other than the `thead` and `tfoot` sections, of a simple table, you can use the `tBodies[0]` array notation. From there, you can get the rows of the table body section via the `rows` property.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to access the `tBodies` array and reveal the number of rows in the one `tbody` segment of the demonstrator table. Enter the following statement into the top text box:

```
document.getElementById("myTable").tBodies[0].rows.length
```

Related Items: `tFoot`, `tHead` properties

tFoot
tHead

Value: Row segment element object Read/Write (see text)

Compatibility: WinIE4+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

Each table can have (at most) one `tfoot` and one `thead` element. If you specify one of these for the table, the `tFoot` and `tHead` properties return references to those element objects, respectively. These properties are read-only in IE, but NN6+/Moz enable you to assign valid `tfoot` and `thead` element objects to these properties in order to insert or replace the elements in the current table. The process for doing this is similar to the sequence described in the `caption` property. For either of these two elements, however, you have to construct the desired number of table cell objects (and row objects, if you want multiple rows) for the newly created row segment object. See the discussions of these two objects for details on accessing rows and cells of the segments.

Related Items: `tbody`, `tfoot`, `thead` objects

width

(See `height`)

Methods

createCaption()
deleteCaption()

Returns: Reference to new `caption` element object; Nothing

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `createCaption()` and `deleteCaption()` convenience methods enable you to add or remove a `caption` element object from the current table. When you create a new caption, the action simply inserts the equivalent of a blank `caption` element tag into the `table` element (this may not, however, be reflected in the source view of the page). You must populate the `caption` element with text or HTML before it appears on the page. Because the method returns a reference to the newly created object, you can use that reference to assign content to its `innerHTML` property, or you can append a child text node.

Because a table can have only one `caption` element nested within it, the `deleteCaption()` method belongs to the `table` element object. The method returns no value.

Example

See Listing 41-2 for an example of creating, inserting, and removing a `caption` element object from a table.

Related Item: `caption` element object

createTFoot()
createTHead()
deleteTFoot()
deleteTHead()

Returns: Element references (create methods); Nothing

Compatibility: WinIE4+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

These four methods enable you to add or remove `tfoot` and `thead` table row section objects. When you create a `thead` or `tfoot` element, the methods return references to the newly inserted elements. But, as with `createCaption()`, these methods do nothing to display content. Instead, use the returned references to populate the row(s) of the header and footer with cells. Regardless of the number of rows associated with a `thead` or `tfoot` element, the `deleteTFoot()` and `deleteTHead()` methods remove all associated rows and return no values.

Example

See Listing 41-2 for an example of creating, inserting, and removing `tfoot` and `thead` element objects from a table.

Related Items: `tfoot`, `thead` element objects

deleteRow(*rowIndex*)
insertRow(*rowIndex*)

Returns: Nothing; Reference to newly created row

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `insertRow()` and `deleteRow()` convenience methods assist in adding `tr` elements to, and removing them from, a `table` element. Inserting a row does little more than the equivalent of inserting a pair of empty `tr` element tags into the HTML (although you may not see them in the source view of the page). It is up to the rest of your scripts to assign properties to the row and populate it with new cells (see the `insertCell()` method of the `tr` element object).

Attributes for both methods are zero-based index numbers. In the case of `insertRow()`, the number indicates the row *before* which the new row is to be inserted. To append the row to the end of the table, use `-1` as a shortcut parameter. To delete a row, use the index value for that row. Be aware that if you intend to employ `deleteRow()` to remove all rows from a table (presumably to repopulate the table with a new set), the most efficient way is to use a `while` loop that continues to remove the first row until there are no more:

```
while (tableRef.rows.length > 0)
{
   tableRef.deleteRow(0);
}
```

Example

See Listing 41-2 for examples of inserting and deleting table rows.

Related Item: `td.insertCell()` method

firstPage()
lastPage()

Returns: Nothing

Compatibility: WinIE5+, MacIE5+, NN-, Moz-, Safari-, Opera-, Chrome-

For tables that are bound to external data sources via IE4+ data binding, the `firstPage()` and `lastPage()` methods zoom to the first and last pages of the data, respectively. You must specify the table's data page size for the Data Source Object to know how many records to assign to a "page" of data. Note that while related methods — `nextPage()` and `previousPage()` — are available in IE4, `firstPage()` and `lastPage()` entered the picture in IE5.

Related Items: `dataPageSize`, `dataSrc`, `dataFld` properties; `nextPage()`, `previousPage()` methods

moveRow(*sourceRowIndex*, *destinationRowIndex*)

Returns: Row element object

Compatibility: WinIE5+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The IE5+ `moveRow()` convenience method enables you to move a row from one position to another within the same table. Both parameters are integer index values. The first parameter is the index of the row you want to move; the second is the index of the destination row. Because no movement takes place when the method is invoked, the removal of the source row does not impact the index count of the destination row. But after the method executes, the row that was in the destination row is pushed down one row. This method returns a reference to the moved row.

You can (and in most cases should) accomplish this same functionality in W3C DOM-compatible syntax (for IE5+, NN6+, Mozilla, Opera, and WebKit-based browsers) via the `replaceChild()` method of the `table` element.

Example

If you want to shift the bottom row of a table to the top, you can use the shortcut reference to the last item's index value (`-1`) for the first parameter:

```
var movedRow = document.getElementById("someTable").moveRow(-1, 0);
```

Related Item: `replaceChild()` method

nextPage()
previousPage()

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

For tables that are bound to external data sources via IE4+ data binding, the `nextPage()` and `previousPage()` methods jump ahead or back by one page of data, respectively. You must specify the table's data page size for the Data Source Object to know how many records to assign to a "page" of data. Typically, navigational buttons associated with the table invoke these methods.

Related Items: `dataPageSize`, `dataSrc`, `dataFld` properties; `firstPage()`, `lastPage()` methods

refresh()

Returns: Nothing

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

For tables that are bound to external data sources via IE4+ data binding, the `refresh()` method retrieves the current data source data for display in the table. A script can use `setTimeout()` to invoke a function that calls this method at an interval of your choice. If you frequently update the database associated with the table, this method can help keep the table up to date, without requiring the client to download the entire page (and perhaps run into cache conflicts).

Related Items: `dataPageSize`, `dataSrc`, `dataFld` properties

tbody, tfoot, and thead Element Objects

For HTML element properties, methods, and event handlers, see Chapter 26, “Generic HTML Element Objects.”

Properties	Methods	Event Handlers
align†	deleteRow()†	
bgColor†	insertRow()†	
ch	moveRow()†	
chOff		
rows†		
vAlign		

†See table element object.

Syntax

Accessing tbody, tfoot, and thead element object properties and methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
           method([parameters])
```

Accessing tbody element object properties and methods:

```
(IE4+)     [window.]document.all.tableID.tBodies[i].property |
           method([parameters])
(IE5+/W3C) [window.]document.getElementById("tableID").tBodies[i].property |
           method([parameters])
```

Accessing tfoot element object properties and methods:

```
(IE4+)     [window.]document.all.tableID.tFoot.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("tableID").tFoot.property |
           method([parameters])
```

Accessing thead element object properties and methods:

```
(IE4+)     [window.]document.all.tableID.tHead.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("tableID").tHead.property |
           method([parameters])
```

Compatibility: WinIE4+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

About these objects

Each of these element objects represents a row grouping within a `table` element (an `HTMLTableSectionElement` in the syntax of the W3C DOM specification). A table can have only one `thead` and one `tfoot`, but it can have as many `tbody` elements as your table organization requires.

These elements share many properties and methods with the `table` element in that they all contain rows. The benefit of defining table segments is apparent if you use table rules (see the `table.rules` property earlier in this chapter) and if you wish to limit the scope of row activities only to rows within one segment. For instance, if your table has a `thead` that is to remain static, your scripts can merrily loop through the rows of only the `tbody` section without coming anywhere near the row(s) in the `thead`.

Properties

ch
chOff

Value: One-character string Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `ch` and `chOff` properties represent the optional `char` and `charoff` attributes of table row section elements in the HTML 4.0 specification. These properties help align cell content within a column or column group, similar to the way word processors allow for formatting features such as decimal tabs; they are yet to be implemented in IE as of version 7. For details on these attributes, see `http://www.w3.org/tr/REC-html40/struct/tables.html#adef-char`.

Related Items: `col`, `colgroup` objects

vAlign

Value: String constant Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Providing the cell-oriented `vAlign` property for a table row section enables you to specify a vertical alignment to apply to all cells within that section rather than having to specify the `valign` attribute for each `td` element. By default, browsers render cell content with a middle vertical alignment within the cell. If you want to modify the setting for an existing table section (or assign the setting to a new one you create), the values must be one of the following string constants: `baseline`, `bottom`, `middle`, or `top`.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to modify the vertical alignment of the content of the `tbody` element in the demonstrator table. Enter the following statement in the top text box to shift the content to the bottom of the cells:

```
document.getElementById("myTBODY").vAlign = "bottom"
```

Notice that the cells of the thead element are untouched by the action imposed on the tbody element.

Related Item: td.vAlign property

caption Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
align†		
vAlign††		

†See table element object.

††See tbody element object.

Syntax

Accessing caption element object properties and methods:

```
(IE4+)      [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
            method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

A caption element is a simple HTML container whose only prerequisite is that it must be nested inside a table element. That nesting allows the table element object to control insertion and removal of a caption element at will. You can modify the content of a caption element just like you do any HTML element (in DOMs that allow such modification). You can see an example of how the table element object uses some of its methods to create and remove a caption element in Listing 41-2.

The only properties that lift the caption element object above a mere contextual element (as described in Chapter 26) are vAlign (IE4+) and the W3C DOM-sanctioned align (IE4+/NN6+/Mozilla/Opera and WebKit-based browsers). We describe these properties, and their values for other objects, in this chapter.

col and colgroup Element Objects

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
align†		
ch††		
chOff††		
span		
vAlign††		
width		

†See table element object.

††See tbody element object.

Syntax

Accessing col and colgroup element object properties and methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
           method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About these objects

The purpose of the col and colgroup elements is to allow cells within one or more columns to be treated as a single entity for purposes of style sheet and other style-related control. In other words, if you want one column of a table to be all boldface, you can assign that style sheet rule to the col element that encompasses that column. All cells within that column inherit the style sheet rule definition. Having two different element names allows for the nesting of column groups, which can come in handy for complex tables. For instance, consider a table that reports the forecasted and actual sales for a list of products across four quarters of a year. The left column of the table stands alone with the product item numbers. To the right is one large grouping of eight columns that encompasses the four pairs of forecasted/actual sales. All eight columns of cells are to be formatted with a particular font style to help differentiate the pairs of columns for

each quarter. You also want to assign a different background color. Therefore, you designate each pair of columns as its own subgroup within the eight-column master grouping. The `colgroup` and `col` tags for this nine-column table are as follows:

```
<col id="productIDs">
<colgroup id="fiscalYear" span="8" width="40">
   <col id="Q1" span="2">
   <col id="Q2" span="2">
   <col id="Q3" span="2">
   <col id="Q4" span="2">
</colgroup>
```

Up in the `head` section of this document are style sheet rules similar to the following:

```
<style type="text/css">
   #productIDs {font-weight:bold}
   #fiscalYear {font-family: Courier, "Courier New", monospace}
   #Q1 {background-color: lightyellow}
   #Q2 {background-color: pink}
   #Q3 {background-color: lightblue}
   #Q4 {background-color: lightgreen}
</style>
```

The HTML code for the column groups demonstrates the two key attributes: `span` and `width`. Both of these attributes are reflected as properties of the objects, and we describe them in the following section. Notice, however, that `col` and `colgroup` elements act cumulatively, and in source code order, to define the column groups for the table. In other words, if the style of the left-hand column is not important, the table still requires the initial one-column `col` element before the eight-column `colgroup` element. Otherwise, the browser makes the first eight columns the column group. Therefore, it is a good idea to account for every column with `col` and/or `colgroup` elements if you intend to use any column grouping in your table.

From a scripter's point of view, you are more likely to modify styles in an existing table for a column or column group than you are to alter properties such as `span` or `width`. But, if your scripts generate new tables, you may create new `col` or `colgroup` elements whose properties you then initialize.

Properties

span

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `span` property represents the number of columns that the column group should encompass. Don't confuse this property with the `colSpan` property of `td` and `th` elements. A `col` or `colgroup span` does not have any impact on the rendering or combination of multiple cells

into one. It simply draws an imaginary lasso around as many columns as are specified, signifying that these columns can be treated as a group for style purposes (and also for drawing divider rules, if you set the table's `rules` property to `groups`).

Example

The following statement assigns a `span` of 3 to a newly created `colgroup` element stored in the variable `colGroupA`:

```
colGroupA.span = 3;
```

Related Item: `width` property

width

Value: Length string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The only reason the `width` property is highlighted for these objects is that the property (and corresponding attribute) impacts the width of table cells inside the scope of the column grouping. For example, if you assign a width of 50 pixels to a `colgroup` whose `span` attribute is set to 3, all cells in all three columns inherit the 50-pixel width specification. For more details on the values acceptable to this property, see the `table.width` property description earlier in this chapter.

Related Item: `table.width` property

tr Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
align†	deleteCell()

†See table element object.

††See tbody element object.

Syntax

Accessing tr element object properties and methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE4+)     [window.]document.all.tableID.rows[i].property | method
           ([parameters])
(IE4+)     [window.]document.all.tableRowSectionID.rows[i].property |
           method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID"). property |
           method([parameters])
(IE5+/W3C) [window.]document.getElementById("tableID").rows[i].property |
           method([parameters])
(IE5+/W3C) [window.]document.getElementById("tableRowSectionID").rows
           [i].property | method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

Table rows are important objects within the complex nesting of table-related elements and objects. When a table represents server database data, one row usually equals one record. And, although you can employ scripting to add columns to a table, the more common table modifications are to add or delete rows — hence the presence of the table element object's insertRow() and deleteRow() methods.

The primary job of the tr element is to act as a container for td elements. All the cells in a row inherit some attributes and properties that you apply to that row. An array of cell objects is available for iteration via for loops. A tr element object, therefore, also has methods that insert and remove individual cells in that row.

The number of columns in a row is determined by the number of td elements or, more specifically, by the number of columns that the cells intend to span. One row can have four td elements, whereas the next row can have only two td elements — each of which is defined to occupy two columns. The row of the table with the most td elements and column reservations determines the column width for the entire table.

Of the properties just listed, the ones related to border color are available in IE4+ only. In IE4+, the border is drawn around each cell of the row rather than the entire row. The HTML 4.0 specification (and, by extension, the W3C DOM Level 2 specification) does not recognize border colors for rows alone, nor are style sheet border rules inherited by the cell children of a row. However, you can define borders for individual cells or classes of cells.

Properties

`cells`

Value: Array of `td` element objects Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cells` property returns an array (collection) of `td` element objects nested inside the current `tr` object. The `length` property of this array indicates the number of actual `td` elements in the row, which may not be the number of columns if one or more cells occupy multiple columns.

Use the `cells` property in `for` loops to iterate through all cells within a row. Assuming your script has a reference to a single row, the loop should look like the following:

```
for (var i = 0; i < rowRef.cells.length; i++)
{
   oneCell = rowRef.cells[i];
   // more statements working with the cell
}
```

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to retrieve the number of `td` elements in the second row of the demonstrator table. Enter the following statement into the top text box (W3C DOM syntax shown here):

```
document.getElementById("myTable").rows[1].cells.length
```

Related Items: `table.rows`, `td.cellIndex` properties

`height`

Value: Integer or length string Read/Write

Compatibility: WinIE5+, MacIE5+, NN-, Moz-, Safari-, Opera+, Chrome-

IE5+ and Opera enable page authors to predefine a height for a table row; this attribute is echoed by the `height` property. The value can be a number of pixels or a percentage length value. Note that this property does not reveal the rendered height of the row unless you explicitly set the attribute in the HTML. To get the actual height (in IE5+ and Mozilla), use the `offsetHeight` property. You cannot adjust the `height` property to be smaller than the table normally renders the row.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") in IE5+ to expand the height of the second row of the demonstrator table. Enter the following statement into the top text box:

```
document.getElementById("myTable").rows[1].height="300"
```

If you attempt to set the value very low, the rendered height goes no smaller than the default height.

Related Item: `offsetHeight` property (Chapter 26, "Generic HTML Element Objects")

rowIndex
sectionRowIndex

Value: Integer — Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Each row occupies a position within the collection of rows in the table, as well as within the collection of rows for a table section (`thead`, `tbody`, or `tfoot`). The `rowIndex` property returns the zero-based index value of the row inside the `rows` collection for the entire table, regardless of table section composition. In contrast, the `sectionRowIndex` property returns the zero-based index value of the row inside its row section container. If the table has no row sections defined for it, a single, all-encompassing `tbody` element is assumed; in this case, the `sectionRowIndex` and `rowIndex` values are equal.

These properties serve in functions that are passed a reference to a row. However, the functions might also need to know the position of the row within the table or section. Although there is no `tr` object property that returns a reference to the next outermost table row section, or to the table itself, the `parent` and parent's `parent` elements, respectively, can reference these objects.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to explore the `rowIndex` and `sectionRowIndex` property values for the second physical row in the demonstrator table. Enter each of the following statements into the top text box:

```
document.getElementById("myTable").rows[1].rowIndex
document.getElementById("myTable").rows[1].sectionRowIndex
```

The result of the first statement is `1` because the second row is the second row of the entire table. But the `sectionRowIndex` property returns `0` because this row is the first row of the `tbody` element in this particular table.

Related Items: table.rows, tbody.rows, tfoot.rows, thead.rows properties

Methods

deleteCell(*cellIndex*)
insertCell(*cellIndex*)

Returns: Nothing; Reference to new cell

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The act of inserting a row into a table is not complete until you also insert cells into the row. The `insertCell()` method does just that, with a parameter indicating the zero-based index of the cell's position among other cells in the row. A value of `-1` appends the cell to the end of existing cells in the row.

When you invoke the `insertCell()` method, it returns a reference to the new cell. This gives you the opportunity to adjust other properties of that cell before moving onto the next cell. For example, if you want to insert a cell that has a column span of `2`, you adjust the `colSpan` property of the cell whose reference just returned, as in the following:

```
var oneCell = tableRowRef.insertCell(-1);
oneCell.colSpan = 2;
```

Scripts that add rows and cells must make sure that they add the identical number of cells (or cell column spaces) from one row to the next. Otherwise, you have an unbalanced table with ugly blank spaces where you probably don't want them.

To remove a cell from a row, use the `deleteCell()` method. The parameter is a zero-based index value of the cell you want to remove. To rid yourself of all cells in a row, use the `deleteRow()` method of the `table` and table row section element objects.

Example

See Listing 41-2 for an example of inserting cells during the row insertion process.

(IE5+/W3C) [window.]document.getElementById("tableRowID").rows[i].property |
            method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About these objects

`td` (table data) and `th` (table header) elements create cells within a table. By common convention, a `th` element is rendered in today's browsers with a distinctive style — usually with a bold font and center alignment. A table cell is as deeply nested as you can get with table-related elements.

Properties of cells that are delivered in the HTML of the page are rarely modified (with the exception of the `innerHTML` property). But you still need full access to properties of cells if your scripts add rows to a table dynamically. After creating each blank table cell object, your scripts can adjust `colSpan`, `rowSpan`, `noWrap`, and other properties that influence the characteristics of that cell within the table.

See the beginning of this chapter for discussions and examples of how to add rows of cells and modify cell content under script control.

Properties

abbr
axis
headers

Value: See text Read/Write

Compatibility: WinIE6+, MacIE5+, NN6+, Moz+, Safari+, Opera+, Chrome+

These three properties are defined for table cell element objects in the W3C DOM. They all represent attributes for these elements in the HTML 4.0 specification. The purposes of these attributes and properties are geared toward browsers that provide alternate means of rendering content, such as through speech synthesis. Although these properties are definitely valid for W3C browsers, they have no practical effect. For general application, you can ignore these properties — consider them reserved for future use.

cellIndex

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `cellIndex` property returns an integer indicating the zero-based count of the current cell within its row. Thus, if a script is passed a reference to a cell, the `cellIndex` property reveals its position within the row. Inserting or deleting cells in the row at lower index values influences the `cellIndex` value after the alteration.

Example

You can rewrite the cell addition portion of Listing 41-2 to utilize the `cellIndex` property. The process entails modifying the `insertTableRow()` function so that it uses a `do...while` construction to keep adding cells to match the number of data slots. The function looks like the following (changes shown in boldface):

```
function insertTableRow(form, where)
{
   var now = new Date();
   var nowData = [now.getHours(), now.getMinutes(), now.getSeconds(),
      now.getMilliseconds()];
   clearBGColors();
```

```
    var newCell;
    var newRow = theTableBody.insertRow(where);
    var i = 0;
    do
    {
       newCell = newRow.insertCell(i);
       while(newCell.firstChild)
       {
          newCell.removeChild(newCell.firstChild);
       }
       newCell.appendChild(document.createTextNode(nowData[i++]));
       newCell.style.backgroundColor = "salmon";
    } while (newCell.cellIndex < nowData.length)
    updateRowCounters(form);
}
```

This version is merely for demonstration purposes and is not as efficient as the sequence shown in Listing 41-2. But the `cellIndex` property version can give you some implementation ideas for the property. It also shows how dynamic the property is, even for brand new cells.

Related Item: `tr.rowIndex` property

colSpan
rowSpan

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `colSpan` and `rowSpan` properties represent the `colspan` and `rowspan` attributes of table cell elements. Assign values to these properties only when you are creating new table rows and cells — and you are firm in your table cell design. If you fail to assign the correct values to either of these properties, your table cell alignment will get out of whack. Modifying these property values on an existing table is extremely risky unless you are performing other cell manipulation to maintain the balance of rows and columns. Values for both properties are integers greater than or equal to 1.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to witness how modifying either of these properties in an existing table can destroy the table. Enter the following statement into the top text box:

```
document.getElementById("myTable").rows[1].cells[0].colSpan = 3
```

Now that the first cell of the second row occupies the space of three columns, the browser has no choice but to shift the two other defined cells for that row out beyond the original boundary of the table. Experiment with the `rowSpan` property the same way. To restore the original settings, assign 1 to each property.

Related Item: `col.span` property

height
width

Value: Integer and length string Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Table cells may be specified to be larger than their default rendered size. This usually happens in the `height` and `width` attributes of the cell. Settings of the `width` attribute of a `col` or `colgroup` element may also govern the width of a cell. A cell's height can be inherited from the `height` attribute setting of a table row or row section. Both `height` and `width` attributes are deprecated in HTML 4.0 in favor of the `height` and `width` style sheet attributes. That said, the `height` and `width` properties of a table cell echo only the settings of the explicit attributes in the cell's tag. If a style sheet in the element tag governs a cell's dimensions, visit the cell object's `style` property to determine the dimensions. Explicit attributes override style sheet rules.

Values for these two properties are length values. These can be pixel integers or percentage values as strings. Attempts to set the sizes smaller than their default rendered sizes results in a cell of default size. Also be aware that enlarging a cell affects the width of the entire column and/or the height of the entire row occupied by that cell.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see the results of setting the `height` and `width` properties of an existing table cell. Enter each of the following statements into the top text box and study the results in the demonstrator table (W3C DOM syntax used here):

```
document.getElementById("myTable").rows[1].cells[1].height = 100
document.getElementById("myTable").rows[2].cells[0].width = 300
```

You can restore both cells to their original sizes by assigning very small values, such as `1` or `0`, to the properties. The browser prevents the cells from rendering any smaller than is necessary to show the content.

Related Items: `col.width`, `tr.height` properties

noWrap

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The default behavior of a table cell is to wrap text lines within the cell if the text would extend beyond the right edge of the cell, as calculated from the width of the entire table. But you can force the table to be wider to accommodate an unwrapped line of text by setting the `noWrap` property (or `nowrap` attribute) of the cell to `true`. The `nowrap` attribute is deprecated in HTML 4.0.

Example

The following statement creates a new cell in a row and sets its `noWrap` property to prevent text from word-wrapping inside the cell:

```
newCell = newRow.insertCell(-1);
newCell.noWrap = true;
```

You need to set this property only if the cell must behave differently than the default, word-wrapping style.

rowSpan

(See `colSpan`)

width

(See `height`)

ol Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
`start`		
`type`		

Syntax

Accessing `ol` element object properties and methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID"). property |
           method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

The `ol` (ordered list) element is a container of `li` (list item) elements. An *ordered list* means that the list items have a sequence and are preceded by a number or letter to signify the

position within the sequence. The few element-specific attributes are being deprecated in favor of style sheet definitions. For the sake of backward compatibility with existing content, however, it is likely that many future generations of browsers will continue to support these deprecated attributes. These attributes are therefore available as properties of the element object.

Most of the special appearance of a list (notably indentation) is handled automatically by the browser's interpretation of how an ordered list should look. You have control over the numbering or lettering schemes and the starting point for those sequences. With CSS you can significantly override the browser's formatting — even eliminating the traditional list appearance via other choices for the display `style` property.

Properties

start

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `start` property governs which number or letter begins the sequence of leading characters for nested `li` items. If the `type` attribute specifies numbers, the corresponding number is used; if it specifies letters, the letter of the alphabet corresponding to the number becomes the starting character. You can change the numbering in the middle of a sequence via the `li.value` property.

It is an extremely rare case that requires you to modify this property for an existing `ol` element. But if your script is creating a new element for a segment of ordered list items that has some other content intervening from an earlier `ol` element, you can use the property to assign a starting value to the `ol` group.

Example

The following statements generate a new `ol` element and assign a value to the `start` property:

```
var newOL = document.createElement("ol");
newOL.start = 5;
```

Related Items: `type`, `li.value` properties

type

Value: String constant Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

***olObject*.type**

An ol element can use any of five different numbering schemes. Each scheme has a type code, whose value you can use for the type property. The following table shows the property values and examples:

Value	Example
A	A, B, C, ...
a	a, b, c, ...
I	I, II, III, ...
i	i, ii, iii, ...
1	1, 2, 3, ...

The default value is 1. You are free to adjust the property after the table has rendered, and you can even stipulate a different type for specific li elements nested inside (see the li.type property). If you want to have further nesting with a different numbering scheme, you can nest the ol elements and specify the desired type for each nesting level, as shown in the following HTML example:

```
<ol type="A">
   <li>One</li>
   <li>Two</li>
   <li>Three</li>
      <ol type="a">
         <li>Sub One</li>
         <li>Sub Two</li>
         <li>Sub Three</li>
      </ol>
   <li>Four</li>
</ol>
```

Indenting the HTML is optional, but it may help you to keep the nesting straight.

Example

The following statements generate a new ol element and assign a value to the type property so that the sequence letters are uppercase Roman numerals:

```
var newOL = document.createElement("ol");
newOL.type = "I";
```

Related Items: start, UL.type, LI.type properties

ul Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
`type`		

Syntax

Accessing `ul` element object properties and methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
           method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

The `ul` (unordered list) element is a container of `li` (list item) elements. An *unordered list* means that the list items have no sequence and are preceded by symbols that don't signify any particular order. The few element-specific attributes are being deprecated in favor of style sheet definitions. For the sake of backward compatibility with existing content, however, it is likely that many future generations of browsers will continue to support these deprecated attributes. These attributes are therefore available as properties of the element object.

Most of the special appearance of a list (notably indentation) is handled automatically by the browser's interpretation of how an ordered list should look. You have control over the three possible characters that precede each item. With CSS you can significantly override the browser's formatting — even eliminating the traditional list appearance via other choices for the display `style` property.

Properties

`type`

Value: String constant   Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

A ul element can use any of three different leading characters. Each leading character has a type code whose value you can employ for the type property. Property values are circle, disc, and square. The difference between a circle and disc is that the circle is unfilled, whereas the disc is solid. The default value is disc.

Example

The following statements generate a new ul element and assign a value to the type property so that the bullet characters are empty circles:

```
var newUL = document.createElement("ul");
newUL.type = "circle";
```

Related Items: OL.type, UL.type properties

li Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
type		
value		

Syntax

Accessing li element object properties and methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID").property |
           method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

An li (list item) element contains the HTML that is displayed for each item within an ol or ul list. Note that you can put any HTML you want inside a list item, including images. Attributes and properties of this element enable you to override the specifications declared in the ol or ul containers (except in MacIE).

Properties

type

Value: String constant — Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Because either an `ol` or `ul` container can own an `li` element, the `type` property accepts any of the values that you assign to the `type` properties of both the `ol` and `ul` element objects. See the `ol.type` and `ul.type` properties earlier in this chapter for lists of those values.

Exercise caution, however, if you attempt to mix and match types. For example, if you try to set the `li.type` property of an `li` element to `circle` inside an `ol` element, the results vary from browser to browser. NN6+/Moz, for example, follows your command; however, IE may display some other characters.

Example

See the examples for the `ol.type` and `ul.type` properties earlier in this chapter.

Related Items: `ol.type`, `ul.type` properties

value

Value: Integer — Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `value` property governs which number or letter is used for the current list item inside an ordered list. Employ this attribute and property to override the natural progression. Because these sequence characters can be letters, numbers, or Roman numerals, the integer you specify for this property is converted to the numbering scheme dictated by the `li` or `ol` element's `type` property.

Example

The following statements generate a new `li` element and assign a value to the `start` property:

```
var newLI = document.createElement("li");
newLI.start = 5;
```

Related Item: `ol.start` property

dl, dt, and dd Element Objects

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

dlObject.compact

Properties	Methods	Event Handlers
compact		

Syntax

Accessing dl, dt, and dd element object properties and methods:

```
(IE4+)        [window.] document.all.elemID.property | method([parameters])
(IE5+/W3C)    [window.] document.getElementById("elemID"). property |
              method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About these objects

Three elements — dl, dt, and dd — provide context and (optionally) formatting for definitions in a document. The dl element is the outer wrapper signifying a definition list. Each definition term should be inside a dt element, whereas the definition description should be in the nested dd element. The HTML for a simple definition list has the following structure:

```
<dl>
   <dt>First term</dt>
      <dd>First term's definition</dd>
   <dt>Second  term</dt>
      <dd>Second  term's definition</dd>
</dl>
```

Although there are no specific requirements for rendering definition lists, by convention, the term and description are usually on different lines, with the description indented. With CSS you can significantly override the browser's formatting — even eliminating the traditional list appearance via other choices for the display style property.

All three of these elements are treated as element objects, sharing the same properties, methods, and event handlers of generic element objects. The only one of the three that has anything special is the dl element, which has a compact property. WinIE4+ does respond to this attribute and property by putting the description and term on the same line if the term is shorter than the usual indentation space of the description.

Properties

compact

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

Although the property is defined for the browsers just shown, the compact property (and the deprecated attribute it echoes) only has an impact on the dl element in WinIE browsers.

dir and menu Element Objects

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Syntax

Accessing `dir` and `menu` element object properties and methods:

```
(IE4+)     [window.]document.all.elemID.property | method([parameters])
(IE5+/W3C) [window.]document.getElementById("elemID"). property |
           method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About these objects

The `dir` and `menu` elements are treated in modern browsers as if they were `ul` elements for unordered lists of items. Both elements are deprecated in HTML 4.0; yet, because they are acknowledged in that standard, they are also acknowledged in the W3C DOM (and the IE DOM, too). Originally intended to assist in creating single and double columns of text (long since supplanted by tables), usage of these elements has fallen out of favor and is discouraged.

CHAPTER

The Navigator and Other Environment Objects

IN THIS CHAPTER

Determining which browser the user has

Branching scripts according to the user's operating system

Detecting plug-in support

Client-side scripting primarily focuses on the document inside a browser window and the content of the document. As discussed in Chapter 27, "Window and Frame Objects," the window, too, is an important part of how you apply JavaScript on the client. Stepping out one more level, we get to the browser application itself. Scripts sometimes need to know about the browser and the computing environment in which it runs so that they can tailor dynamic content for the current browser and operating system.

To that end, browsers provide objects that expose as much about the client computer and browser as is feasible within accepted principles of preserving a user's privacy. In addition to providing some of the same information that server-side programs receive as environment variables, these browser-level objects may also include information about how well equipped the browser is with regard to plug-ins and Java. Another object reveals information about the user's video monitor, which may influence the way your scripts calculate information displayed on the page.

The objects in this chapter don't show up on the document object hierarchy diagrams, except as free-standing groups. The IE4+ object model, however, incorporates these environmental objects as properties of the `window` object. Because the `window` reference is optional, in many cases you can omit it and wind up with a cross-browser compatible script.

Although these objects were first implemented outside of the object model hierarchy, they are now treated as belonging to the `window` object. As you learn in this chapter, the IE for Windows methodology can be a bit roundabout. And yet the Macintosh version of IE5 adopted the approach initiated by NN3. Go figure!

clientInformation Object (IE4+) and navigator Object (All)

Properties	Methods	Event Handlers
appCodeName	javaEnabled()	
appMinorVersion	preference()	
appName		
appVersion		
browserLanguage		
cookieEnabled		
cpuClass		
language		
mimeTypes		
online		
oscpu		
platform		
plugins		
product		
productSub		
securityPolicy		
systemLanguage		
userAgent		
userLanguage		
userProfile		
vendor		
vendorSub		

Syntax

Accessing `clientInformation` and `navigator` object properties and methods:

```
(All)        navigator.property | method()
(IE4+/Moz)   [window.]navigator.property | method()
(IE4+/Moz)   [window.]clientInformation.property | method()
```

About this object

In Chapter 27, we repeatedly mention that the `window` object is the top banana of the document object hierarchy. In other programming environments, you likely can find a level higher than the window — perhaps referred to as the *application level*. You may think that an object known as the `navigator` object is that all-encompassing object in JavaScript. That is not the case, however.

Although Netscape originally invented the `navigator` object for the Navigator 2 browser, Microsoft Internet Explorer also supports this object in its object model. For those who have partisan feelings in favor of Microsoft, IE4+ provides an alternate object — `clientInformation` — that acts as an alias to the `navigator` object. You are free to use the IE-specific terminology if your development is intended only for IE browsers, but there is really no good reason not to use `navigator` in case you should ever need to support browsers beyond IE. All properties and methods of the `navigator` and `clientInformation` objects are identical. In the rest of this section, all references to the `navigator` object also apply to the `clientInformation` object.

Be aware that the number of properties for this object has grown with virtually every browser version. Moreover, other than some basic items that have been around since the early days, most of the more recent properties are browser-specific. Observe the compatibility ratings for each of the following properties very carefully.

Most of the properties of the `navigator` object deal with the browser program that the user runs to view documents. Properties include those for extracting the versions of the browser and of the platform of the client running the browser. Because so many properties of the `navigator` object are related to one another, we begin this discussion by grouping four of the most popular ones together.

Properties

appCodeName
appName
appVersion
userAgent

Value: String Read-Only

Compatibility: WinIE3+, MacIE3+, NN2+, Moz+, Safari+, Opera+, Chrome+

These four properties reveal just about everything that browser-sniffing code needs to know about the user's browser brand, version, and other tidbits. Of these four, only the last three are particularly valuable. The first property in the list, `appCodeName`, defines a class of client that encompasses essentially every standard browser. The value returned, `Mozilla`, is the code name of the first browser engine, on which NN and IE browsers at one time were based (the NCSA Mosaic browser). This information does nothing to help your scripts distinguish among browser flavors, so you can ignore the property. The other three properties are the ones with all the goodies.

The appName property returns the official name for the browser application. For Netscape and Mozilla browsers, the appName value is Netscape; for Internet Explorer, the value is Microsoft Internet Explorer. The situation is murkier for other browsers. For example, Opera gives users a preference option to have the browser identify itself as IE, NN, or Opera — and the appName property value changes accordingly. And Safari identifies itself as Netscape in the appName property. Thus, the appName property is no longer a reliable browser brand determinant.

The appVersion and userAgent properties provide more meaningful detail. We start with the appVersion property because it is revealing and, at times, misleading.

Using the appVersion property

A typical appVersion property value looks like the following (one is from FF1.5-3.5.6 running on Windows, the other from IE8):

```
5.0 (Windows; en-US)
4.0 (compatible; MSIE 8.0; Windows NT 5.1; Trident/4.0; .NET CLR 2.0.50727;
    .NET CLR 3.0.04506.30; .NET CLR 3.0.04506.648)
```

Because most version decisions are based on numeric comparisons (for example, the version is equal to or greater than 4), you frequently need to extract just the number part of the string returned by the appVersion property. The cleanest way to do this is through the parseInt() or parseFloat() methods. Use

```
parseInt(navigator.appVersion)
```

if you are interested only in the number to the left of the decimal; to get the complete leading floating-point number, use

```
parseFloat(navigator.appVersion)
```

All other characters after the leading numbers are ignored.

Also notice that the number does not always accurately represent the version of the browser at hand. For example, IE6 through IE8 report that they are version 4.0. The number is more indicative of a broad generation number than a specific browser version number. In other words, the browser exhibits characteristics of the first browsers to wear the appVersion of 4 (IE 4.0, it turns out). Although this means that IE8 can use everything that is in the language and object model of IE4, it obviously doesn't help your script to know if the browser is capable of IE8 scripting features.

At the same time, however, buried elsewhere in the appVersion string, is the wording MSIE 8.0 — the "true" version of the browser. IE uses this technique to distinguish the actual version number from the generational number. Therefore, for IE, you may have to dig deeper by using string methods such as indexOf() to see if the appVersion contains the desired string. For example, to see if the browser is a variant of IE8, you can test for just "MSIE 8" as follows:

```
var isIE8x = navigator.appVersion.indexOf("MSIE 8") != -1
```

***navigatorObject*.appVersion**

This kind of testing is not without risk, however. Going forward, your code will break if future versions of IE have larger version numbers. Therefore, if you want to use IE7 features with an IE8 browser, your testing for the presence of `"MSIE 7"` fails, and the script thinks that it cannot use IE7 features even though they most certainly would be available in IE8. To find out if the current IE browser is the same or newer than a particular version, you must use JavaScript string parsing to deal with the `MSIE x.x` substring of the `appVersion` (or `userAgent`) property. The following example shows one function that extracts the precise IE version name and another function that confirms whether the version is at least IE7.0 for Windows.

```
var ua = navigator.userAgent;
function getIEVersion()
{
   var IEOffset = ua.indexOf("MSIE ");
   return parseFloat(ua.substring(IEOffset + 5, ua.indexOf(";", IEOffset)));
}
function qualifyBrowser()
{
   var qualified = false;
      if (navigator.appName == "Microsoft Internet Explorer")
      {
         if (parseInt(getIEVersion()) >= 7)
         {
            if (ua.indexOf("Windows") != -1)
            {
               qualified = true;
            }
         }
      }
      if (!qualified)
      {
         var msg = "These scripts are currently certified to run on:\n";
         msg += " - MS Internet Explorer 7.0 or later for Windows\n";
         alert(msg);
      }
   return qualified;
}
```

As clever as the preceding code looks, using it assumes that the version string surrounding the `MSIE` characters will be immutable in the future. We do not have that kind of guarantee, so you have to remain vigilant for possible changes in future versions.

Thus, with each browser generation's pollution of the `appVersion` and `userAgent` properties, the properties become increasingly less useful for browser sniffing — unless you want to burden your code with a lot of general-purpose sniffing code, very little of which any one browser uses.

Even Mozilla is not free of problems. For example, the main numbering in the `appVersion` property for Firefox 3.5.6 is 5 (in other words, the fifth generation of the original Mozilla code). A potentially thornier problem arises due to the elimination of some nonstandard NN4 DOM features from the Mozilla DOM (`layer` objects and some event object behaviors). Many

scripters followed the previously recommended technique to “prepare for the future” by using an `appVersion` of 4 as a minimum:

```
var isNN4 = parseInt(navigator.appVersion) >= 4;
```

But any code that relies on the `isNN4` variable to branch to code that talks to the dead-end NN4 objects and properties breaks when it runs in Mozilla. This is the dreaded scenario where not every browser feature was retained for backward compatibility as the browser evolved.

The bottom-line question is, “What do I do for browser version detection?” Unfortunately, there are dozens of answers to that question, depending on what you need browser detection to do and what level of code you produce.

At one end of the spectrum is code that tries to be many things to many browsers, implementing multiple levels of features for many different generations of browser. This is clearly the most difficult tactic, and you have to create quite a long list of variables for the conditions for which you establish branches. Some branches may work on one combination of browsers, whereas you may need to split other branches differently because the scripted features have more browser-specific implementations.

At the other end of the spectrum is the code that tries to support, say, only IE5+ and other modern browsers with W3C DOM-compatible syntax to the extent that both browser families implement the object model features. Life for this scripter is much easier in that the amount of branching is little or none, depending on what the scripts do with the objects. Given that modern browsers are now prevalent in mainstream computing, it’s not unreasonable to take this approach and simplify the whole browser compatibility issue.

If you can’t make the assumption that your users have a modern browser, then there are other options for cluing in your scripts to what a particular browser is capable of handling. Object detection (for example, seeing if `document.images` exists before manipulating image objects) is a good solution at times, not so much for determining the browser version, but for knowing whether some code that addresses those objects works. As described in Chapter 25, “Document Object Model Essentials,” it is hazardous to use the existence of, say, `document.all` as an indicator that the browser is IE4+. Some other browser in the future may also implement the `document.all` property, but not necessarily all the other IE4+ objects and syntax. Code that thinks it’s running in IE4+ just because `document.all` exists can easily break if another browser implements `document.all` but not the rest of the IE4+ DOM. Using object detection to branch code that addresses the detected objects is, however, very desirable in the long run because it frees your code from getting trapped in the ever-changing browser version game.

Don’t write off the `appVersion` and `userAgent` properties entirely. The combination of features that you script may benefit from some of the data in that string, especially when the decisions are made in concert with the `navigator.appName` property. A number of other properties can also provide sufficient clues for your code to perform the branching that your application needs. For example, it may be very helpful to your scripts to know whether the `navigator.platform` property informs them that they are running in a Windows or Macintosh environment because of the way each operating system renders fonts.

userAgent property details

The string returned by the `navigator.userAgent` property contains a more complete rundown of the browser. The `userAgent` property is a string, similar to the `USER_AGENT` header, that the browser sends to the server at certain points during the connection process between client and server.

Unfortunately, there is no standard for the way information in the `userAgent` property is formatted or how details about operating systems and browser versions are presented. Table 42-1 shows some of the values that your scripts are likely to see. This table does not include, of course, the many values that are not reflected by browsers that do not support JavaScript. The purpose of the table is to show you just a sampling of data that the property can contain from a variety of browsers and operating systems (particularly enlightening if you do not have access to Macintosh or UNIX computers).

Because the `userAgent` property contains a lot of the same information as the `appVersion` property, the same cautions just described apply to the `userAgent` string and the environment data it returns.

Speaking of compatibility and browser versions, the question often arises whether your scripts should distinguish among incremental releases within a browser's generation (for example, 7.0, 7.01, 7.02, and so on). The latest incremental release occasionally contains bug fixes and (rarely) new features on which you may rely. If that is the case, we suggest you look for this information when the page loads and recommend to the user that he or she download the latest browser version. Beyond that, we suggest scripting for the latest version of a given generation and not bothering with branching for incremental releases.

See Chapters 4 and 25 for more information about designing pages for cross-platform deployment.

Example

Listing 42-1 provides a number of reusable functions that your scripts can employ to determine a variety of information about the currently running browser. This is not intended in any way to be an all-inclusive browser-sniffing routine; instead, we offer samples of how to extract information from the key `navigator` properties to determine various browser conditions. Note especially the test for Apple's Safari browser.

All functions in Listing 42-1 return a Boolean value inline with the pseudo-question presented in the function's name. For example, the `isWindows()` function returns `true` if the browser is any type of Windows browser; otherwise, it returns `false`. If this kind of browser detection occurs frequently in your pages, consider moving these functions into an external `.js` source library for inclusion in your pages (see Chapter 4).

When you load this page, it presents fields that display the results of each function, depending on the type of browser and client operating system you use. This page serves as a simple test bed for ensuring that a browser reveals the correct version information. (Note that Firefox is still considered a variant of Netscape Navigator, at least in terms of version info.) This example also provides a quick test for how a browser enables you to reference objects: whether it supports `document.all`, `getElementById`, or both.

TABLE 42-1

Typical navigator.userAgent Values

navigator.userAgent	Description
`Mozilla/5.0 (Windows; U; Windows NT 5.1; en-US; rv:1.8.1) Gecko/20061003 Firefox/2.0`	Firefox 2.0 for Windows, running under Windows XP Professional
`Mozilla/5.0 (Windows; U; Windows NT 5.1; en-US; rv:1.8.0.7) Gecko/20060909 Firefox/1.5.0.7`	Firefox 1.5 for Windows, running under Windows XP Home Edition
`Mozilla/5.0 (Macintosh; U; PPC Mac OS X Mach-O; en-US; rv:1.4) Gecko/20030624`	Mozilla 1.4 for MacOS X
`Mozilla/5.0 (Windows; U; Windows NT 5.1; en-US; rv:1.4) Gecko/20030624 Netscape/7.1 (ax)`	Navigator 7.1 for Windows, running under Windows XP Home Edition
`Mozilla/4.74 [en] (X11; U; Linux 2.2.154mdksmp i686)`	Navigator 4.74, English edition for Linux with U.S. encryption
`Mozilla/4.0 (compatible; MSIE 7.0; Windows NT 5.1; .NET CLR 1.1.4322)`	IE 7.0 running under Windows XP Home Edition
`Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; .NET CLR 1.0.3705)`	IE 6.0 running under Windows XP Home Edition
`Mozilla/4.0 (compatible; MSIE 5.5; Windows NT 5.0)`	IE 5.5 running under Windows NT 5.0
`Mozilla/4.0 (compatible; MSIE 5.0; Windows 98; DigExt)`	IE 5.0 for Windows 98 with digital signature
`Mozilla/4.0 (compatible; MSIE 5.0; Mac_PowerPC)`	IE 5.0 running on a PowerPC-equipped Macintosh
`Mozilla/5.0 (Macintosh; U; PPC Mac OS X; en-us)`	Apple Safari 2.0.4 (release no. 419.3) for Mac OS X
`Opera/9.01 (WindowsNT 5.1; U; en) AppleWebKit /418.9 (KHTML, like Gecko) Safari/419.3`	Opera 9.01 (set to identify as Opera) for Windows XP Professional
`Mozilla/5.0 (Windows; U; Windows NT 5.1; en-US) AppleWebKit/532.0 (KHTML, like Gecko) Chrome/3.0.195.38 Safari/532.0`	Google Chrome 3.0.195.38 for Windows XP Professional
`Opera/9.80 (Macintosh; Intel Mac OS X; U; en Presto/2.2.15 Version/10.00`	Opera 10.00 Build 6652 for Mac OS X 10.5.8 with the Java Runtime Environment installed

LISTING 42-1

Functions to Examine Browsers

```
<!DOCTYPE html>

```

Related Items: `appMinorVersion`, `cpuClass`, `oscpu`, `platform` properties

appMinorVersion

Value: One-character string — Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera+, Chrome-

In IE parlance, the *minor version* is indicated by the first digit to the right of the decimal in a full version number. But the “version number” referred to here is the number that the `navigator.appVersion` property reports, not the actual version of the browser. For example, although IE5.5 seems to have a version number of 5 and a minor version number of 5, the `appVersion` reports version 4.0. In this case, the `minorAppVersion` reports 0. Thus, you cannot use the `appMinorVersion` property to detect differences between, say, IE5 and IE5.5.

That information is buried deeper within the string returned by `appVersion` and `userAgent`. Note that although Opera supports this property, it currently does not populate it.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to examine the two related version properties of your IE browser(s). Type the following two statements into the top text box and observe the results:

```
navigator.appVersion
navigator.minorAppVersion
```

There is a good chance that the values returned are not related to the browser version number shown after `MSIE` in the `appVersion` value.

Related Item: `appVersion` property

browserLanguage

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera+, Chrome-

The `browserLanguage` property in IE4+ (and the `language` property in NN4+/Moz) returns the identifier for a localized language version of the program (it has nothing to do with scripting or programming language). The value of the `browserLanguage` property almost always is the same as the other IE language-related properties, unless the user changes the Windows control panel for regional settings after installing IE. In that case, `browserLanguage` returns the original language of the browser application, whereas the other properties report the language indicated in the system-level preferences panel.

Note

Users of the multilanguage version of Windows XP and Windows Vista can choose alternate languages for menus and dialog boxes. The `browserLanguage` property returns the language you choose for those settings. ■

These short strings may resemble, but are not identical to, the URL suffixes for countries. Moreover, when a language has multiple dialects, the dialect can also be a part of the identifier. For example, `en` is the identifier for English. However, `en-us` (or `en-US`) represents the American dialect of English, whereas `en-gb` (or `en-GB`) represents the dialect recognized in Great Britain. NN sometimes includes these values as part of the `userAgent` data as well. Table 42-2 shows a sampling of language identifiers used for all language-related properties of the `navigator` object.

You can assume that a user of a particular language version of the browser or system is also interested in content in the same language. If your site offers multiple language paths, you can use this property setting to automate the navigation to the proper section for the user.

TABLE 42-2

Sample navigator.browserLanguage Values

navigator.language	Language
En	English
De	German
Es	Spanish
Fr	French
Ja	Japanese
Da	Danish
It	Italian
Ko	Korean
nl	Dutch
pt	Brazilian Portuguese
sv	Swedish

Related Items: navigator.userAgent, navigator.language, navigator.systemLanguage, navigator.userLanguage properties

cookieEnabled

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The cookieEnabled property allows your scripts to easily determine if the browser has cookie functionality turned on. You can surround cookie-related statements with an if construction as follows:

```
if (navigator.cookieEnabled)
{
   // do cookie stuff here
}
```

This works reliably only on browsers that implement the property, which includes all modern browsers. Because legacy browsers do not have this navigator object property, the if condition appears false (even though cookies may be turned on).

You can still check for cookie functionality in older browsers, but only clumsily. The technique entails assigning a "dummy" cookie value to the document.cookie property and attempting to read back the cookie value. If the value is there, cookies are enabled.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see the value of the `navigator.cookieEnabled` property on your browsers. Enter the following statement into the top text box:

```
navigator.cookieEnabled
```

Feel free to change the cookie preferences setting temporarily to see the new value of the property. You do not have to relaunch the browser for the new setting to take effect.

Related Item: `document.cookie` property

cpuClass

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `cpuClass` property returns one of several fixed strings that identifies the family of central processing units running IE. Possible values and their meanings are as follows:

cpuClass	Description
`x86`	Intel processor (and some emulators)
`PPC`	Motorola Power PC processor (for example, Macintosh)
`68K`	Motorola 68000-family processor (for example, Macintosh)
`Alpha`	Digital Equipment Alpha processor
`Other`	Other processors, such as SPARC

The processor is not a good guide to determining the operating system because you can run multiple operating systems on most of the preceding processor families. As an example, Apple's shift to Intel microprocessors in 2006 confused the familiar notion that Macs are Motorola and Windows PCs are Intel. Moreover, the `cpuClass` value represents the processor that the browser "thinks" it is running on. For example, when a Windows version of IE is hosted by the *Virtual PC* emulator on a PowerPC (Motorola) Macintosh, the `cpuClass` is reported as `x86` even though the actual hardware processor is `PPC`.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see how IE reports the `cpuClass` of your PC. Enter the following statement into the top text box:

```
navigator.cpuClass
```

Related Item: `navigator.oscpu` property

`language`

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari+, Opera+, Chrome+

The NN4+/Moz `language` property returns the language code for the browser application. Although the comparable IE property (`navigator.browserLanguage`) has morphed in later versions to focus on the operating system language, `language` deals exclusively with the language for which the browser application is written.

Related Item: `navigator.browserLanguage` property

`mimeTypes`

Value: Array of `mimeType` objects Read-Only

Compatibility: WinIE-, MacIE5, NN4+, Moz+, Safari+, Opera+, Chrome+

A `mime` *(Multipurpose Internet Mail Extension)* type is a file format for information that travels across the Internet. Browsers usually have a limited built-in capability for displaying or playing information beyond HTML text and one or two image standards (`.gif`, `.jpg`, and now, more frequently, `.png` are the most common formats). To fill in the gap, browsers maintain an internal list of `mime` types with corresponding instructions on what to do when information of a particular `mime` type arrives at the client. For example, when a server application serves up an audio stream in an audio format, the browser locates that `mime` type in its table (the `mime` type is among the first chunks of information to reach the browser from the server), and then launches a helper application or activates a plug-in capable of playing that `mime` type. Your browser is not equipped to display every `mime` type, but it does know how to alert you when you don't have the helper application or plug-in needed to handle an incoming file. For instance, the browser may ask if you want to save the file for later use or switch to a web page containing more information about the necessary plug-in.

The `mimeTypes` property of the `navigator` object is simply the array of `mime` types about which your browser knows (see the "mimeType Object" section later in this chapter). NN/Moz browsers come with dozens of `mime` types already listed in their tables (even if the browser doesn't have the capability to handle all those items automatically). If you have third-party plug-ins in Mozilla's plug-ins directory/folder, or helper applications registered with your browser, that array contains these new entries as well.

If your web pages are media-rich, you want to be sure that each visitor's browser is capable of playing the media your page has to offer. With JavaScript and NN/Moz, you can cycle through the `mimeTypes` array to find a match for the `mime` type of your media. Then use the properties of the `mimeType` object (detailed later in this chapter) to ensure that the optimum plug-in is available. If your media still requires a helper application instead of a plug-in, the array only lists the `mime` type; thus, you can't determine whether a helper application is assigned to this `mime` type from the array list.

Example

For examples of the `mimeTypes` property and details about using the `mimeType` object, see the discussion of this object later in the chapter. A number of simple examples showing how to use this property to see whether the `navigator` object has a particular MIME type do not go far enough in determining whether a plug-in is installed and enabled to play the incoming data.

Related Item: `navigator.plugins` property; `mimeType` object

onLine

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, FF+, Safari+, Opera+, Chrome+

The `onLine` property lets scripts determine the state of the offline browsing setting for the browser. Bear in mind that this property does not reveal whether the page is accessed via the Net or a local hard disk. The browser can be in online mode and still access a local page; in this case, the `onLine` property returns `true`.

With the offline browsing capabilities of many modern browsers, users may prefer to download copies of pages they wish to reference frequently (perhaps on a disconnected laptop computer). In such cases, your pages may want to avoid network-reliant content when accessed offline. For example, if your page includes a link to a live audio feed, you can dynamically generate that link with JavaScript — but only if the user is online:

```
if (navigator.onLine)
{
   document.write("<a href='broadcast.rna'>Listen to Audio</a>");
}
```

Example

Use The Evaluator (Chapter 4, “JavaScript Essentials”) to see the online state of your IE browsers. Enter the following statement into the top text box:

```
navigator.onLine
```

Verify your browsing mode by checking the Work Offline choice in the File menu. If it is checked, the `onLine` property should return `false`.

oscpu

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari-, Opera-, Chrome-

The `oscpu` property of Mozilla-based browsers returns a string that reveals OS- or CPU-related information about the user’s environment. The precise string varies widely with the client OS.

For instance, a Windows 98 machine reports `Win98`, whereas a Macintosh running MacOS X reports `PPC Mac OS X Mach-O`. The string formats for Windows NT/XP versions are not standardized, so they offer values such as `WinNT4.0` and `Windows NT 5.1`. Windows XP reports as being `Windows NT 5.x` in the `oscpu` property (as it does in the `userAgent` property), whereas Windows Vista reports as being Windows NT 6.x. UNIX platforms reveal more details, such as the system version and hardware.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") with NN6+/Moz to see what your client machine reports to you by entering the following statement into the top text box:

```
navigator.oscpu
```

Related Item: `navigator.cpuClass` property

platform

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

The `navigator.platform` value reflects the operating system according to the codes established initially by Netscape for its `userAgent` values. Table 42-3 lists the typical values of several operating systems.

TABLE 42-3

Sample navigator.platform Values

navigator.platform	Operating System
`Win32`	Windows XP
`Win98`	Windows 98
`WinNT`	Windows NT
`Win16`	Windows 3.*x*
`MacIntel`	Mac (CPU)
`MacPPC`	Mac (PowerPC CPU)
`SunOS`	Solaris

In the long list of browser detection functions in Listing 42-1, we elected not to use the `navigator.platform` property because it is not backward-compatible. Meanwhile, the other properties in that listing are available to all scriptable browsers.

Notice that the `navigator.platform` property does not go into versioning of the operating system. Only the raw name is provided. Also, there is a `Win64` value that should be reported for 64-bit Windows versions, such as the 64-bit version of Windows Vista. However, this value hasn't been reliably reported in previous 64-bit Windows operating systems.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") to see what your computer reports as its operating system. Enter the following statement into the top text box:

```
navigator.platform
```

Related Item: `navigator.userAgent` property

plugins

Value: Array of plug-in objects Read-Only

Compatibility: WinIE-, MacIE5, NN3+, Moz+, Safari+, Opera+, Chrome+

You rarely find people involved with web page design who have not heard about *plug-ins* — the technology that enables you to embed new media types and foreign file formats directly into web documents. For instance, instead of requiring you to watch a video clip in a separate viewer atop the main browser window, a plug-in enables you to make that viewer as much a part of the page design as a static image. The same goes for audio players, 3-D animation, chat sessions — even the display of Microsoft Office documents, such as PowerPoint and Word.

When many browsers launch, they create an internal list of available plug-ins located in a special directory/folder (the name varies with the browser and operating system). The `navigator.plugins` array lists the items registered at launch time. Each plug-in is, itself, an object with several properties.

The Windows version of IE4+ supports this property only to return an empty array. In other words, the property is defined, but it does not contain `plugin` objects — a nonexistent object in IE for Windows. But on the Macintosh side, IE5 supports the way Netscape Navigator, Mozilla, and Safari allow script inspection of `mime` types and plug-ins. To see ways of determining plug-in support for WinIE, see the section "'Plug-in' detection in WinIE" later in this chapter.

Having your scripts investigate the visitor's browser for a particular installed plug-in is a valuable capability if you want to guide the user through the process of downloading and installing the plug-in if the system does not have it currently.

Example

For examples of the `plugins` property and for details about using the `plugin` object, see the section "`plugin` Object" later in this chapter. Also see Chapter 44, "Embedded Objects," for information on embedded element objects.

Related Items: `navigator.mimeTypes property`; `plugin` object

product
productSub
vendor
vendorSub

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera-, Chrome+

With the Mozilla browser engine being developed in an Open Source environment, any number of vendors might adapt the engine for any number of browser products. Some distributors of the browser, such as ISPs and computer manufacturers, may also tailor the browser slightly for their customers. These four properties can reveal some of the pedigree of the browser currently running scripts on the page.

Two categories of properties — one for the product, one for the vendor — each have a pair of fields (a primary and secondary field) that can be populated as the vendor sees fit. Some of this information may contain data, such as the identifying number of the *build* (development version) used to generate the product. A script at a computer maker's web site may look for a particular series of values in these properties to welcome the customer, or to advise the customer of a later build version that is recommended as an upgrade.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") on NN6+/Moz and WebKit-based browers to see the values returned for these four properties (Safari 1.0 doesn't support `vendorSub`). Enter each of the following statements into the top text box of the page and see the values for each in the Results box:

```
navigator.product
navigator.productSub
navigator.vendor
navigator.vendorSub
```

Also check the value of the `navigator.userAgent` property to see how many of these four property values are revealed in the `userAgent` property.

Related Item: `navigator.userAgent` property

securityPolicy

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari-, Opera-, Chrome-

The Netscape-specific `securityPolicy` property returns a string that indicates which cryptographic scheme is implemented in the current browser. Typical string values include `US and CA domestic policy` and `export policy`. Each policy indicates the number of bits

used for encryption, usually governed by technology export laws. The corresponding IE property is `document.security`. All Mozilla-based browsers have only one version, and the property's value is an empty string.

Related Item: `document.security` property

systemLanguage
userLanguage

Value: Language code string Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera+, Chrome-

These two IE-specific properties report the language code of the written language specified for the operating system. For most operating system versions, these two values are the same. Some Windows versions enable you to set system preferences differently for the base operating system and the language for a given user. Both of these property values can differ from the `navigator.browserLanguage` property if the user downloads and installs the browser with the system set to one language, and then changes the system settings to another language. Note that Opera only supports `systemLanguage`.

Example

Use The Evaluator (Chapter 4, "JavaScript Essentials") with your IE4+ browser to compare the values of the three language-related properties running on your computer. Enter each of the following statements into the top text box:

```
navigator.browserLanguage
navigator.systemLanguage
navigator.userLanguage
```

Don't be surprised if all three properties return the same value.

Related Item: `navigator.browserLanguage` property

userAgent

(See `appCodeName`)

userLanguage

(See `systemLanguage`)

userProfile

Value: `userProfile` object Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `userProfile` property returns a reference to the IE `userProfile` object. This object provides scripted access to a limited range of user profile settings, with the user's permission. For details, see the `userProfile` object discussion later in this chapter.

Related Item: `userProfile` object

`vendor`
`vendorSub`

Methods

`javaEnabled()`

Returns: Boolean

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

Although most modern browsers ship with Java support turned on, a user can easily turn it off in a preferences dialog box (or even elect not to install it with the browser). Some corporate installations may also turn off Java as the default setting for their users. If your pages specify Java applets, you don't normally have to worry about this property because the applet tag's alternate text fills the page in the places where the applet normally goes. But if you script applets from JavaScript (see Chapter 47), you don't want your scripts making calls to applets or Java classes if Java support is turned off. In a similar vein, if you create a page with JavaScript, you can fashion two different layouts, depending on the availability of Java.

The `navigator.javaEnabled()` method returns a Boolean value reflecting the preferences setting. This value does not necessarily reflect Java support in the browser (and certainly not the Java version supported), but rather whether Java is turned on inside the browsers for which this method is supported. A script cannot change the browser's preference setting, but its value does change immediately when the user toggles the setting.

Related Items: `navigator.preference()` method; NPAPI (Chapter 47, "Scripting Java Applets and Plug-Ins")

`preference(`*`name`*`[, `*`val`*`])`

Returns: Preference value

Compatibility: WinIE-, MacIE-, NN4+, Moz1+, Safari-, Opera-, Chrome-

The user normally sets browser preferences. Until NN4 and the advent of signed scripts, almost all settings were completely out of view of scripts — even when it made sense to expose them. But with signed scripts and the `navigator.preference()` method, many NN preferences are now viewable and settable with the user's permission. These preferences were exposed to scripting primarily for the purposes of centralized configuration administration for enterprise installations. We don't recommend altering the browser preferences of a public web site visitor, even if given permission to do so — the user may not know how much trouble you can cause.

When you want to read a particular preference setting, you pass only the preference name parameter with the method. Reading a preference requires a signed script with the target of `UniversalPreferencesRead` (see Chapter 49, "Security and Netscape Signed Scripts," on the

navigatorObject.**preference()**

CD-ROM). To change a preference, pass both the preference name and the value (with a signed script target of `UniversalPreferencesWrite`).

Table 42-4 shows a handful of scriptable preferences in Mozilla-based browsers (learn more about Mozilla preferences at `http://www.mozilla.org/catalog/end-user/customizing/briefprefs.html`). Most items have corresponding entries in the preferences window in NN4+ (shown in parentheses) and are available in Firefox via the Options window. Notice that the preference name uses dot syntax. The cookie security level is a single preference value with a matrix of integer values indicating the level.

Tip

One preference to watch out for is the one that disables JavaScript. If you disable JavaScript, only the user can reenable JavaScript by manually changing the setting in the browser's preferences dialog box. ■

TABLE 42-4

navigator.preference() Values Sampler

navigator.preference	Value	Preference Dialog Listing
`security.enable_java`	Boolean	(Advanced) Enables Java
`javascript.enabled`	Boolean	(Advanced) Enables JavaScript
`autoupdate.enabled`	Boolean	(Advanced) Enables AutoInstall
`network.cookie.cookieBehavior`	0	(Advanced) Accepts all cookies
`network.cookie.cookieBehavior`	1	(Advanced) Accepts only cookies that get sent back to the originating server
`network.cookie.cookieBehavior`	2	(Advanced) Disables cookies
`network.cookie.warnAboutCookies`	Boolean	(Advanced) Warns you before accepting a cookie

Example

The page in Listing 42-2 displays check boxes or radio buttons for several preference settings, plus one text box, to show a preference setting value for the size of the browser's disk cache. You will receive a security warning each time the scripts enable the Privilege Manager.

One function reads all the preferences and sets the form control values accordingly. Another function sets a preference when you click its check box. Rerunning the `showPreferences()` function also helps verify that you set the preference.

   </body>
</html>
```

Note

The property assignment event handling technique used in this example and throughout the chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects."** ■

mimeType Object

Properties	Methods	Event Handlers
description		
enabledPlugin		
type		
suffixes		

Syntax

Accessing mimeType properties:

```
navigator.mimeTypes[i].property
navigator.mimeTypes["MIMEtype"].property
```

Compatibility: WinIE-, MacIE5, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

A mimeType object is essentially an entry in the internal array of mime types about which the browser knows. NN3+/Moz, for example, ships with an internal list of more than five dozen mime types. Only a handful of these types are associated with helper applications or plug-ins. But add to that list all of the plug-ins and other helpers you've installed, and the number of mime types can grow to more than a hundred.

The mime type for the data is usually among the first bits of information to arrive at a browser from the server. A mime type consists of two pieces of information: type and subtype. The traditional way of representing these pieces is as a pair separated by a slash, as in

```
text/html
image/gif
audio/wav
video/quicktime
application/pdf
application/x-zip-compressed
```

If a file does not contain the mime type "header" (or a CGI program sending the file does not precede the transmission with the mime type string), the browser receives the data as a text/plain mime type. When you load the file from a local hard drive, the browser looks to the filename's extension (the suffix after the period) to figure out the file's type.

Regardless of the way it determines the mime type of the incoming data, the browser then acts according to instructions it maintains internally. You can see these settings by looking at preferences settings usually associated with the name "Applications."

By having the `mimeType` object available to JavaScript, your page can query a visitor's NN3+/Moz, MacIE5, or WebKit-based browser to discover whether it has a particular `mime` type listed currently, and whether the browser has a corresponding plug-in installed and enabled. In such queries, the `mimeType` and `plugin` objects work together to help scripts make these determinations. (For plug-in detection in WinIE, see the section "'Plug-in' detection in WinIE," later in this chapter.)

Because of the close relationship between `mimeType` and `plugin` objects, we save the examples of using these objects and their properties for a section later in this chapter. There you can see how to build functions into your scripts that enable you to examine how well a visitor's browser is equipped for either a `mime` type or data that requires a specific plug-in. In the meantime, be sure that you understand the properties of both objects.

Properties

description

Value: String Read-Only

Compatibility: WinIE-, MacIE5, NN3+, Moz+, Safari+, Opera+, Chrome+

While registering with the browser at launch time, plug-ins provide the browser with an extra field of information: a plain-language description of the plug-in. If a particular `mime` type has a plug-in associated with it and enabled for it, the plug-in's description passes through to become the description of the `mimeType` object. For example, the Adobe Acrobat plug-in (whose `mime` type is `application/pdf`) supplies the following description fields:

```
(NN3/NN4)   Acrobat
(Moz)       Acrobat Portable Document Format
```

To verify this in your own browser, enter the following line of code into the Evaluator (with NN3+/Moz, MacIE5, and Safari):

```
navigator.mimeTypes["application/pdf"].description
```

When a `mime` type does not have a plug-in associated with it (either no plug-in is installed or a helper application is used instead), you often see the `type` property value repeated in the description field.

enabledPlugin

Value: `plugin` object Read-Only

Compatibility: WinIE-, MacIE5, NN3+, Moz+, Safari+, Opera+, Chrome+

The descriptions of the `mimeType` and `plugin` objects seem to come full circle when you reach the `mimeType.enabledPlugin` property. The reason is that the property is a vital link between a known `mime` type and the plug-in that the browser engages when data of that type arrives.

Knowing which plug-in is associated with a `mime` type is very important when you have more than one plug-in capable of playing a given `mime` type. For example, the Crescendo `midi` audio plug-in can take the place of the default audio plug-in if you set up your browser that way. Therefore, all `midi` data streams play through the Crescendo plug-in. If you prefer to have your web page's `midi` sound played only through another plug-in, your script needs to know which plug-in is set to receive your data and perhaps alert the user accordingly. These kinds of conflicts are not common, except where there is strong competition for players of various audio and video media. For other kinds of content, each plug-in developer typically creates a new type of data that has a unique `mime` type. But you have no guarantee of such uniqueness, so we highly recommend a careful check of `mime` type and plug-in if you want your page to look professional.

The `enabledPlugin` property evaluates to a `plugin` object. Therefore, you can dig a bit deeper with this information to fetch the name or filename properties of a plug-in directly from a `mimeType` object. You can use The Evaluator to study the relationship between `mimeType` and `plugin` objects:

1. Enter the following statement into the bottom text box to examine the properties of a `mimeType` object:

   ```
   navigator.mimeTypes[0]
   ```

   Notice that the `mimeTypes` array returns an object.

2. Inspect the `plugin` object from the bottom text box:

   ```
   navigator.mimeTypes[0].enabledPlugin
   ```

   You then see properties and values for a `plugin` object (described later in this chapter).

3. Check the `plugin` object for a different `mimeType` object by using a different index value:

   ```
   navigator.mimeTypes[7].enabledPlugin
   ```

The `mimeTypes` array index values vary with almost every browser, depending on what the user has installed. Therefore, do not rely on the index position in a script to assume that a particular `mimeType` object is in that position on all browsers.

Example

See the section "Looking for `mime` Types and Plug-ins" later in this chapter.

Related Item: `plugin` object

`type`

Value: String — Read-Only

Compatibility: WinIE-, MacIE5, NN3+, Moz+, Safari+, Opera+, Chrome+

A `mimeType` object's `type` property is the combination of the type and subtype commonly used to identify the kind of data coming from the server. Server applications, for

example, typically precede a data transmission with a special header string in the following format:

```
Content-type: type/subtype
```

This string prompts a browser to look up how to treat an incoming data stream of this kind. As you see later in this chapter, knowing whether a particular `mime` type is listed in the `navigator.mimeTypes` array is not enough. A good script must dig deeper to uncover additional information about what is truly available for your data.

The `type` property has a special place in the `mimeType` object, in that its string value can act as the index to the `navigator.mimeTypes` array. Therefore, to get straight to the `mimeType` object for, say, the `audio/wav mime` type, your script can reference it directly through the `mimeTypes` array:

```
navigator.mimeTypes["audio/wav"]
```

This same reference can then get you straight to the enabled plug-in (if any) for the `mime` type:

```
navigator.mimeTypes["audio/wav"].enabledPlugin
```

Example

See the section “Looking for `mime` Types and Plug-ins” later in this chapter.

Related Item: `description` property

suffixes

Value: String Read-Only

Compatibility: WinIE-, MacIE5, NN3+, Moz+, Safari+, Opera+, Chrome+

Every `mime` type has one or more filename extension, or suffix, associated with it. You can read this information for any `mimeType` object via the `suffixes` property. The value of this property is a string. If the `mime` type has more than one suffix associated with it, the string contains a comma-delimited listing, as in

```
mpg, mpeg, mpe
```

Multiple versions of a suffix have no distinction among them. Those `mime` types that are best described in four or more characters (derived from a meaningful acronym, such as mpeg) have three-character versions to accommodate the “8-dot-3” filename conventions of MS-DOS and its derivatives.

Example

See the section “Looking for `mime` Types and Plug-ins” later in this chapter.

plugin Object

Properties	Methods	Event Handlers
name	refresh()	
filename		
description		
length		

Syntax

Accessing plugin object properties or method:

```
navigator.plugins[i].property | method()
navigator.plugins["plugInName"].property | method()
```

Compatibility: WinIE-, MacIE5, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

The plugin object offers a view of the plug-in mechanism from the browser's perspective: The software items registered with the browser at launch time stand ready for any matching mime type that comes from the Net. One of the main purposes of having these objects scriptable is to let your scripts determine whether a desired plug-in is currently registered with the browser and to help with installing the plug-in if it isn't.

The close association between the plugin and mimeType objects, demonstrated by the mimeType.enabledPlugin property, is equally visible coming from the direction of the plug-in. A plugin object evaluates to an array of mime types that the plug-in interprets. Use The Evaluator (Chapter 4, "JavaScript Essentials") to experiment with mime types from the point of view of a plug-in. Begin by finding the name of the plug-in that your browser uses for a common video mime type:

1. Enter the following statement into the top text box:

   ```
   navigator.mimeTypes["video/quicktime"].enabledPlugin.name
   ```

   If you use NN7+/Moz, MacIE5, or a WebKit-based browser, the value returned is probably "QuickTime Plug-in 7.6.5", possibly with a different version number. Copy the name onto the clipboard so that you can use it in subsequent statements. The remaining examples show "QuickTime Plug-in 7.6.5" where you should paste in your plug-in's name.

2. Enter the following statement into the top text box:

```
navigator.plugins["QuickTime Plug-in 7.6.5"].length
```

   Instead of the typical index value for the array notation, use the actual name of the plug-in. This expression evaluates to a number indicating the total number of different `mime` types that the plug-in recognizes.

3. Look at the first `mime` type specified for the plug-in by entering the following statement into the top text box:

```
navigator.plugins["QuickTime Plug-in 7.6.5"][0].type
```

The two successive pairs of square brackets is not a typo: Because the entry in the `plugins` array evaluates to an array itself, the second set of square brackets describes the index of the array returned by `plugins["QuickTime Plug-in 7.6.5"]` — a period does not separate the sets of brackets. In other words, this statement evaluates to the `type` property of the first `mimeType` object contained by the Quicktime plug-in.

We doubt that you will have to use this kind of construction much; if you know the name of the desired plug-in, you know what `mime` types it already supports. In most cases, you come at the search from the `mime` type direction and look for a specific, enabled plug-in. See the section "Looking for `mime` Types and Plug-Ins" later in this chapter for details on how to use the `plugin` object in a production setting.

Properties

name
filename
description
length

Value: String Read-Only

Compatibility: WinIE-, MacIE5, NN3+, Moz+, Safari+, Opera+, Chrome+

The first three properties of the `plugin` object provide descriptive information about the plug-in file. The plug-in developer supplies the name and description. It's not a strict requirement that future versions of plug-ins differentiate themselves from earlier ones via either of these fields, although some do. Thus, while there is no explicit property that defines a plug-in's version number, that information may be part of the string returned by the `name` or `description` properties.

Be aware that plug-in authors may not assign the same name to every OS platform version of a plug-in. Be prepared for discrepancies across platforms. You should hope that the plug-in you're interested in has a uniform name across platforms, because the value of the `name` property can function as an index to the `navigator.plugins` array to access a particular `plugin` object directly.

Another piece of information available from a script is the plug-in's filename. On some platforms, such as Windows, this data comes in the form of a complete pathname to the plug-in DLL file; on other platforms, only the plug-in filename appears.

Finally, the `length` property of a `plugin` object counts the number of `mime` types that the plug-in recognizes (but not that are necessarily enabled). Although you can use this information to loop through all possible `mime` types for a plug-in, a more instructive way is to have your scripts approach the issue via the `mime` type (as discussed later in this chapter).

Example

See the section "Looking for `mime` Types and Plug-ins" later in this chapter.

Related Item: `mimeType.description` property

Methods

`refresh()`

Returns: Nothing

Compatibility: WinIE-, MacIE5, NN3+, Moz+, Safari+, Opera+, Chrome+

You may have guessed that many browsers determine their lists of installed plug-ins while they launch. If you drop a new plug-in file into the plug-ins directory/folder, you have to quit the browser and relaunch it before the browser sees the new plug-in file. But that isn't a very friendly approach if you've taken pains to guide a user through downloading and installing a new plug-in file. Once the user quits the browser, you have a slim chance of getting that person right back. That's where the `refresh()` method comes in.

The `refresh()` method is directed primarily at the browser, but the syntax of the call reminds the browser to refresh just the plug-ins:

```
navigator.plugins.refresh()
```

Interestingly, this command works only for adding a plug-in to the existing collection. If the user removes a plug-in and invokes this method, the removed one stays in the `navigator.plugins` array — although it may not be available for use. Only the act of quitting and relaunching the browser makes a plug-in removal take full effect.

Looking for mime Types and Plug-Ins

If you go to great lengths to add new media and data types to your web pages, you certainly want your visitors to reap the benefits of those additions. But you cannot guarantee that they have the requisite plug-ins installed to accommodate that fancy data. Most modern browser versions provide a bit of internal "smarts" by noticing when data requiring an uninstalled plug-in is

about to load, and trying to help the user install a missing plug-in. You may wish, however, to take more control over the process by examining the user's browser plug-in functionality prior to loading the external data file.

The best source of information, when available, is the software developer of the plug-in. Adobe, for example, provides numerous technical notes on their web site (`www.adobe.com`) about plug-in detection for their various plug-ins and versions. Unfortunately, that kind of assistance is not always easy to find from other vendors.

Much of the discussion thus far in this chapter addresses the objects that make plug-in and `mime` type support detection possible in some browsers. Microsoft makes it possible — but not easy — to determine whether a particular plug-in is available for WinIE. The approach for WinIE is entirely different from what we have covered so far; if you wish to perform cross-browser detection, you have to branch your code accordingly. We outline each approach next in its own section, starting with the NN3+/Moz/MacIE5/WebKit browser way.

Overview: Using mimeType and plugin objects

The value of performing your own inspection of plug-in support is that you can maintain better control of your site for visitors who don't have the necessary plug-in yet. Rather than merely providing a link to the plug-in's download site, you can build a more complete interface around the download and installation of the plug-in without losing your visitor. We have some suggestions about such an interface at the end of this discussion.

How you go about inspecting a visitor's plug-in library depends on what information you have about the data file or stream, and how precise you must be in locating a particular plug-in. Some plug-ins may override `mime` type settings that you normally expect to find in a browser. Another issue that complicates matters is that the same plug-in may have a different name (`navigator.plugins[i].name` property), depending on the operating system. Therefore, searching your script for the presence of a plug-in by name is not good enough if the name differs from the Macintosh version to the Windows version. Fortunately, this is less of an issue today than it was in earlier plug-in generations.

One other point that can help you decide the precise approach to take is which information about the plug-in is important to your page and scripts — support for the data `mime` type or the presence of a particular plug-in. If your scripts rely on the existence of a plug-in that you can script via the NPAPI, be sure that the plug-in is present and enabled for the desired `mime` type (so that the plug-in is ensured of loading when it encounters a reference to the URL of the external data). But if you care only that a plug-in of any kind supports your data's `mime` type, you can simply make sure that any plug-in is enabled for your MIME type.

To help you jump-start the process, we discuss three utility functions you can use in your own scripts. These functions are excerpts from a long listing (Listing 42-3), which is located in its entirety with the Chapter 42 listing files on the CD-ROM. The pieces not shown here are merely user interface elements that enable you to experiment with these functions.

Verifying a mime type

Listing 42-3A is a function whose narrow purpose is to determine if the browser currently has plug-in support enabled for a given `mime` type (as a string in the *type/subtype* format). The first `if` construction verifies that there is a `mimeType` object for the supplied `mime` type string. If such an object exists, the next `if` construction determines whether the `enabledPlugin` property of the `mimeType` object returns a valid object. If so, the function returns `true` — meaning that the `mime` type has a plug-in (of unknown supplier) available to play the external media.

LISTING 42-3A

Verifying a MIME Type

```
// Pass "<type>/<subtype>" string to this function to find
// out if the MIME type is registered with this browser
// and that at least some plug-in is enabled for that type.
function mimeIsReady(mime_type)
{
   if (navigator.mimeTypes[mime_type])
   {
      if (navigator.mimeTypes[mime_type].enabledPlugin)
      {
         return true;
      }
   }
   return false;
}
```

Verifying a plug-in

In Listing 42-3B, you let JavaScript see if the browser has a specific plug-in registered in the `navigator.plugins` array. This method approaches the installation question from a different angle. Instead of querying the browser about a known `mime` type, the function inquires about the presence of a known plug-in. But because more than one registered plug-in can support a given `mime` type, this function explores one step further to see whether at least one of the plug-in's `mime` types (of any kind) is enabled in the browser.

LISTING 42-3B

Verifying a Plug-in

```
// Pass the name of a plug-in for this function to see
// if the plug-in is registered with this browser and
// that it is enabled for at least one MIME type of any kind.
function pluginIsReady(plug_in)
{
```

continued

LISTING 42-3B *(continued)*

```
   plug_in = plug_in.toLowerCase();
   for (var i = 0; i < navigator.plugins.length; i++)
   {
      if (navigator.plugins[i].name.toLowerCase().indexOf(plug_in) != -1)
      {
         for (var j = 0; j < navigator.plugins[i].length; j++)
         {
            if (navigator.plugins[i][j].enabledPlugin)
            {
               return true;
            }
         }
         return false;
      }
   }
   return false;
}
```

The parameter for the `pluginIsReady()` function is a string consisting of the plug-in's name. As discussed earlier, the precise name may vary from OS to OS, or from version to version. The function here assumes that you aren't concerned about plug-in versioning. It also assumes (with reasonably good experience behind the assumption) that a brand-name plug-in contains a string with the brand in it. Thus, the `pluginIsRead()` function simply looks for the existence of the passed name within the `plugin` object's `name` property. For example, this function accepts `QuickTime` as a parameter and agrees that there is a match with the plug-in named `QuickTime Plug-in 7.6.5`. The script loops through all registered plug-ins for a substring comparison (converting both strings to all lowercase to help overcome discrepancies in capitalization).

Next comes a second repeat loop, which looks through the `mime` types associated with a plug-in (in this case, only a plug-in whose name contains the parameter string). Notice the use of the strange, double-array syntax for the most nested `if` statement: For a given plug-in (denoted by the `i` index), you have to loop through all items in the `mime` types array (`j`) connected to that plug-in. The conditional phrase for the last `if` statement has an implied comparison against `null`. (See another way of explicitly showing the `null` comparison in Listing 42-3A.) The conditional statement evaluates to either an object or `null`, which JavaScript can accept as `true` or `false`, respectively. The point is that if an enabled plug-in is found for the given `mime` type of the given plug-in, this function returns `true`.

Verifying both plug-in and mime type

The last utility function (Listing 42-3C) is the safest way of determining whether a visitor's browser is equipped with the "right stuff" to play your media. This function requires both a MIME type and a plug-in name as parameters and also makes sure that both items are supported and enabled in the browser before returning `true`.

LISTING 42-3C

Verifying Plug-in and mime Type

```
// Pass "<type>/<subtype>" and plug-in name strings for this
// function to see if both the MIME type and plug-in are
// registered with this browser, and that the plug-in is
// enabled for the desired MIME type.
function mimeAndPluginReady(mime_type,plug_in)
{
   if (mimeIsReady(mime_type))
   {
      var plugInOfRecord = navigator.mimeTypes[mime_type].enabledPlugin;
      plug_in = plug_in.toLowerCase();
      for (var i = 0; i < navigator.plugins.length; i++)
      {
         if (navigator.plugins[i].name.toLowerCase().indexOf(plug_in) != -1)
         {
            if (navigator.plugins[i] == plugInOfRecord)
            {
               return true;
            }
         }
      }
   }
   return false;
}
```

This function starts by calling the `mimeIsReady()` function from Listing 42-3A. After that, the function resembles the one in Listing 42-3B until you reach the most nested statements. Here, instead of looking for any old `mime` type, you insist on the existence of an explicit match between the `mime` type passed as a parameter and an enabled `mime` type associated with the plug-in. To see how these functions work on your NN3+/Moz, MacIE5, or Safari browser, open the complete file (`jsb42-03.html`) from this CD-ROM. The actual listing also includes code that branches around IE for Windows and other browsers that don't support this way of inspecting `mime` types and plug-ins.

Managing manual plug-in installation

If your scripts determine that a visitor does not have the plug-in your data expects, you may want to consider providing an electronic guide to installing the plug-in. One way to do this is to open a new frameset (in the main window). One frame can contain step-by-step instructions with links to the plug-in's download site. The download site's page can appear in the other frame of this temporary window. The steps must take into account all installation requirements for every platform, or, alternatively, you can create a separate installation document for each unique class of platform. For instance, you must frequently decode Macintosh files from binhex format

and then uncompress them before you move them into the plug-ins folder. Some plug-ins have their own, separate installation program. The final step should include a call to

```
navigator.plugins.refresh()
```

to make sure that the browser updates its internal listings. After that, the script can return to the `document.referrer`, which should be the page that sends the visitor to the installation pages. All in all, the process is cumbersome — it's not like downloading a Java applet. But if you provide some guidance, there's a better chance that the user will return to play your cool media. Also consider letting the browser's own updating facilities handle the job (albeit not as smoothly in many cases) by simply loading the data into the page, ready or not.

"Plug-in" detection in WinIE

WinIE4+ provides some built-in facilities that may take the place of plug-in detection in some circumstances. First of all, it's important to recognize that WinIE does not use the term "plug-in" in the same way that Netscape and other browsers use it. Due to the integration between IE and the Windows operating system, WinIE employs system-wide ActiveX controls to handle the job of rendering external content. Some of these controls are designed to be accessed from outside their walls, thus allowing client-side scripts to get and set properties or invoke methods built into the controls. These controls behave a lot like plug-ins, so you frequently see them referenced as "plug-ins," as they are in this book.

WinIE prefers the `<object>` tag for both loading the plug-in (ActiveX control) and assigning external content to it. One of the attributes of the `object` element is `classid`, which points to a monstrously long string of hexadecimal numbers known as the `guid` (Globally Unique Identifier). When the browser encounters one of these `guids`, it looks into the Windows Registry to get the path to the actual plug-in file. If the plug-in is not installed on the user's machine, the object doesn't load, and any other HTML nested inside the `<object>` tag renders instead. Thus, you can display a static image placeholder or HTML message about the lack of the plug-in. But plug-in detection comes in most handy when your scripts need to communicate with the plug-in, such as directing an embedded Windows Media Player plug-in to change sound files or to play. When you build code around a scriptable plug-in, your scripts should make sure that the plug-in object is indeed present so they don't generate errors.

The idea of using the `<object>` tag instead of the older `<embed>` tag is that the `<object>` tag loads a specific plug-in, whereas the `mime` type of the data referenced by the `<embed>` tag lets the browser determine which plug-in to use for that `mime` type. It's not uncommon, therefore, to see an `<object>` tag definition surround an `<embed>` tag — both referencing the same external data file. If the optimum plug-in fails to load, the `<embed>` tag is observed, and the browser tries to find any plug-in for the file's `mime` type. This two-tiered approach to referencing a plug-in is used primarily for backward compatibility with version 4 browsers, whereas pages designed exclusively for modern browsers typically utilize the `<object>` tag alone.

With an `object` element as part of the HTML page, the element itself is a valid object — even if the plug-in fails to load. Therefore, you must do more to validate the existence of the loaded

plug-in than simply test for the existence of the `object` element. To that end, you need to know at least one scriptable property of the plug-in. Unfortunately, not all scriptable plug-ins are fully documented, so you occasionally must perform some detective work to determine which scriptable properties are available. While you're on the search for clues, you can also determine the version of the plug-in and set the minimum version that your `object` element allows to load.

Tracking down plug-in details

Not everyone has access to the Microsoft programming development environments (for example, Visual Studio) through which you can find out all kinds of information about an installed ActiveX control. If you don't have access, you can still dig deep to get most (if not all) of the information you need. The tools you can use include the Windows Registry Editor (`regedit`), The Evaluator, and, of course, your text editor and WinIE4+ browser. The following steps take you through finding out everything you need to know about the Windows Media Player control:

1. If you don't know the `guid` for the Media Player (most people get it by copying someone else's code that employs it), you can use the Registry Editor (`regedit.exe`) to find it. Open the Registry Editor. In Win95/98/NT/XP/Vista, choose Run from the Start menu and enter `regedit`; if that option is not available in your Windows version, search for the file named `regedit`.
2. Expand the `HKEY_CLASSES_ROOT` folder.
3. Scroll down to the nested folder named `CLSID`, and click that folder.
4. Choose Edit/Find, and enter `Windows Media Player`. If you were searching for a different plug-in, you would enter an identifying name (usually the product name) in this place.
5. Keep pressing F3 (Find Next) until the editor lands upon a folder whose default value (in the right side of the Registry Editor window) shows `Windows Media Player`.
6. The number inside curly braces next to the highlighted folder is the plug-in's `guid`. Right-click the number and choose Copy Key Name. Paste the number into your document somewhere for future reference. Eventually, it will be part of the value assigned to the `classid` attribute of the `object` element.
7. Expand the highlighted folder.
8. Click the folder named `InprocServer32`. The default value should show a pathname to the actual ActiveX control for the Windows Media Player plug-in.
9. Right-click the (`Default`) name for the path and choose Modify. The full pathname is visible in an editable field.
10. Armed with this pathname information, open My Computer and locate the actual file inside a directory listing.
11. Right-click the file and choose Properties.
12. Click the Version tab (if present).

13. Copy the version number (generally four sets of numbers delimited by commas), and paste it into your document for future reference. Eventually, it will be assigned to the `codebase` attribute of the `object` element.

    You are now ready to try loading the plug-in as an object and look for properties you can test for.

14. Add an `object` tag to The Evaluator source code. This can go inside the `head` or just before the `</body>` tag. For example, your tag should look something like the following:

```
<object id="wmp" width="1" height="1"
        classid="CLSID:0A4286EA-E355-44FB-8086-AF3DF7645BD9"
        codebase="#Version=10,0,0,3802">
</object>
```

    Copy and paste the numbers for the `guid` and version. Two points to watch out for: First, be sure that the `guid` value is preceded by `CLSID:` in the value assigned to `classid`; second, be sure the version numbers are preceded by the prefix shown.

15. Load (or reload) the page in WinIE4+.

    At this point, the `wmp` object should exist. If the associated plug-in loads successfully, the `wmp` object's properties include properties exposed by the plug-in.

16. Enter `wmp` into the bottom text box to inspect properties of the `wmp` object. Be patient: It may take many seconds for the retrieval of all properties.

    In case you can't readily distinguish between the `object` element object properties and properties of the scriptable plug-in, scroll down to the `wmp.innerHTML` property and its values. When an object loads successfully, any parameters that it accepts are reflected in the `innerHTML` for the `object` element. Each `param` element has a name — the name of one of the scriptable properties of the plug-in.

17. Look for one of the properties that has some kind of value by default (in other words, other than an empty string or `false`). In Windows Media Player, this can be `CreationDate`. Use this property as an object detection condition in scripts that need to access the Windows Media Player properties or methods:

```
if (wmp && wmp.CreationDate)
{
   // statements that "talk to" plug-in
}
```

Setting a minimum version number

The four numbers that you grab in step 13 in the previous section represent the version of the plug-in as installed on your computer. Unless you have a way of verifying that your external content runs on earlier versions of the plug-in (if there are earlier versions), you can safely specify *your* version as the minimum.

Specific rankings for the four numbers of a version decrease as you move from left to right. For example, version 9,0,25,2 is later than 9,0,0,0; version 10,0,0,0 is later than both of them. If you specify 9,0,25,2, and the user has 9,0,24,0 installed, the plug-in does not load, and the

object isn't available for scripting. On the other hand, a user with 9,0,26,0 has the object present because the `codebase` attribute for the version specifies a minimum allowable version to load.

When an object requires VBScript

Not all objects that load via the `object` element are scriptable through JavaScript (or JScript, in this case). Occasionally, an object is designed so that its properties are exposed only to VBScript. This happens, for example, with the Microsoft Windows Media Rights Manager (DRM) object. To find out if the browser (and thus, the operating system) is equipped with DRM, your page loads the object via the `object` element as usual; however, a separate VBScript section must access the object to test for the existence of one of its properties. Because script segments written in either language can access each other, this isn't a problem, provided you know what the property or method is for the object. The following fragment from the `head` section of a document demonstrates how JavaScript and VBScript can interact so that JavaScript code can branch based on the availability of DRM:

```
<head>
   <object id="drmObj" height="1" width="1"
           classid="CLSID:760C4B83-E211-11D2-BF3E-00805FBE84A6"></object>
   <script type="text/vbscript">
      function hasDRM()
         on error resume next
         drmObj.StoreLicense("")
         if (err.number = 0) then
            hasDRM = true
         else
            hasDRM = false
         end if
      end function
   </script>
   <script type="text/javascript">
      var gHasDRM;
         if (drmObj && hasDRM())
         {
            gHasDRM = true;
         }
         else
         {
            gHasDRM = false;
         }
   </script>
</head>
```

The JavaScript segment sets a Boolean global variable to indicate whether the object has loaded correctly. Part of the job is accomplished via the `hasDRM()` function in the VBScript segment. From VBScript, the `drmObj` object responds to the `StoreLicense()` method call, but it throws a VBScript error indicating that no parameter was sent along with the method. Any subsequent scripts in this page can use the `gHasDRM` global variable as a conditional expression before performing any actions requiring the object (which works in tandem with the Windows Media Player).

screen Object

Properties	Methods	Event Handlers
availHeight

fontSmoothingEnabled		
height		
pixelDepth		
updateInterval		
width		

Syntax

Accessing screen object properties:

```
(All)    screen.property
(IE4+)   [window.]navigator.screen.property
```

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

About this object

Browsers other than from the earliest generations provide a `screen` object that lets your scripts inquire about the size and color settings of the video monitor used to display a page. Properties are carefully designed to reveal not only the raw width and height of the monitor (in pixels), but also what the available width and height are once you take into account the operating system's screen-hogging interface elements (for example, the Windows taskbar and the Mac menu bar).

Internet Explorer 4 provides a `screen` object, although it appears as a property of the `window` object in the IE4 through IE6 object model. Only five properties of the IE4-6 `screen` object — `height`, `availHeight`, `width`, `availWidth`, and `colorDepth` — share the same syntax as NN4+'s `screen` object. However, as of IE7 you can now use the NN/Moz approach of accessing the `screen` object without the `window` object, as in `screen.availWidth`.

Properties

`availHeight`
`availWidth`
`height`
`width`

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

With the availability of window sizing methods in modern browsers, your scripts may want to know how large the user's monitor is. This is particularly important if you set up an application to run in kiosk mode, which occupies the entire screen. Two pairs of properties let scripts extract the dimensions of the screen. All dimensions are in pixels.

You can extract the gross height and width of the monitor from the `screen.height` and `screen.width` properties. Thus, a monitor rated as a 1024×768 monitor returns values of 1024 and 768 for `width` and `height`, respectively.

But not every pixel of the screen's gross size is available as displayable area for a window. To the rescue come the `screen.availWidth` and `screen.availHeight` properties. For example, modern Windows operating systems display the taskbar. The default location for this bar is at the bottom of the window, but users can reorient it along any edge of the screen. If the default behavior of always showing the taskbar is in force, the bar uses up real estate available for window display (unless you intentionally size or position a window so that part of the window extends under the bar). When along the top or bottom edge of the screen, the taskbar occupies 28 vertical pixels; when positioned along one of the sides, the bar occupies 60 horizontal pixels. On the Macintosh platform, the 22-pixel-deep menu bar occupies a top strip of the screen. Unlike previous versions, however, Mac OS X does not let you position a window behind the menu bar.

You can use the available screen size values as settings for window properties. For example, to arrange a window so that it occupies all available space on the monitor, you must position the window at the top left of the screen and then set the outer window dimensions to the available sizes, as follows:

```
function maximize()
{
   window.moveTo(0,0);
   window.resizeTo(screen.availWidth, screen.availHeight);
}
```

The preceding function positions a Safari window appropriately on the Macintosh, just below the menu bar, so that the menu bar does not obscure the window. If, however, the client is running Windows and the user positions the taskbar at the top of the screen, the window is partially

hidden under the taskbar (you cannot query the available screen space's coordinates). Also in Windows, the appearance is not exactly the same as a maximized window. See the discussion of the `window.resizeTo()` method in Chapter 27 for more details. Note that MacIE generally returns a value for `screen.availHeight` that is about 24 pixels fewer than the actual available height (even after taking into account the Mac menu bar).

For Navigator 3+ and Mozilla, you can use the NPAPI to access a native Java class that reveals the overall screen size (not the available screen size). If Java is enabled, you can place the following script fragment in the Head portion of your document to set variables with screen width and height:

```
var toolkit = java.awt.Toolkit.getDefaultToolkit();
var screenSize = toolkit.getScreenSize();
```

The `screenSize` variable is an object whose properties (`width` and `height`) contain the pixel measures of the current screen. This NPAPI technique works only in Netscape and Mozilla browsers (IE does not provide direct access to Java classes). In fact, you can also extract the screen resolution (pixels per inch) in the same manner. The following statement, added after the preceding ones, sets the variable resolution to that value:

```
var resolution = toolkit.getScreenResolution();
```

availLeft
availTop

Value: Integer Read-Only

Compatibility: WinIE-, MacIE-, NN4+, Moz+, Safari+, Opera-, Chrome+

The `availLeft` and `availTop` properties return the pixel measure of where the available space of the screen begins. The only time these values are anything other than zero is when a user positions the taskbar along the left or top edges of the screen. For example, if the user positions the taskbar along the top of the screen, you do not want to position a window any higher than the 28 pixels occupied by the taskbar. There are no corresponding properties for IE.

Example

If you are a Windows user, you can experiment with these NN4+/Moz properties via The Evaluator (Chapter 4, "JavaScript Essentials"). With the taskbar at the bottom of the screen, enter these two statements into the top text box:

```
screen.availLeft
screen.availTop
```

Next, drag the taskbar to the top of the screen and try both statements again. Now, drag the taskbar to the left edge of the screen and try the statements once more.

Related Items: `screen.availWidth`, `screen.availHeight` properties; `window.moveTo()` method

bufferDepth

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

By default, IE does not use any offscreen buffering of page content. But adjusting the `bufferDepth` property enables you to turn on offscreen buffering and control the color depth of the buffer. Using offscreen buffering may improve the smoothness of path-oriented animation through positioning.

The default value (buffering turned off) is `0`. By setting the property to `-1`, you instruct IE to set the color depth of the offscreen buffer to the same color depth as the screen (as set in the control panel). This should be the optimum value, but you can also force the offscreen buffer to have one of the following bit depths: `1`, `4`, `8`, `15`, `16`, `24`, or `32`.

Related Items: `screen.colorDepth`, `screen.pixelDepth` properties

colorDepth
pixelDepth

Value: Integer Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz+, Safari+, Opera+, Chrome+

You can design a page with different color models in mind because your scripts can query the client to find out how many colors the user sets the monitor to display. This is helpful if you have more subtle color schemes that require 32-bit color settings, or images tailored to specific palette sizes.

Both the `screen.colorDepth` and `screen.pixelDepth` properties return the number of color bits to which the client computer's video display control panel is set. The `screen.colorDepth` value may take into account a custom color palette; so, for NN4+, you may prefer to rely only on the `screen.pixelDepth` value. (IE4+, however, supports only the `screen.colorDepth` property of this pair.) You can use this value to determine which of two image versions to load, as shown in the following script fragment that runs as the document loads:

```
if (screen.colorDepth > 8 )
{
   document.write("<img src='logoHI.jpg' height='60' width='100' />");
}
else
{
   document.write("<img src='logoLO.jpg' height='60' width='100' />");
}
```

In this example, the `logoHI.jpg` image is designed for 16-bit displays or better, whereas the colors in `logoLO.jpg` are tuned for 8-bit display.

Related Item: `screen.bufferDepth` property

fontSmoothingEnabled

Value: Boolean Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Some versions of the Windows OS have a Display control panel setting for "Smooth Edges" on screen fonts. The `fontSmoothingEnabled` property lets your script see the state of that setting. This setting can affect, for example, which stylesheet you enable because it has font specifications that look good only when smoothing is enabled. A default installation of Windows has this feature turned off.

updateInterval

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `updateInterval` property is the number of milliseconds between screen updates. The default value of zero lets IE arbitrate among the demands for screen updates in a highly animated setting. If you set this value to a large number, more screen updates are accumulated in a buffer — preventing some animated steps from updating the screen.

userProfile Object

Properties	Methods	Event Handlers
	`addReadRequest()`	
	`clearRequest()`	
	`doReadRequest()`	
	`getAttribute()`	

Syntax

Accessing `userProfile` object methods:

```
(IE4+)  [window.]navigator.userProfile.method()
```

Compatibility: WinIE-6, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

About this object

The `userProfile` object is an IE-specific (and Windows, at that) property that acts as the gateway to the user profile information that the client computer collects from the user. You can retrieve none of this information via JavaScript without permission from the user. Access to this information is performed in a strict sequence, part of which enables you to define how the request for this private information is worded when the user is presented with the request. As of IE7, this object no longer appears to be accessible, thereby relegating its usage to IE versions 4 through 6.

User profile data consists of nearly 30 fields of personal information about the user's contact information. Each of these fields has a name, which by and large conforms to the vCard standard. Your scripts can request one or more specific fields from the list, rather than having to deal with the entire set of fields.

The sequence for accessing this data entails four basic steps:

1. Put the request for each vCard field into a queue that is maintained in the browser's memory (via the `addReadRequest()` method).
2. Execute the batch request, which displays a detailed dialog box to the user (via the `doReadRequest()` method). If a user profile is in effect, the user sees which fields you are requesting, plus the data in the vCard. The user then has the chance to deselect one or more of your choices — or to disallow access completely.
3. Get each attribute by name (via the `getAttribute()` method). You invoke this method once for each vCard field.
4. Clear the queue of requests (via the `clearRequest()` method).

Returned values are strings. Thus, you can prefill the customer information for an order form or capture the information in hidden fields that are submitted with a visible form.

Listing 42-4 demonstrates the use of the four key methods of the `userProfile` object. After the page loads, it attempts to extract the data from every vCard field and displays both the attribute name and the value, as associated with the current user profile, in a table. Notice that the names of the attributes are hard-wired because the object does not provide a list of implemented attributes.

LISTING 42-4

Accessing userProfile Data

```

      <script type="text/javascript">
         var attrs = ["Business.City","Business.Country","Business.Fax",
                      "Business.Phone","Business.State",
                      "Business.StreetAddress","Business.URL",
                      "Business.Zipcode","Cellular","Company","Department",
                      "DisplayName","Email","FirstName","Gender","Home.City",vfill
```

continued

LISTING 42-4 *(continued)*

```
                  "Home.Country","Home.Fax","Home.Phone","Home.State",
                  "Home.StreetAddress","Home.Zipcode","Homepage",
                  "JobTitle","LastName","MiddleName","Office","Pager"];
         function loadTable()
         {
            // make sure this executes only in IE4+ for Windows
            if ((navigator.userAgent.indexOf("Win") != -1) && navigator.userProfile)
            {
               var newRow, newCell, attrValue;
               // queue up requests for every vCard attribute
               for (var i = 0; i < attrs.length; i++)
               {
                  navigator.userProfile.addReadRequest("vCard." + attrs[i]);
               }
               // dispatch the request to let user accept or deny access
               navigator.userProfile.doReadRequest(1, "JavaScript Bible");
               // append rows to the table with attribute/value pairs
               for (var j = 0; j < attrs.length; j++)
               {
                  newRow = document.all.attrTable.insertRow(-1);
                  newRow.bgColor = "#FFFF99";
                  newCell = newRow.insertCell(0);
                  newCell.innerText = "vCard." + attrs[j];
                  newCell = newRow.insertCell(1);
                  // get the actual value
                  attrValue = navigator.userProfile.getAttribute
                     ("vCard." + attrs[j]);
                  newCell.innerHTML = (attrValue) ? attrValue : " ";
               }
               // clean up after ourselves
               navigator.userProfile.clearRequest();
            }
            else
            {
               alert("This example requires IE4+ for Windows.");
            }
         }
      </script>
   </head>
   <body onload="loadTable()">
      <h1>userProfile Object</h1>
      <hr />
      <table id="attrTable" border="1" cellpadding="5">
         <tr bgcolor="#CCFFFF">
            <th>vCard Property</th>
            <th>Value</th>
         </tr>
      </table>
   </body>
</html>
```

Note

As handy as it may be, in a strict W3C approach to JavaScript, you wouldn't use the `innerHTML` property since it isn't officially part of the W3C standard. However, it is often too powerful a convenience property to ignore, as much of the code throughout this book is a testament. The book does show the W3C node manipulation alternative to `innerHTML` in some examples. Refer to Chapter 29, "Document and Body Objects," for a thorough explanation and examples of the W3C alternative to `innerHTML`. ■

It appears that the newer the version of Windows that the user runs, the more likely that user profile data is available. Even so, there may be little more than name and address data for those users who are careful not to fill out optional fields of Microsoft web site forms requesting personal information.

Comparable information may be available from NN4+/Moz users on any OS platform, via signed scripts that access `ldap` preferences. See the discussion earlier in this chapter about the `navigator.preference()` method.

Methods

addReadRequest("*attributeName*")

Returns: Boolean

Compatibility: WinIE-6, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Before the user is asked for permission to reveal any personal information, you must queue up requests — even if there is just one field in which you are interested. For each field, use the `addReadRequest()` method and specify a string of the attribute name as the parameter. Acceptable attribute names are as follows:

```
vCard.Business.City
vCard.Business.Country
vCard.Business.Fax
vCard.Business.Phone
vCard.Business.State
vCard.Business.StreetAddress
vCard.Business.URL
vCard.Business.Zipcode
vCard.Cellular
vCard.Company
vCard.Department
vCard.DisplayName
vCard.Email
vCard.FirstName
vCard.Gender
vCard.Home.City
vCard.Home.Country
vCard.Home.Fax
vCard.Home.Phone
vCard.Home.State
```

```
vCard.Home.StreetAddress
vCard.Home.Zipcode
vCard.Homepage
vCard.JobTitle
vCard.LastName
vCard.MiddleName
vCard.Office
vCard.Pager
```

All attribute values are case-insensitive.

This method returns a Boolean value of `true` if the addition to the queue succeeds. A returned value of `false` usually means that the attribute value is not valid or that a request for that attribute name is already in the queue. If you fail to clear the queue after compiling one list of attributes, attempts to read the attribute result in a return value of `false`.

Example

See Listing 42-4 for an example of the `addReadRequest()` method in action. You can also invoke it from the top text box in The Evaluator. For example, enter the following statement to queue one request:

```
navigator.userProfile.addReadRequest("vCard.LastName")
```

To continue the process, see examples for `doReadRequest()` and `getAttribute()` later in this chapter.

Related Items: `clearRequest()`, `doReadRequest()`, and `getAttribute()` methods

clearRequest()

Returns: Nothing

Compatibility: WinIE-6, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

After retrieving the attributes whose names are stacked in the request queue, invoke the `clearRequest()` method to empty the queue. It is always good programming practice to clean up after yourself, especially when security concerns are involved.

Related Items: `addReadRequest()`, `doReadRequest()`, and `getAttribute()` methods

doReadRequest(*reasonCode*, *identification*[, *domain*[, *path*[, *expiration*]]])

Returns: Nothing

Compatibility: WinIE-6, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

Once the names of the desired vCard attributes are stacked in the queue (via the `addReadRequest()` method), invoke the `doReadRequest()` method to prompt the user

for the permission that your scripts need to gain access to the data. The user sees a detailed dialog box that lists the vCard fields you are requesting, as well as a description about your reason for wanting the data and who you are.

The first required parameter is an integer representing one of the standard descriptions as defined by the Internet Privacy Working Group. Associated text is displayed in the permission request dialog box that the user sees. The codes and their strings are as follows:

Code	Description String
0	Used for system administration.
1	Used for research and/or product development.
2	Used for completion and support of current transaction.
3	Used to customize the content and design of a site.
4	Used to improve the content of the site, including advertisements.
5	Used for notifying visitors about updates to the site.
6	Used for contacting visitors for marketing of services or products.
7	Used for linking other collected information.
8	Used by site for other purposes.
9	Disclosed to others for customization or improvement of the content and design of the site.
10	Disclosed to others, who may contact you, for marketing of services and/or products.
11	Disclosed to others, who may contact you, for marketing of services and/or products; you have the opportunity to ask a site not to do this.
12	Disclosed to others for any other purpose.

Although these description strings are fixed, you do have an opportunity to include some customized information in the second parameter. This parameter is intended to enable you to identify the web site or organization requesting the information. Standards recommendations suggest you include a URL to the site as well. In any case, the second parameter can be any string. But it is not treated like HTML, so do not attempt to include a clickable link here.

Two optional parameters enable you to specify a domain and path within that domain for which the user permissions are to apply. Both of these parameters closely mirror their usage in cookies, but they also depend on the capability to set an expiration date via the fifth parameter. Through IE6, however, the expiration date parameter is ignored. Therefore, permissions expire when the user quits the browser (just like temporary cookies do).

Example

See Listing 42-4 for an example of the `doReadRequest()` method in action. If you entered the `addReadRequest()` example for The Evaluator earlier in this chapter, you can now bring up the permissions dialog box (if you have a user profile for your version of Windows) by entering the following statement into the top text box:

```
navigator.userProfile.doReadRequest(1, "Just me!")
```

Related Items: `addReadRequest()`, `clearRequest()`, and `getAttribute()` methods

getAttribute("attributeName")

Returns: String

Compatibility: WinIE-6, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `getAttribute()` method attempts to retrieve the vCard data based on the items queued via the `addReadRequest()` method. A permission dialog box provides the user an opportunity to choose which of the requested items to reveal, or to deny all access to the information. Only one attribute name is permitted as a parameter to the `getAttribute()` method, requiring that you invoke the method for each attribute you want to fetch.

Example

See Listing 42-4 for an example of the `getAttribute()` method in action. Also, if you followed The Evaluator examples for this object, you can now extract the desired information (provided it is in your user profile). Enter the following statement into the top text box:

```
navigator.userProfile.getAttribute("vCard.LastName")
```

Related Items: `addReadRequest()`, `clearRequest()`, and `doReadRequest()` methods

CHAPTER

Positioned Objects

IN THIS CHAPTER

Layer concepts

Moving, hiding, and showing content

Layering objects in the modern DOM

This chapter tackles positioned objects and layers, briefly acknowledging the early contribution that Netscape Navigator 4 made to the subject. Having survived a turbulent time of severe browser compatibility problems in this area, modern browsers have now adopted W3C standards for positioned content. Since current browsers explicitly do not provide backward compatibility with the original NN4 scripted `layerelement` object, this chapter won't do so either.

The modern solution to scripted layering is through Cascading Style Sheets (CSS) and the scripting thereof. This chapter therefore focuses on how to apply CSS and modern DOM techniques to manage positioned elements in modern browsers. When reading and working through this chapter, keep in mind something we pointed out in Chapter 38, "Style Sheet and Style Objects": although defining styles in style sheets is a best practice, if an element object presents a scriptable property that reflects an attribute for that element's tag, the first time a script tries to read that property, a value will be associated with that property *only* if the attribute is explicitly assigned in the HTML code. You'll notice in this chapter's listings, therefore, that we have put the styles we are not manipulating into a style sheet, and the ones we are into `style` attributes.

What Is a Layer?

Terminology in the area of positioned elements has become a bit confusing over time. Because NN4 was the earliest browser to be released with positioned elements (the `layer` element), the term *layer* became synonymous with any positioned element. When IE4 came on the scene, it was convenient to call a stylesheet-positioned element (in other words, an element governed by a stylesheet rule with the `position` attribute) a *layer*, as a

generic term for any positioned element. In fact, NN4 even treated an element that was positioned through style sheets as if it were a genuine layer object (although with some minor differences).

In the end, the layer term made good sense because no matter how it was achieved, a positioned element acted like a layer in front of the body content of a page. Perhaps you have seen how animated cartoons were created before computer animation changed the art. Layers of clear acetate sheets were assembled atop a static background. Each sheet contained one character or portion of a character. When all the sheets were carefully positioned on top of each other, the view (as captured by a still camera) formed a composite frame of the cartoon. To create the next frame of the cartoon, the artist moved one of the layers a fraction of an inch along its intended path and then took another picture.

If you can visualize how that operation works, you have a good starting point for understanding how layers work. Each layer contains some kind of HTML content that exists in its own plane above the main document that loads in a window. You can change or replace the content of an individual layer on-the-fly without affecting the layout of the other layers; you can also reposition, resize, or hide the entire layer under script control.

One aspect of layers that goes beyond the cartoon analogy is the ability to contain other layers. When that happens, any change that affects the primary layer — such as moving the layer 10 pixels downward — also affects the layers nested inside. It's as if the nested layers are passengers of the outer layer. When the outer layer goes somewhere, the passengers do, too. And yet, within the vehicle, the passengers may change seats by moving around without regard for what's going on outside.

With this analogy in mind, many commercial DHTML development tools and content authors refer to positioned elements as layers, which you can move, resize, stack, and hide independently of the body background. Therefore, even though this chapter focuses on style sheet–positioned elements, we'll continue to use the *layer* term in a generic sense.

Positioned Elements in the Modern DOM

Thanks to the tireless efforts of the W3C, modern browsers all share the `style` property of every renderable element object. Most adjustments to the location, layering, size, and visibility of positioned elements use the `style` object associated with each element. Even so, differences still exist between the IE and non-IE browsers with respect to the event objects — how to reference the `event` object and the names of its properties.

Changing element backgrounds

Listing 43-1 demonstrates the syntax and behavior of setting background images through the `style.backgroundImage` property. Note the CSS-style syntax for the URL value assigned to the `style.backgroundImage` property. It's a good lesson to learn that most `style` properties are strings, and their values are in the same format as the values normally assigned in a stylesheet definition.

Removing a background image requires setting the URL to an empty string or `null`. We use an empty string because that will work in all browsers, whereas a `null` will not. Also, a background image overlays whatever color (if any) you assign to the element. If the background image has transparent regions, the background color shows through, as you can see when you click the Not So Usual button. (Try experimenting with different background colors.)

      <h1>Layer Backgrounds</h1>
      <hr />
      <div id="buttons">
         <form>
            <input type="button" value="The Usual"
                   onclick="setBg('cr_kraft.gif')" /><br />
            <input type="button" value="A Big One"
                   onclick="setBg('arch.gif')" /><br />
            <input type="button" value="Not So Usual"
                   onclick="setBg('wh86.gif')" /><br />
            <input type="button" value="Decidedly Unusual"
                   onclick="setBg('sb23.gif')" /><br />
            <input type="button" value="Quick as..."
                   onclick="setBg('lightnin.gif')" />
            <p><input type="button" value="Remove Image"
                      onclick="setBg('')" /><br />
            </p>
```

continued

LISTING 43-1 *(continued)*

```
      </form>
    </div>
    <div id="bgExpo">
      <span id="someText">Some text, which may or
      may not read well with the various backgrounds.</span>
    </div>
  </body>
</html>
```

Note

The property assignment event handling technique employed throughout the code in most of this chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." Listings 43-9 and 43-10, later in the chapter, demonstrate how to use the modern technique to bind and unbind mouse events. ■

Listing 43-2 focuses on background color. A color palette is laid out as a series of rectangles. As the user rolls atop a color in the palette, the color is assigned to the background of the layer. Because of the regularity of the `div` elements generated for the palette, this example uses scripts to write them dynamically to the page as the page loads. This lets the `for` loop handle all the positioning math based on initial values set as global variables.

Perhaps of more interest here than the background color setting is the event handling. First of all, because the target browsers all employ event bubbling, the page lets a single event handler at the document level wait for `mouseover` events to bubble up to the document level. But because the `mouseover` event of every element on the page bubbles there, the event handler must filter the events and process only those on the palette elements.

The `setColor()` method begins by equalizing the IE4+ and W3C DOM event object models. If an object is assigned to the `evt` parameter variable, that means the W3C DOM browser is processing the event; otherwise, it's IE4+ — meaning that the `window.event` object contains the event information. Whichever browser performs the processing, the event object is assigned to the `evt` variable. After verifying that a valid event triggered the function, the next step is to equalize the different, event-model–specific property names for the event's target element. For W3C DOM browsers, the property is `target`, whereas IE4+ uses `srcElement`. The final validation is to check the `className` property of the event's target element. Because all elements acting as palette colors share the same `class` attribute, the `className` property is examined. If the value is `palette`, the `mouseover` event has occurred on one of the colors. Now it's time to extract the target element's `style.backgroundColor` property and assign that color to the same property of the main positioned element.

LISTING 43-2

Layer Background Colors

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Layer Background Colors</title>
      <style type="text/css">
         #display { position:absolute;
                    top:150px; left:80px;
                    width:200px; height:200px;
                    background-color:gray;
                  }
         #someText { font-weight:bold; color:white;
                     text-align:center;
                   }
      </style>
      <script type="text/javascript">
         function setColor(evt)
         {
            evt = (evt) ? evt : (window.event) ? window.event : "";
               if (evt)
               {
                  var elem = (evt.target) ? evt.target : evt.srcElement;
                     if (elem.className == "palette")
                     {
                        document.getElementById("display").style.backgroundColor =
                           elem.style.backgroundColor;
                     }
               }
         }
         document.onmouseover = setColor;
      </script>
   </head>
   <body>
      <h1>Layer Background Colors</h1>
      <hr />
      <script type="text/javascript">
         var oneLayer;
         var colorTop = 100;
         var colorLeft = 20;
         var colorWidth = 40;
         var colorHeight = 40;
         var colorPalette = new Array("aquamarine","coral","forestgreen",
                "goldenrod","red","magenta","navy","teal");
         for (var i = 0; i < colorPalette.length; i++)
         {
           oneLayer = "<div id='swatch" + i + "' class='palette' ";
           oneLayer += "style='position:absolute; top:" + colorTop + "px; ";
```

continued

LISTING 43-2 *(continued)*

```
          oneLayer += "left:" + ((colorWidth * i) + colorLeft) + "px; ";
          oneLayer += "width:" + colorWidth + "px; height:" + colorHeight + "px; ";
          oneLayer += "background-color:" + colorPalette[i] + ";'><\/div>\n";
          document.write(oneLayer);
        }
      </script>
      <div id="display">
        <span id="someText">Some
        reversed text to test against background colors.</span>
      </div>
   </body>
</html>
```

Layer clipping

Working with clipping rectangles is a bit cumbersome using CSS syntax because the object model standard does not provide separate readouts or controls over individual edges of a clipping rectangle. IE5+ enables you to read individual edge dimensions via the `currentStyle` object (for example, `currentStyle.clipTop`), but these properties are read-only.

Based on these limitations, Listing 43-3 is implemented in a way that, for the sake of convenience, preserves the current clipping rectangle edge values as global variables. Any adjustments to individual edge values are first recorded in those variables (in the `setClip()` function), and then the `style.clip` property is assigned the long string of values in the required format (in the `adjustClip()` function). The `showValues()` function reads the variable values and displays updated values after making the necessary calculations for the width and height of the clipping rectangle.

As a demonstration of a “reveal” visual effect (which you can carry out more simply in WinIE4+ via a transition filter), the `revealClip()` function establishes beginning clip values at the midpoints of the width and height of the layer. Then the `setInterval()` method loops through `stepClip()` until the clipping rectangle dimensions match those of the layer.

LISTING 43-3

Adjusting Layer Clip Properties

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Layer Clip</title>
      <style type="text/css">
         #form4clipValues
         {
```

```
         position:absolute; left:10px; top:130px;
      }
      #display
      {
         position:absolute;top:130px; left:220px;
         clip:rect(0px 360px 180px 0px);
         background-color:coral;
      }
   </style>
   <script type="text/javascript">
      var origLayerWidth = 0
      var origLayerHeight = 0
      var currTop, currRight, currBottom, currLeft
      function init()
      {
         origLayerWidth = 360;
         origLayerHeight = 180;
         currTop = 0;
         currRight = origLayerWidth;
         currBottom = origLayerHeight;
         currLeft = 0;
         showValues();
      }

      function setClip(field)
      {
         var val = parseInt(field.value);
         switch (field.name)
         {
            case "top" :
               currTop = val;
               break;
            case "right" :
               currRight = val;
               break;
            case "bottom" :
               currBottom = val;

Listing 43-4 enables you to compare the results of adjusting a clipping rectangle versus the size of a positioned element. This example is interesting in that it enables you to adjust the dimensions of the entire layer (through the `style.left` and `style.right` properties), as well as the right and bottom edges of the clipping rectangle associated with the layer. Additionally, the code includes a function that converts the `style.clip` string into an object representing the rectangle of the clipping rectangle (in other words, with four properties, one for each edge). Values from that `rectangle` object populate two of the fields on the page, providing dynamic readouts of the clipping rectangle's right and bottom edges.

Global variables temporarily store the clipping rectangle values so that the `adjustClip()` function can operate just as it does in Listing 43-3. Note that the clipping rectangle is explicitly defined in the style sheet rule for the positioned element. This is necessary for the element's `style.clip` property to have some values with which to start. Lastly, note the differences in how the different browsers render the results (see Chapter 38, "Style Sheet and Style Objects").

Scripting nested layers

Working with nested layer locations, especially in a cross-browser manner, presents numerous browser-specific syntax problems that need equalization to behave the same to all users. Some discrepancies even appear between Windows and Macintosh versions of IE. (Granted, MacIE is in limited use these days, but it's still worth mentioning the inconsistencies between IE browsers on different platforms.)

The scenario for Listing 43-5 consists of one positioned layer (greenish) nested inside another (reddish). The inner layer is initially sized and positioned so that the outer layer extends 5 pixels in each direction. Text boxes enable you to adjust the coordinates for either layer relative to the entire page, as well as the layer's positioning context. If you make a change to any one value, all the others are recalculated and displayed to show you the effect the change has on other coordinate values.

As you see when you load the page, the outer element's positioning context is the page, so the *page* and *container* coordinates are the same (although the calculations to achieve this equality are not so simple across all browsers). The inner layer's initial page coordinates are to the right and down 5 pixels in each direction, and the coordinates within the container show those 5 pixels.

Because of browser idiosyncrasies, calculating the coordinates within the page takes the most work. The `getGrossOffsetLeft()` and `getGrossOffsetTop()` functions perform those calculations in the page. Passed a reference to the positioned element to be measured, the first number to grab is whatever the browser returns as the `offsetLeft` or `offsetTop` value of the element (see Chapter 26, "Generic HTML Element Objects"). These values are independent of the `style` property, and they can report different values for different browsers. IE, for example, measures the offset with respect to whatever it determines as the next outermost positioning context. Mozilla browsers, on the other hand, treat the page as the positioning context regardless of nesting. So, as long as there is an `offsetParent` element, a `while` loop starts accumulating the `offsetLeft` measures of each succeeding offset parent element going outward from the element. But even before that happens, a correction for MacIE must be accounted for. If there is a difference between the `style.left` and `offsetLeft` property values of an element, that difference is added to the offset. In MacIE5+, for example, failure to correct this results in the page and container values of the outer layer being 10 pixels different in each direction. Values returned from these two gross measures are inserted in the readouts for the page measures of both inner and outer elements.

Reading the coordinates relative to each element's container is easy: The `style.left` and `style.top` properties have the correct values for all browsers. Moving a layer with respect to its positioning context (the container values) is equally easy: assign the entered values to the same `style.left` and `style.top` properties.

Moving the layers with respect to the page coordinate planes (via the `setOuterPage()` and `setInnerPage()` functions) involves going the long way to assign values that take each browser's positioning idiosyncrasies into account. The way you move a positioned element (cross-browser, anyway) is to assign a value to the `style.left` and `style.top` properties. These values are relative to their positioning context, but Mozilla doesn't offer any shortcuts to reveal what element defines the positioning context for a nested element. Calls

to the getNetOffsetLeft() and getNetOffsetTop() functions do the inverse of the getGrossOffsetLeft() and getGrossOffsetTop() functions. Because the values received from the text box are relative to the entire page, the values must have any intervening positioning contexts subtracted from that value in order to achieve the net positioning values that can be applied to the style.left and style.top properties. To get there, however, a call to the getParentLayer() function cuts through the browser-specific implementations of container references to locate the positioning context so that its coordinate values can be subtracted properly. The same kind of correction for MacIE is required here as in the gross offset calculations; but here, the correction is subtracted from the value that eventually is returned as the value for either the style.left or style.top of the layer.

Let us add one quick word about the condition statements of the while constructions in the getNetOffsetLeft() and getNetOffsetTop() functions. You see here a construction not used frequently in this book, but one that is perfectly legal. When the conditional expression evaluates, the getParentLayer() method is invoked, and its returned value is assigned to the elem variable. That expression evaluates to the value returned by the function. As you can see from the getParentLayer() function definition, a value is returned as either an element reference or null. The while condition treats a value of null as false; any reference to an object is treated as true. Thus, the conditional expression does not use a comparison operator, but rather executes some code, and then branches based on the value returned by that code. Mozilla reports JavaScript warnings for this construction because it tries to alert you to a common scripting bug that occurs when you use the = operator when you really mean the == operator. But a warning is not the same as a script error, so don't be concerned when you see these messages in the JavaScript Console window during your debugging.

      </div>
   </div>
  </body>
</html>
```

Try entering a variety of values in all text boxes to see what happens. Here is one possible sequence of tests and explanations:

1. Increase the red Page X value to 250. This moves the outer layer to the right by 50 pixels. Because the green layer is nested inside, it moves along with it. The green Page X value also increases by 50, but its Container X value remains the same because the inner layer maintains the same relationship with the outer layer as before.
2. Increase the green Page X value to 300. This action shifts the position of the green inner layer by 45 pixels, making it a total of 50 pixels inset within its positioning context. Because the outer layer does not have its clipping rectangle set, the inner layer's content bleeds beyond the width of the red layer.
3. Set the green Container Y value to −50. This action moves the green inner layer upward so that its top is 50 pixels above the top of its red container. As a result, the Page Y value of the green inner layer is 80, while the Page Y value of the red outer layer remains at 130 (thus, the 50-pixel difference).

As you experiment with moving the layers around, you may encounter some screen refresh problems where traces of the inner layer remain when moved beyond the outer layer's rectangle. Take these bugs into account when you design the actions of your script-controlled positioning.

Loading external HTML into a layer

A handy approach to loading external HTML content into a layer involves the `iframe` element. This element makes it possible to assign a style sheet rule that absolute-positions the `iframe` precisely on the page where you want it. Be sure to set the `frameborder` attribute to `0` unless you want the border to be visible to the user (and then watch out for content that may overrun the rectangle and cause scrollbars to appear). In this case, you must then leave all the formatting and style sheet control of that content to the HTML loaded into the `iframe`, just as if it were in a separate window or frame. To load different content into the element, assign a different URL to the `src` property of the `iframe` element object.

As an example that more closely simulates the loading of external content into a layer, Listing 43-6 demonstrates a somewhat ugly workaround that lets a layer's background color or image show through some kinds of HTML content.

A hidden `iframe` element is the initial recipient of the external HTML file, as loaded by the `loadOuter()` method. When that file loads, the `transferHTML()` method is invoked to copy the `innerHTML` of just the `body` element of the content window of the `iframe` (note the different syntax for Mozilla — the `contentDocument` property — and IE5.5+ — the `contentWindow` property). By eliminating the `body` element and any tags in the `head`, you prevent the tags in the layer from conflicting with the tags for the main document. As a result, however, notice how the background color you've set for the layer shows through the HTML plugged into the layer.

HTML element objects (other than `iframe`) were not designed to get their content from external files. But, as Listing 43-6 shows, where there is a will there is a way — even if the workaround isn't pretty.

LISTING 43-6

Setting Layer Source Content

</html>
```

Note

As handy as it may be, in a strict W3C approach to JavaScript, you wouldn't use the `innerHTML` property since it isn't officially part of the W3C standard. However, it is often too powerful a convenience property to ignore, as much of the code throughout this book is a testament. The book does show the W3C node manipulation alternative to `innerHTML` in some examples. Refer to Chapter 29, "The Document and Body Objects," for a thorough explanation and examples of the W3C alternative to `innerHTML`. ■

Positioned element visibility behavior

There is very little code in Listing 43-7 because it simply adjusts the `style.visibility` property of an outer layer and a nested, inner layer. You can see that when the page loads, the green inner layer's `visibility` is automatically set to inherit the `visibility` of its containing outer layer. When you click the outer layer buttons, the inner layer blindly follows the settings.

Things change, however, when you start adjusting the properties of the inner layer independently of the outer layer. With the outer layer hidden, you can show the inner layer. Only by setting the `visibility` property of the inner layer to `inherit` can you make it rejoin the outer layer in its behavior.

LISTING 43-7

Nested Layer Visibility Relationships

   </body>
</html>
```

Scripting layer stacking order

Unlike layers in earlier Netscape browsers, the modern W3C DOM does not have properties that reveal the equivalent of the `layerObject.above` or `layerObject.below` properties. Therefore, Listing 43-8 confines itself to enabling you to adjust the `style.zIndex` property values of three overlapping layers. All three layers (none of which are nested inside another) initially set their `zIndex` values to `0`, meaning that the source code order rules the stacking order.

LISTING 43-8

Relationships Among zIndex Values

```

Dragging and resizing a layer

Listing 43-9 shows a script that enables you to click and drag a layer around the screen. The script employs the coordinate values of the `mousemove` event; after compensating for the offset within the layer at which the click occurs, the script moves the layer to track the mouse action.

Note in the following listing how several mouse events are handled. Event bubbling is used so that all mouse events are handled at the document level. Thus, all of the event handlers need to equalize the `event` object and the `event` target element, as well as filter events, so that the action occurs only when a draggable element (as identified by its `className` property) is the target of the event action. Note also how the `mousedown` event is bound for the entire life of the application, whereas the `mouseup` and `mousemove` events are bound and unbound with each new drag operation.

Within the `engage()` function, the `mousedown` event sets a global variable (`draggedElem`) that contains the element being dragged. At the same time, the script records how far away from the layer's top-left corner the `mousedown` event occurred. This offset information is needed so that any setting of the layer's location takes this offset into account (otherwise, the top-left corner of the layer would jump to the cursor position and be dragged from there).

The engage() function is a bit tricky because it must use the two different event and element object models to establish the offset of the mousedown event within the draggable element. For WinIE, this also means taking the scrolling of the body element into account. To get the element to reposition itself with mouse motion, the dragIt() function applies browser-specific coordinate values to the style.left and style.top properties of the draggable element. This function is invoked very frequently in response to the mousemove event.

During the drag (which are mousedown events firing with each mouse movement), the dragIt() function checks whether the drag mode is engaged. If so, the layer is moved to the page location calculated by subtracting the original downstroke offset from the mousemove event location on the page. When the user releases the mouse button, the mouseup event turns off the drag mode by clearing the global dragged element object.

It's worth noting that nothing in this example treats the zIndex stacking order, which must be addressed if the page contains multiple draggable items.

Cross-Reference

See the map puzzle game in Chapter 59, "Application: Cross-Browser DHTML Map Puzzle" (on the CD-ROM) for an example of processing multiple draggable items. ■

      <span class="draggable">Drag me around the window.</span>
   </div>
</body>
</html>
```

Listing 43-10 applies many of the example components used thus far to let scripts control the resizing of a positionable element by dragging the lower-right, 20-pixel region. A lot of the hairy code in the `engage()` function is for determining if the `onmousedown` event occurs in the invisible 20-pixel square.

The `resizeIt()` function resembles the `dragIt()` function of Listing 43-9, but the adjustments are made to the width and height of the positionable element. A fair amount of math determines the width of the element in response to the cursor's instantaneous location and sets the `style.width` and `style.height` properties accordingly.

```

This chapter only scratches the surface of the kinds of positioned element actions you can control with scripts. You may have seen examples of positioned element scripting at sites around the Web. For example, some pages have subject headers fly into place — even bounce around until they settle into position. Or elements can go in circles or spirals to get your attention (or distract you, as the case may be). The authors of those tricks apply formulas from other disciplines (such as games programming) to the `style` object properties of a positioned element.

Sometimes, the effects are there just for the sake of looking cool (at first, anyway) or because the page author knows how to script those effects. Your chief guide in implementing such features, however, should be whether the scripting genuinely adds value to the content offering. If you don't improve the content by adding flying doo-dads or pulsating images, then leave them out. A greater challenge is finding meaningful ways to apply positioning techniques. Done the right way and for the right reason, they can significantly enhance the visitor's enjoyment of your application.

CHAPTER

Embedded Objects

IN THIS CHAPTER

Using applet and embed element objects

Exploring the object element object

Understanding the unusual param element

In addition to the typical content that you see in web pages — primarily text and images — you can embed other kinds of content into the page. Such embedded content usually requires the powers of additional software, such as plug-in players or other external code processors, to load and display the content. Historically, all of this external content has been added to web pages by one of three HTML elements: `applet`, `embed`, or `object`. In the HTML 4.0 standard, the `applet` element, which was intended originally for loading Java applets, is deprecated in favor of the newer `object` element. That has not stopped modern browser makers from supporting the `applet` element (which they must for backward compatibility anyway), and even Java's maker recommends continued use of the `applet` element for loading applets over the Internet.

A similar standards trend exists for the `embed` element, which, in theory anyway, may ultimately be replaced exclusively by the `object` element. Mozilla browsers, however, prefer that embedded content requiring plug-ins (such as Flash content) be loaded through an `embed` element.

An `object` element is intended to be more extensible than `applet` and `embed`, meaning that it has enough attributes and power to summon the Java virtual machine if the incoming code is a Java applet, or to run an ActiveX program (in Internet Explorer for Windows, that is). In time, the `object` element may be the primary element for this kind of content, but for now it is the preferred approach for Internet Explorer and WebKit-based browsers.

It is possible to combine support for both the `object` and `embed` elements in one chunk of source code, and let the browser deploy the version itknows best. By nesting an `embed` element within an `object` element, you can cover both worlds easily, as in the following example:

```
<object width="425" height="350">
    <param name="movie" value="http://www.example.com/vid/2bq"></param>
    <embed src="http://www.example.com/vid/2bq"
          type="application/x-shockwave-flash" width="425" height="350">
    </embed>
</object>
```

In all cases, when a visual object is embedded through any of these elements, the control panel or applet occupies a segregated rectangular space on the page and generally confines its activities to that rectangle. But in some browsers and plug-in player types, JavaScript can also interact with the content or the player, allowing your scripts to extend themselves with powers for actions, such as controlling audio playback or the operation of a Java applet. Don't expect universal browser support for controlling plug-ins.

This chapter's primary focus is not on the content and players that you can control, but on the HTML element objects that load the content or players into the page in the first place. Most of the properties represent nothing more than scriptable access to the element HTML attributes. The property descriptions in this chapter are therefore not extensive. Online HTML references (including the W3C HTML 4.01 and the upcoming HTML5 specifications, and the Microsoft Developer Network documentation) should fill in the attribute value information quite well. In practice, scripts have very little interaction with these element objects, but if you ever need to know what's scriptable, you'll find that information here. As for controlling applets and plug-ins, you can find information about that in Chapter 47, "Scripting Java Applets and Plugs-Ins" (on the CD-ROM).

applet Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
`align`	(Applet methods)	`oncellchange`
`alt`		`ondataavailable`
`altHTML`		`ondatasetchanged`
`archive`		`ondatasetcomplete`
`code`		`onload`
`codebase`		`onrowenter`
`height`		`onrowexit`
`hspace`		`onrowsdelete`
`name`		`onrowsinserted`

Properties	Methods	Event Handlers
object		onscroll
vspace		
width		
(Applet variables)		

Syntax

Accessing applet element object properties or methods:

```
(NN3+/IE4+)    [window.]document.appletName.property | method([parameters])
(NN3+/IE4+)    [window.]document.applets[index].property | method([parameters])
(IE4+)         [window.]document.all.appletID.property | method([parameters])
(IE5+/W3C)     [window.]document.getElementById("appletID").property |
               method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

The fact that the applet itself can expose public instance variables and public methods as properties and methods of the applet object means that the scriptable characteristics of an applet object are highly dependent upon the way the applet was written. You can learn more about how to compose an applet that exposes its innards to JavaScript in Chapter 47.

Perhaps the most important point to remember about accessing applets is that you must have them loaded and running before you can address them as objects. Although you cannot query an applet to find out whether it's loaded (as you can with an image), you can rely on the onload event handler of a window to fire only when all applets in the window are loaded and running. Internet Explorer also features an onload event handler for the applet element directly, but applets tend to be the last things to load on a page. Therefore, you won't be able to use an applet embedded in a document to help you create the HTML content of that page as it loads. But an applet can provide content for new documents or for modifiable elements of a page. With the highly dynamic object models of modern browsers, this can lead to all kinds of possibilities.

Java applets have also been used to maintain contact with a server after the page has loaded by way of a servlet running on the server. A servlet allows the applet to query or be refreshed with instantaneously updated information without having to reload the page. Of course, getting a sophisticated applet to run in a wide range of browsers and operating systems is a challenge unto itself.

A large set of event handlers for this element (all but onload and onscroll) is related to the application of WinIE data binding for param elements nested inside an applet element. These events fire when a variety of actions occur to the data source or recordset associated with the applet. For more about applying data binding, see http://msdn.microsoft.com/en-us/library/ms531385%28VS.85%29.aspx.

Properties

`align`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `align` property controls either the horizontal or vertical alignment of the element with regard to surrounding content. String values of `left` or `right` cause the applet rectangle to cling to the left or right edges of its immediate positioning context. String values of `absbottom`, `absmiddle`, `baseline`, `bottom`, `middle`, `texttop`, or `top` influence the vertical alignment with respect to adjacent text, with the same kinds of results as corresponding values of the `style.verticalAlign` property.

Keep in mind that CSS alignment properties offer a more standards-compliant way to align applets. Then again, since the `applet` element is itself deprecated, using it at all runs against the grain of web standards (HTML 4+). Chapter 47 shows you how to resolve the deprecation problem and use the `object` element instead of the `applet` element to embed applets in pages.

Related Items: `style.verticalAlign` property

`alt`

Value: String Read/Write

Compatibility: WinIE6+, MacIE6+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `alt` property represents the `alt` attribute, which should contain text that displays in the browser in the event that the applet does not load or the user has Java turned off in the browser preferences. This information should be set as the `applet` element's attribute, because assigning text to the property after the applet attempts to load does not insert the text into the page.

Related Items: `altHTML` property

`altHTML`

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `altHTML` property is supposed to provide an `applet` element with HTML content to render if the applet doesn't load. In practice, assigning an HTML string to this property has no effect on an `applet` element.

Related Items: `alt` property

`archive`

Value: String Read/Write

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `archive` property represents the `archive` attribute, which points to the URL of a compressed (`.zip`) file containing Java class files needed for the applet. The archive must include the class file that is assigned to the `code` attribute to get the applet loaded and started.

Related Items: `code` property

code

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `code` property is the URL string of the Java class file that is to begin loading the applet (or the property may be the entire applet if it consists of a single class file). You cannot change the code assigned to an applet after the element has loaded (even if the applet code did not load successfully).

Related Items: `codeBase` property

codeBase

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `codeBase` property is the string of the path on the server to the Java class file that is to begin loading the applet (or the property may be the entire applet if it consists of a single class file). The actual Java class filename is not part of the `codeBase` property.

Related Items: `code` property

height
width

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `height` and `width` properties represent the `height` and `width` attributes of the `applet` element. Although these values should be set through attributes in the tag, these properties can adjust the size of the applet after the fact in IE5+.

Related Items: `hspace`, `vspace` properties

hspace
vspace

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `hspace` and `vspace` properties represent the `hspace` and `vspace` attributes of the `applet` element, which control the number of pixels of transparent padding around the `applet` element

on the page. Although these values should be set through attributes in the tag, these properties can adjust the size of the applet padding after the fact in IE5+.

Related Items: `height`, `width` properties

name

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `name` property represents the `name` attribute, a holdover from the early implementations of the `applet` element before `id` attributes were used to identify elements. The value assigned to the `name` attribute is the name you can use to reference applets in all browsers that support accessing applets: `document.appletName`.

object

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `object` property represents the `object` attribute, which, according to the W3C HTML standard, points to the URL of a serialized (that is, saved) version of the applet's current state.

Related Items: `code` property

vspace

(See `hspace`)

width

(See `height`)

object Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
`align`	(Object methods)	`oncellchange`
`alt`		`ondataavailable`
`altHTML`		`ondatasetchanged`
`archive`		`ondatasetcomplete`
`baseHref`		`onload`
`baseURI`		`onrowenter`

Properties	Methods	Event Handlers
border		onrowexit
classid		onrowsdelete
code		onrowsinserted
codeBase		onscroll

width		
(Object variables)		

Syntax

Accessing `object` element object properties or methods:

```
(IE4+)        [window.]document.all.objectID.property | method([parameters])
(IE5+/W3C)    [window.]document.getElementById("objectID").property |
              method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

About this object

The `object` element is intended to be the primary way to add external content (that is, content that the browser itself does not render) to a page. For example, Flash animations created with

Macromedia Flash are inserted into pages through the `object` element. The `object` element is also intended to replace usage of the `applet` and `embed` elements.

As with the `applet` element object, scripts can frequently control the programs and plug-ins that get loaded into the browser through the `object` tag. Chapter 47 shows you how to do that for common objects. The property listings here are merely for the properties of the element, most of which mimic the attributes available for the `object` element. Even though the properties are exposed, they are very rarely scripted, except perhaps to adjust the size of the space occupied by a media controller. Most properties are read-only after their values are set by attributes in the element's tag. But if your scripts are creating the `object` element anew, you can set the property values the first time to initialize the object.

Properties

align

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, FF+, Safari+, Opera+, Chrome+

The `align` property controls either the horizontal or vertical alignment of the element with regard to surrounding content. String values of `left` or `right` cause the object rectangle to cling to the left or right edges of its immediate positioning context. String values of `absbottom`, `absmiddle`, `baseline`, `bottom`, `middle`, `texttop`, or `top` influence the vertical alignment with respect to adjacent text, with the same kinds of results as corresponding values of the `style.verticalAlign` property.

Related Items: `style.verticalAlign` property

alt

Value: String Read/Write

Compatibility: WinIE6+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `alt` property represents the `alt` attribute, which should contain text that displays in the browser in the event that the object or its data do not load. This information should be set as the `object` element's attribute, because assigning text to the property after the object attempts to load does not insert the text into the page.

Related Items: `altHTML` property

altHTML

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `altHTML` property is supposed to provide an `object` element with HTML content to render if the object doesn't load. In practice, assigning an HTML string to this property has no effect on an `object` element.

Related Items: `alt` property

archive

Value: URI list as string Read/Write

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `archive` property is used to specify one or more URIs for archives that contain resources associated with the object. If more than one URI is provided in the `archive` property, just separate them by a space. Although the property is implemented in the preceding browser versions (that is, you won't get script errors if you read or write its value), most browsers do not respond to changes of property values.

Related Items: `code`, `codeBase` properties

baseHref

Value: String Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `baseHref` property returns the full URL path to the current document.

Related Items: `baseURI` property

baseURI

Value: String Read-Only

Compatibility: WinIE-, MacIE-, NN7+, Moz+, Safari+, Opera+, Chrome+

The `baseURI` property returns the full URL (URI) path to the current document.

Related Items: `baseHref` property

border

Value: Number as string Read/Write

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `border` property controls the thickness of the border around the object, in pixels. You must specify the border thickness as a string, as in `"6"` for six pixels.

classid

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `classid` property represents the `classid` attribute of the `object` element. Internet Explorer for Windows uses this attribute to assign the Globally Unique ID (GUID) of an ActiveX control. For example, to load a (nearly) invisible Windows Media Player object into a page, the HTML is as follows:

```
<object id="medPlayer" width="1" height="1"
        classid="CLSID:22d6f312-b0f6-11d0-94ab-0080c74c7e95"
        codebase="#Version=1,0,0,0">
```

If your script then accesses the `classid` property of the `medPlayer` object, the value returned is the complete string, as assigned to the attribute:

```
CLSID:22d6f312-b0f6-11d0-94ab-0080c74c7e95
```

Note that the `CLSID:` prefix is also part of the string value. Even if the object does not load (for example, because the object is missing or an error is in the long `classid` string), the property value reports the value as assigned to the attribute.

The HTML 4.0 specification indicates that the `classid` attribute be used for any kind of external class files, including Java applets. But in practice, Internet Explorer wants applet URLs supplied to the `code` attribute (a non-HTML attribute).

Related Items: `code` property

code

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `code` property is the URL string of a Java class file that is to begin loading the applet (or the property may be the entire applet if it consists of a single class file). You cannot change the code assigned to an applet after the element has loaded (even if the applet code did not load successfully).

Related Items: `codeBase` property

codeBase

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `codeBase` property is the string of the path on the server to the source of the applet or ActiveX control referenced by the `classid` or `code` attributes. IE4+ also uses the `codebase` attribute to specify a minimum version of control that is to load, if the attribute is available. This facet is discussed in the coverage of plug-in detection for WinIE in Chapter 42, “The Navigator and Other Environment Objects.”

Related Items: `code` property

codeType

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `codeType` property is a string of the `mime` type of whatever object is pointed to by the `code` attribute value.

Related Items: `type` property

contentDocument

Value: Document node reference Read-Only

Compatibility: WinIE-, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `contentDocument` property returns the document node created by the object, if it exists.

data

Value: URL as string Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `data` property provides access to the URL of a file containing data for the object, as opposed to the object itself.

declare

Value: Boolean Read/Write

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `declare` property is used to indicate that an object is a declaration and not a definition. In other words, a declared object doesn't actually appear on the page — it must be instantiated by an additional object definition. Although the property is implemented in the preceding browser versions (that is, you won't get script errors if you read or write its value), most browsers do not respond to changes of property values.

form

Value: Object reference Read-Only

Compatibility: WinIE4+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

The `form` property returns a reference to the `form` element that contains the object, if there is one. This property only applies if the object is acting as a control within a form.

height
width

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `height` and `width` properties represent the `height` and `width` attributes of the `object` element. Although these values should be set through attributes in the tag, these properties can adjust the size of the embedded element after the fact in IE5+.

Related Items: `hspace`, `vspace` properties

hspace
vspace

Value: Integer — Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `hspace` and `vspace` properties represent the `hspace` and `vspace` attributes of the `object` element; these attributes control the number of pixels of transparent padding around the `object` element on the page. Although these values should be set through attributes in the tag, these properties can adjust the size of the padding around the element after the fact in IE5+.

Related Items: `height`, `width` properties

name

Value: String — Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `name` property represents the `name` attribute of the `object` element. It's better form to assign an `id` to the `object` element and use accepted reference syntax for element IDs.

object

Value: External object — Read-Only

Compatibility: WinIE4+, MacIE4+, NN-, Moz-, Safari-, Opera-, Chrome-

The `object` property returns a reference to the object contained by the `object` element. This property is essential if the program running inside the `object` element has the same property or method names as the `object` element itself. For example, consider a Java applet loaded into the `object` element, as follows:

```
<object code="coolApplet" id="myAPPLET" ... >
```

If the applet code contained a public variable called `height`, an attempt to read or write that property through the `object` element will cause the element's properties to be read, and not the applet's properties. Therefore, if you insert the `object` property in the reference, the script reaches into the `applet` object for the property:

```
document.getElementById("myAPPLET").object.height = 40;
```

If there is no ambiguity between element and object property and method names, the browser looks first at the element and then at the object to find a match.

standby

Value: String Read/Write

Compatibility: WinIE6+, MacIE5, NN6+, Moz+, Safari+, Opera+, Chrome+

The `standby` property enables you to set a text message that appears while an object is loading. By setting the `standby` property to a message, such as "Object loading . . . ," you provide the user with a visual cue for why the object hasn't yet sprung to life. Although the property is implemented in the preceding browser versions (that is, you won't get script errors if you read or write its value), most browsers do not respond to changes of property values.

type

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+, Opera+, Chrome+

The `type` property represents the `type` attribute of the `object` element, which is intended to warn the browser about the `mime` type of data that is to be loaded into the object's process.

Related Items: `codeType` property

useMap

Value: String Read/Write

Compatibility: WinIE6+, MacIE-, NN6+, Moz+, Safari+, Opera+, Chrome+

The `useMap` property identifies the URL of an image map; the image map is described by the `map` element in the same document. The value of the `useMap` property includes a hash mark followed by the name of the image map, as specified in the `usemap` attribute of the `object` element.

vspace

(See `hspace`)

width

(See `height`)

embed Element Object

For HTML element properties, methods, and event handlers, see Chapter 26, "Generic HTML Element Objects."

Properties	Methods	Event Handlers
align	(Object methods)	onload
height		onscroll
hidden		
name		
pluginspage		
src		
units		
width		
(Object variables)		

Syntax

Accessing embed element object properties or methods:

```
(IE4+)        [window.]document.all.objectID.property | method([parameters])
(IE5+/W3C)    [window.]document.getElementById("objectID").property |
              method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN3+, Moz+, Safari+, Opera+, Chrome+

About this object

The embed element is a carryover from the early browser days, although it will probably be adopted by the W3C HTML standard as part of HTML5. The embed element has been used as a way to embed non-native content (for example, sounds, video clips, and custom mime types for plug-ins, such as Shockwave) into a page. What gets embedded into the page is the controller or viewer for whatever kind of data the embed element points to (through the src attribute).

The embed element is far less sophisticated than the object element, but current browsers continue to support it. If you have been using the embed element in previous applications, it may be a good idea to start gravitating toward the object element. For backward-compatibility purposes, nesting an embed element inside an object element is not uncommon, since both attempt to load the same content and plug-in. Browsers that know about the object element will load the content that way; older browsers will use the embed element and its attributes and parameters.

Because an `embed` element loads a plug-in (including ActiveX control types of plug-ins in WinIE), you could reference the plug-in's properties and methods through the `embed` object's reference, even if the browser has disabled scripting. Be aware that most browsers will alert the visitor if there is an attempt to use these properties and methods, giving the visitor the opportunity to cancel the activity.

Properties

align

Value: String Read/Write

Compatibility: WinIE-, MacIE5+, NN6+, Moz+, Safari+-, Opera+, Chrome+

The `align` property controls either the horizontal or vertical alignment of the element with regard to surrounding content. String values of `left` or `right` cause the object rectangle to cling to the left or right edges of its next outermost positioning context. String values of `absbottom`, `absmiddle`, `baseline`, `bottom`, `middle`, `texttop`, or `top` influence the vertical alignment with respect to adjacent text, with the same kinds of results as corresponding values of the `style.verticalAlign` property.

Related Items: `style.verticalAlign` property

height
width

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari-, Opera+, Chrome+

The `height` and `width` properties represent the `height` and `width` attributes of the `embed` element. Although these values should be set through attributes in the tag, these properties can adjust the size of the element after the fact in IE5+.

hidden

Value: Boolean Read/Write

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `hidden` property represents the `hidden` attribute of the `embed` element. When an `embed` element is hidden, neither the controller nor the content is shown. Application of this element in modern browsers should use style sheets to hide and show the element.

Related Items: `style.visibility` property

`name`

Value: String | Read-Only

Compatibility: WinIE4+, MacIE4+, NN6+, Moz+, Safari+-, Opera+, Chrome+

The `name` property represents the `name` attribute of the `embed` element. It's better form to assign an `id` to the `embed` element and use accepted reference syntax for element IDs.

`pluginspage`

Value: String | Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `pluginspage` property represents the `pluginspage` attribute of the `embed` element. This attribute is a URL that is applied to a link in the browser if the plug-in associated with the external file's `mime` type cannot be found on the client.

`src`

Value: String | Read/Write

Compatibility: WinIE4+, MacIE-, NN-, Moz-, FF+, Safari+, Opera+, Chrome+

The `src` property represents the `src` attribute of the `embed` element. This attribute points to the external file that is to be loaded into the browser through the associated plug-in. Scripts can assign a new URL string to this property to load a different file into the current plug-in.

`units`

Value: String | Read-Only

Compatibility: WinIE4+, MacIE-, NN-, Moz-, Safari-, Opera-, Chrome-

The `units` property returns the unit of measure assigned with the length value of the `height` and `width` properties, in pixels.

Related Items: `height`, `width` properties

The Odd Case of the param Element

HTML pages pass parameters to Java applets, plug-ins, and ActiveX controls by way of `param` elements that are nested inside `applet`, `embed`, and `object` elements. Although a `param` element object is defined by the W3C DOM Level 2 specification, it does not show up on some

browsers' radar when you try to reference the `param` element by itself. Even assigning an `id` to a `param` element or using `document.getElementsByTagName("param")` fail to allow references to access an individual `param` element object.

In practice, this limitation is not particularly important. For one thing, even if you could access the `param` elements of an embedded object or program, attempts to modify the values would be wasted: Those values are read at load time only. Secondly, a well-designed plug-in, applet, or ActiveX control will provide its own properties or methods to retrieve the current settings of whatever properties are initialized through the `param` elements.

CHAPTER

The Regular Expression and RegExp Objects

IN THIS CHAPTER

What regular expressions are

How to use regular expressions for text search-and-replace

How to apply regular expressions to string object methods

Web programmers who have worked in Perl (and other web application programming languages) know the power of regular expressions for processing incoming data, and formatting it for readability in an HTML page or for accurate storage in a server database. Any task that requires extensive search and replacement of text can greatly benefit from the flexibility and conciseness of regular expressions.

Most of the benefit of JavaScript regular expressions accrues to those who script their server-side programs on servers that support a JavaScript version that contains regular expressions. But that's not to exclude the client-side from application of this "language within a language." If your scripts perform client-side data validations or any other extensive text entry parsing, consider using regular expressions rather than cobbling together comparatively complex JavaScript functions to perform the same tasks.

Regular Expressions and Patterns

In several chapters earlier in this book, we describe expressions as any sequence of identifiers, keywords, and/or operators that evaluate to some value. A regular expression follows that description, but has much more power behind it. In essence, a regular expression uses a sequence of characters and symbols to define a pattern of text. Such a pattern is used to locate a chunk of text in a string by matching up the pattern against the characters in the string.

An experienced JavaScript writer may point out the availability of the `string.indexOf()` and `string.lastIndexOf()` methods that can instantly reveal whether a string contains a substring, and even where in the

string that substring begins. These methods work perfectly well when the match is exact, character for character. But if you want to do more sophisticated matching (for example, does the string contain a five-digit ZIP code?), you'd have to cast aside those handy string methods and write some parsing functions. That's the beauty of a regular expression: It lets you define a matching substring that has some intelligence about it and can follow guidelines you set as to what should or should not match.

The simplest kind of regular expression pattern is the same kind you use in the `string.indexOf()` method. Such a pattern is nothing more than the text that you want to match. In JavaScript, one way to create a regular expression is to surround the expression by forward slashes. For example, consider the string

```
Oh, hello, do you want to play Othello in the school play?
```

This string and others may be examined by a script whose job it is to turn formal terms into informal ones. Therefore, one of its tasks is to replace the word "hello" with "hi." A typical brute force search-and-replace function starts with a simple search string pattern. In JavaScript, you define a pattern (a regular expression) by surrounding it with forward slashes. For convenience and readability, we usually assign the regular expression to a variable, as in the following example:

```
var myRegExpression = /hello/;
```

In concert with some regular expression or string object methods, this pattern matches the string "hello" wherever that series of letters appears. The problem is that this simple pattern causes problems during the loop that searches and replaces the strings in the example string: It finds not only the standalone word "hello," but also the "hello" in "Othello."

Trying to write another brute force routine for this search-and-replace operation that looks only for standalone words would be a nightmare. You can't merely extend the simple pattern to include spaces on either or both sides of "hello," because there could be punctuation — a comma, a dash, a colon, or whatever — before or after the letters. Fortunately, regular expressions provide a shortcut way to specify general characteristics, including a feature known as a word boundary. The symbol for a word boundary is `\b` (backslash, lowercase b). If you redefine the pattern to include these specifications on both ends of the text to match, the regular expression creation statement looks like this:

```
var myRegExpression = /\bhello\b/;
```

When JavaScript uses this regular expression as a parameter in a special string object method that performs search-and-replace operations, it changes only the standalone word "hello" to "hi," and passes over "Othello" entirely.

If you are still learning JavaScript and don't have experience with regular expressions in other languages, you have a price to pay for this power: Learning the regular expression lingo, which is filled with so many symbols that expressions sometimes look like cartoon substitutions for swear words. The goal of this chapter is to introduce you to regular expression syntax as implemented in JavaScript rather than engage in lengthy tutorials on it. Of more importance in the long run, is understanding how JavaScript treats regular expressions as objects, and distinctions between

instances of regular expression objects and the `RegExp` static object. We hope the examples in the following sections begin to reveal the powers of regular expressions.

Language Basics

To cover the depth of the regular expression syntax, we divide the subject into three sections. The first covers simple expressions (some of which you've already seen). Then we get into the wide range of special characters used to define specifications for search strings. Last comes an introduction to using parentheses in the language, and how they not only help in grouping expressions for influencing calculation precedence (as they do for regular math expressions), but also how they temporarily store intermediate results of more complex expressions for use in reconstructing strings after their dissection by the regular expression.

Simple patterns

A simple regular expression uses no special characters for defining the string to be used in a search. Therefore, if you want to replace every space in a string with an underscore character, the simple pattern to match the space character is

```
var re = / /;
```

A space appears between the regular expression start and end forward slashes. The problem with this expression, however, is that it knows only how to find a single instance of a space in a long string. Regular expressions can be instructed to apply the matching string on a global basis by appending the `g` modifier:

```
var re = / /g;
```

When this `re` value is supplied as a parameter to the `replace()` method that uses regular expressions (described later in this chapter), the replacement is performed throughout the entire string, rather than just once on the first match found. Notice that the modifier appears after the final forward slash of the regular expression creation statement.

Regular expression matching — like a lot of other aspects of JavaScript — is case-sensitive. But you can override this behavior by using one other modifier (`i`) that lets you specify a case-insensitive match. Therefore, the following expression

```
var re = /web/i;
```

finds a match for "web," "Web," or any combination of uppercase and lowercase letters in the word. You can combine the two modifiers together at the end of a regular expression. For example, the following expression is both case-insensitive and global in scope:

```
var re = /web/gi;
```

In compliance with the ECMA-262 Edition 3 standard, modern browsers also allow a flag to force the regular expression to treat carriage-return-delimited lines of a multiline string as separate substrings with their own start and end boundaries. That modifier is the letter `m`.

Special characters

The regular expression in JavaScript borrows most of its vocabulary from the Perl regular expression. In a few instances, JavaScript offers alternatives to simplify the syntax, but also accepts the Perl version for those with experience in that arena.

Significant programming power comes from the way regular expressions allow you to include terse specifications about such facets as types of characters to accept in a match, how the characters are surrounded within a string, and how often a type of character can appear in the matching string. A series of escaped one-character commands (that is, letters preceded by the backslash) handle most of the character issues; punctuation and grouping symbols help define issues of frequency and range.

You saw an example earlier how `\b` specified a word boundary on one side of a search string. Table 45-1 lists the escaped character specifiers in JavaScript regular expressions. The vocabulary forms part of what are known as metacharacters — characters in expressions that are not matchable characters themselves, but act more as commands or guidelines of the regular expression language.

TABLE 45-1

JavaScript Regular Expression Matching Metacharacters

Character	Matches	Example
`\b`	Word boundary	`/\bor/` matches "origami" and "or" but not "normal" `/or\b/` matches "traitor" and "or" but not "perform" `/\bor\b/` matches full word "or" and nothing else
`\B`	Word non-boundary	`/\Bor/` matches "normal" but not "origami" `/or\B/` matches "normal" and "origami" but not "traitor" `/\Bor\B/` matches "normal" but not "origami" or "traitor"
`\d`	Numeral 0 through 9	`/\d\d\d/` matches "212" and "415" but not "B17"
`\D`	Non-numeral	`/\D\D\D/` matches "ABC" but not "212" or "B17"
`\s`	Single white space	`/over\sbite/` matches "over bite" but not "overbite" or "over bite"
`\S`	Single non-white space	`/over\Sbite/` matches "over-bite" but not "overbite" or "over bite"
`\w`	Letter, numeral, or underscore	`/A\w/` matches "A1" and "AA" but not "A+"
`\W`	Not letter, numeral, or underscore	`/A\W/` matches "A+" but not "A1" and "AA"
`.`	Any character except newline	`/.../` matches "ABC", "1+3", "A 3", or any three characters
`[...]`	Character set	`/[AN]BC/` matches "ABC" and "NBC" but not "BBC"
`[^...]`	Negated character set	`/[^AN]BC/` matches "BBC" and "CBC" but not "ABC" or "NBC"

Not to be confused with the metacharacters listed in Table 45-1, are the escaped string characters for tab (\t), newline (\n), carriage return (\r), formfeed (\f), and vertical tab (\v).

Let us further clarify the use of the [...] and [^...] metacharacters. You can specify either individual characters between the brackets (as shown in Table 45-1) or a contiguous range of characters, or both. For example, the \d metacharacter can also be defined by [0-9], meaning any numeral from zero through nine. If you only want to accept a value of 2 and a range from 6 through 8, the specification would be [26-8]. Similarly, the accommodating \w metacharacter is defined as [A-Za-z0-9_], reminding you of the case-sensitivity of regular expression matches not otherwise modified.

All but the bracketed character set items listed in Table 45-1 apply to a single character in the regular expression. In most cases, however, you cannot predict how incoming data will be formatted — the length of a word or the number of digits in a number. A batch of extra metacharacters lets you set the frequency of the occurrence of either a specific character or a type of character (specified like the ones in Table 45-1). If you have experience in command-line operating systems, you can see that some of the same ideas that apply to wildcards also apply to regular expressions. Table 45-2 lists the counting metacharacters in JavaScript regular expressions.

TABLE 45-2

JavaScript Regular Expression Counting Metacharacters

Character	Matches Last Character	Example
*	Zero or more times	/Ja*vaScript/ matches "JvaScript", "JavaScript", and "JaaavaScript" but not "JovaScript"
?	Zero or one time	/Ja?vaScript/ matches "JvaScript" or "JavaScript" but not "JaaavaScript"
+	One or more times	/Ja+vaScript/ matches "JavaScript" or "JaavaScript" but not "JvaScript"
{n}	Exactly n times	/Ja{2}vaScript/ matches "JaavaScript" but not "JvaScript" or "JavaScript"
{n,}	n or more times	/Ja{2,}vaScript/ matches "JaavaScript" or "JaaavaScript" but not "JavaScript"
{n,m}	At least n, at most m times	/Ja{2,3}vaScript/ matches "JaavaScript" or "JaaavaScript" but not "JavaScript"

Every metacharacter in Table 45-2 applies to the character immediately preceding it in the regular expression. Preceding characters may also be matching metacharacters from Table 45-1. For example, a match occurs for the following expression if the string contains two digits separated by one or more vowels:

```
/\d[aeiouy]+\d/
```

The last major contribution of metacharacters is helping the regular expression search a particular position in a string. By position, we don't mean something such as an offset — the matching functionality of regular expressions can tell us that. But, rather, whether the string to look for should be at the beginning or end of a larger string, or (if the `m` modifier is added to the regular expression assignment) at the beginning or end of a line of that larger string. Table 45-3 shows the positional metacharacters for JavaScript's regular expressions.

TABLE 45-3

JavaScript Regular Expression Positional Metacharacters

Character	Matches Located	Example
^	At beginning of a string or line	`/^Fred/` matches "Fred is OK" but not "I'm with Fred" or "Is Fred here?"
$	At end of a string or line	`/Fred$/` matches "I'm with Fred" but not "Fred is OK" or "Is Fred here?"

For example, you may want to make sure that a match for a Roman numeral is found only when it is at the start of a string, rather than when it is used inline somewhere else. If the document contains Roman numerals in an outline, you can match all the top-level items that are flush left with the document with a regular expression, such as the following:

```
/^[IVXMDCL]+\./m
```

This expression matches any combination of Roman numeral characters that begin at the start of a line and end with a period (the period is a special character in regular expressions, as shown in Table 45-1, so that you have to escape the period to offer it as a character), provided the Roman numeral is at the beginning of a line and has no tabs or spaces before it. There would also not be a match in a line that contains, for example, the phrase "see Part IV" because the Roman numeral is not at the beginning of a line.

Speaking of lines, a line of text is a contiguous string of characters delimited by a newline and/or carriage return (depending on the operating system platform). Word wrapping in `textarea` elements does not affect the starts and ends of true lines of text.

Grouping and backreferencing

Regular expressions obey most of the JavaScript operator precedence laws with regard to grouping by parentheses and the logical OR operator. One difference is that the regular expression OR operator is a single pipe character (`|`) rather than JavaScript's double pipe.

Parentheses have additional powers that go beyond influencing the precedence of calculation. Any set of parentheses (that is, a matched pair of left and right) stores the results of a found

match of the expression within those parentheses. Parentheses can be nested inside one another. Storage is accomplished automatically, with the data stored in an indexed array accessible to your scripts and to your regular expressions (although through different syntax). Access to these storage bins is known as *backreferencing*, because a regular expression can point backward to the result of an expression component earlier in the overall expression. These stored subcomponents come in handy for replace operations, as demonstrated later in this chapter.

Object Relationships

JavaScript has a lot going on behind the scenes when you create a regular expression and perform the simplest operation with it. As important as the regular expression language described earlier in this chapter is to applying regular expressions in your scripts, the JavaScript object interrelationships are perhaps even more important if you want to exploit regular expressions to the fullest.

The first concept to master is that two entities are involved: a regular expression instance object and the `RegExp` static object. Both objects are core objects of JavaScript and are not part of the document object model. Both objects work together, but have entirely different sets of properties that may be useful to your application.

When you create a regular expression (even via the `/.../` syntax), JavaScript invokes the `new RegExp()` constructor, much the way a `new Date()` constructor creates a date object around one specific date. The regular expression instance object returned by the constructor is endowed with several properties containing details of its data. At the same time, the single, static `RegExp` object maintains its own properties that monitor regular expression activity in the current window (or frame).

To help you see the typically unseen operations, we step you through the creation and application of a regular expression. In the process, we show you what happens to all of the related object properties when you use one of the regular expression methods to search for a match.

The starting text that we use to search through is the beginning of Hamlet’s soliloquy (assigned to an arbitrary variable named `mainString`):

```
var mainString = "To be, or not to be: That is the question:";
```

If our ultimate goal is to locate each instance of the word “be,” we must first create a regular expression that matches the word “be.” We set the regular expression up to perform a global search when eventually called upon (assigning the expression to an arbitrary variable named `re`):

```
var re = /\bbe\b/g;
```

To guarantee that only the complete word “be” is matched, we surround the letters with the word boundary metacharacters. The final “g” is the global modifier. The variable to which the

expression is assigned, re, represents a regular expression object whose properties and values are as follows:

Object.PropertyName	Value
re.source	"\bbe\bg"
re.global	true
re.ignoreCase	false
re.lastIndex	0

A regular expression's source property is the string consisting of the regular expression syntax (less the literal forward slashes). Each of the two possible modifiers, g and i, have their own properties, global and ignoreCase, whose values are Booleans indicating whether the modifiers are part of the source expression. The final property, lastIndex, indicates the index value within the main string at which the next search for a match should start. The default value for this property in a newly hatched regular expression is zero so that the search starts with the first character of the string. This property is read/write, so your scripts may want to adjust the value if they must have special control over the search process. As you see in a moment, JavaScript modifies this value over time if a global search is indicated for the object.

The RegExp constructor does more than just create regular expression objects. Like the Math object, the RegExp object is always "around" — one RegExp per window or frame — and tracks regular expression activity in a script. Its properties reveal what, if any, regular expression pattern matching has just taken place in the window. At this stage of the regular expression creation process, the RegExp object has only one of its properties set:

Object.PropertyName	Value
RegExp.input	
RegExp.multiline	false
RegExp.lastMatch	
RegExp.lastParen	
RegExp.leftContext	
RegExp.rightContext	
RegExp.$1	
...	
RegExp.$9	

The last group of properties ($1 through $9) is for storage of backreferences. But because the regular expression we define above doesn't have any parentheses in it, these properties are empty

for the duration of this examination and omitted from future listings in this "walk-through" section.

With the regular expression object ready to go, we invoke the `exec()` regular expression method, which looks through a string for a match defined by the regular expression. If the method is successful in finding a match, it returns a third object whose properties reveal a great deal about the item it found (we arbitrarily assign the variable `foundArray` to this returned object):

```
var foundArray = re.exec(mainString);
```

JavaScript includes a shortcut for the `exec()` method if you turn the regular expression object into a method:

```
var foundArray = re(mainString);
```

Normally, a script would check whether `foundArray` is `null` (meaning that there was no match) before proceeding to inspect the rest of the related objects. Because this is a controlled experiment, we know that at least one match exists, so we first look into some other results. Running this simple method has not only generated the `foundArray` data, but also altered several properties of the `RegExp` and regular expression objects. The following shows you the current stage of the regular expression object:

Object.PropertyName	Value
`re.source`	`"\bbe\bg"`
`re.global`	`true`
`re.ignoreCase`	`false`
`re.lastIndex`	`5`

The only change is an important one: The `lastIndex` value has bumped up to `5`. In other words, this one invocation of the `exec()` method must have found a match whose offset plus length of matching string shifts the starting point of any successive searches with this regular expression to character index `5`. That's exactly where the comma after the first "be" word is in the main string. If the global (`g`) modifier had not been appended to the regular expression, the `lastIndex` value would have remained at zero, because no subsequent search would be anticipated.

As the result of the `exec()` method, the `RegExp` object has had a number of its properties filled with results of the search:

Object.PropertyName	Value
`RegExp.input`	
`RegExp.multiline`	`False`
`RegExp.lastMatch`	`"be"`

Object.PropertyName	Value
`RegExp.lastParen`	
`RegExp.leftContext`	`"To "`
`RegExp.rightContext`	`", or not to be: That is the question:"`

From this object you can extract the string segment that was found to match the regular expression definition. The main string segments before and after the matching text are also available individually (in this example, the `leftContext` property has a space after "To"). Finally, looking into the array returned from the `exec()` method, some additional data is readily accessible:

Object.PropertyName	Value
`foundArray[0]`	`"be"`
`foundArray.index`	`3`
`foundArray.input`	`"To be, or not to be: That is the question:"`

The first element in the array, indexed as the zeroth element, is the string segment found to match the regular expression, which is the same as the `RegExp.lastMatch` value. The complete main string value is available as the input property. A potentially valuable piece of information to a script is the index for the start of the matched string found in the main string. From this last bit of data, you can extract from the found data array the same values as `RegExp.leftContext` (with `foundArray.input.substring(0, foundArray.index)`) and `RegExp.rightContext` (with `foundArray.input.substring(foundArray.index, foundArray[0].length)`).

Because the regular expression suggested a multiple execution sequence to fulfill the global flag, we can run the `exec()` method again without any change. Although the JavaScript statement may not be any different, the search starts from the new `re.lastIndex` value. The effects of this second time through ripple through the resulting values of all three objects associated with this method:

```
var foundArray = re.exec(mainString);
```

Results of this execution are as follows.

Object.PropertyName	Value
`re.source`	`"\bbe\bg"`
`re.global`	`True`
`re.ignoreCase`	`False`

Object.PropertyName	Value
re.lastIndex	19
RegExp.input	
RegExp.multiline	False
RegExp.lastMatch	"be"
RegExp.lastParen	
RegExp.leftContext	", or not to "
RegExp.rightContext	": That is the question:"
foundArray[0]	"be"
foundArray.index	17
foundArray.input	"To be, or not to be: That is the question:"

Because there was a second match, `foundArray` comes back again with data. Its index property now points to the location of the second instance of the string matching the regular expression definition. The regular expression object's `lastIndex` value points to where the next search would begin (after the second "be"). And the `RegExp` properties that store the left and right contexts have adjusted accordingly.

If the regular expression were looking for something less stringent than a hard-coded word, some other properties may also be different. For example, if the regular expression defined a format for a ZIP code, the `RegExp.lastMatch` and `foundArray[0]` values would contain the actual found ZIP codes, which would likely be different from one match to the next.

Running the same `exec()` method once more does not find a third match in our original `mainString` value, but the impact of that lack of a match is worth noting. First of all, the `foundArray` value is `null` — a signal to our script that no more matches are available. The regular expression object's `lastIndex` property reverts to zero, ready to start its search from the beginning of another string. Most importantly, however, the `RegExp` object's properties maintain the same values from the last successful match. Therefore, if you put the `exec()` method invocations in a repeat loop that exits after no more matches are found, the `RegExp` object still has the data from the last successful match, ready for further processing by your scripts.

Using Regular Expressions

Despite the seemingly complex hidden workings of regular expressions, JavaScript provides a series of methods that make common tasks involving regular expressions quite simple to use (assuming you figure out the regular expression syntax to create good specifications). In this section, we present examples of syntax for specific kinds of tasks for which regular expressions can be beneficial in your pages.

Is there a match?

We said earlier that you can use `string.indexOf()` or `string.lastIndexOf()` to look for the presence of simple substrings within larger strings. But if you need the matching power of regular expressions, you have two other methods to choose from:

```
regexObject.test(string)
string.search(regexObject)
```

The first is a regular expression object method, the second a string object method. Both perform the same task and influence the same related objects, but they return different values: a Boolean value for `test()` and a character offset value for `search()` (or `-1` if no match is found). Which method you choose depends on whether you need only a true/false verdict on a match or the location within the main string of the start of the substring.

Listing 45-1 demonstrates the `search()` method on a page that lets you get the Boolean and offset values for a match. Some default text and regular expression is provided (it looks for a five-digit number). You can experiment with other strings and regular expressions. Because this script creates a regular expression object with the `RegExp()` constructor method, you do not include the literal forward slashes around the regular expression.

LISTING 45-1

Looking for a Match

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Got a Match?</title>
      <style type="text/css">
         #instructions
         {
            font-weight:bold;
         }
      </style>
      <script type="text/javascript">
         function findIt(form)
         {
            var re = new RegExp(form.regexp.value);
            var input = form.main.value;
               if (input.search(re) != -1)
               {
                  form.output[0].checked = true;
               }
               else
               {
                  form.output[1].checked = true;
               }
```

```
        }
        function locateIt(form)
        {
           var re = new RegExp(form.regexp.value);
           var input = form.main.value;
           form.offset.value = input.search(re);
        }
     </script>
  </head>
  <body>
     <span id="instructions">Use a regular expression to test for
               the existence of a string:</span>
     <hr />
     <form>
        Enter some text to be searched:<br />
        <textarea name="main" cols="40" rows="4" wrap="virtual">
           The most famous ZIP code on Earth may be 90210.</textarea><br />
        Enter a regular expression to search:<br />
        <input type="text" name="regexp" size="30" value="\b\d\d\d\d\d\b" />
        <p>
           <input type="button" value="Is There a Match?"
                  onclick="findIt(this.form)" />
           <input type="radio"
                  name="output" />Yes
           <input type="radio" name="output" />No
        </p>
        <p>
           <input type="button" value="Where is it?"
                  onclick="locateIt(this.form)" />
           <input type="text" name="offset"
                  size="4" />
        </p>
        <p><input type="reset" /></p>
     </form>
  </body>
</html>
```

Note

The property assignment event handling technique used in the examples in this chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects."** ■

Getting information about a match

For the next application example, the task is not only to verify that a one-field date entry is in the desired format, but also to extract match components of the entry and use those values to perform further calculations in determining the day of the week. The regular expression in the

example that follows is a fairly complex one, because it performs some rudimentary range checking to make sure the user doesn't enter a month over 12 or a date over 31. What it does not take into account is the variety of lengths of each month. Nor does it take into account that the visitor might enter a date such as `1/30-2013` that would validate successfully, something we would not normally want. Though we would obviously want a much more complex regular expression for real world work, this example is complex enough for our purposes. But the regular expression, and method invoked with it, extract each date object component in such a way that you can perform additional validation on the range to make sure the user doesn't try to give September 31 days. Also be aware that this is not the only way to perform date validations in forms. Chapter 46, "Data-Entry Validation," offers additional thoughts on the matter, that work, for backward compatibility, without regular expressions.

Listing 45-2 contains a page that has a field for date entry, a button to process the date, and an output field for displaying a long version of the date, including the day of the week. At the start of the function that does all the work, we create two arrays to hold the plain language names of the months and days. These arrays are used only if the user enters a valid date.

Next comes the regular expression to be matched against the user entry. If you can decipher all the symbols, you see that three components are separated by potential hyphen or forward slash entries (`[\-\/]`). These symbols must be escaped in the regular expression. Importantly, each of the three component definitions is surrounded by parentheses, which are essential for the various objects created with the regular expression to remember their values for extraction later.

Here is a brief rundown of what the regular expression is looking for:

- A string beginning after a word break
- A string value for the month that contains a `1` plus a `0` through `2`; or an optional `0` plus a `1` through `9`
- A hyphen or forward slash
- A string value for the date that starts with a `0` plus a `1` through `9`; or starts with a `1` or `2` and ends with a `0` through `9`; or starts with a `3` and ends with `0` or `1`
- Another hyphen or forward slash
- A string value for the year that begins with `19` or `20`, followed by two digits

An extra pair of parentheses must surround the `19|20` segment to make sure that either one of the matching values is attached to the two succeeding digits. Without the parentheses, the logic of the expression attaches the digits only to 20. One other thing to notice: we allow the string value for the month to be followed by a hyphen or forward slash, and the same after the string value for the date.

For invoking the regular expression action, we select the `exec()` method, assigning the returned object to the variable `matchArray`. We can also use the `string.match()` method here. Only if the match is successful (that is, all conditions of the regular expression specification are met) does the major processing continue in the script.

The parentheses around the segments of the regular expression instruct JavaScript to assign each found value to a slot in the `matchArray` object. The month segment is assigned

to `matchArray[1]`, the date to `matchArray[2]`, and the year to `matchArray[3]` (`matchArray[0]` contains the entire matched string). Therefore, the script can extract each component to build a plain-language date string with the help of the arrays defined at the start of the function. We even use the values to create a new date object that calculates the day of the week for us. After we have all pieces, we concatenate them and assign the result to the value of the output field. If the regular expression `exec()` method doesn't match the typed entry with the expression, the script provides an error message in the field.

LISTING 45-2

Extracting Data from a Match

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Got a Match?</title>
      <style type="text/css">
         #instructions
         {
            font-weight:bold;
         }
      </style>
      <script type="text/javascript">
         function extractIt(form)
         {
            var months = ["January","February","March","April","May","June",
                          "July","August","September","October",
                          "November","December"];
            var days = ["Sunday","Monday","Tuesday","Wednesday","Thursday",
                        "Friday","Saturday"];
            var re = /\b(1[0-2]|0?[1-9])[\-\/](0?[1-9]|[12][0-9]
                     |3[01])[\-\/]((19|20)\d{2})/;
            var input = form.entry.value;
            var matchArray = re.exec(input);
               if (matchArray)
               {
                  var theMonth = months[matchArray[1] - 1] + " ";
                  var theDate = matchArray[2] + ", ";
                  var theYear = matchArray[3];
                  var dateObj = new Date(matchArray[3],
                                matchArray[1]-1,matchArray[2]);
                  var theDay = days[dateObj.getDay()] + " ";
                  form.output.value = theDay + theMonth + theDate + theYear;
               }
               else
               {
                  form.output.value = "An invalid date.";
               }
         }
      </script>
```

String replacement

To demonstrate using regular expressions for performing search-and-replace operations, we choose an application that may be of value to many page authors who have to display and format large numbers. Databases typically store large integers without commas. After five or six digits, however, such numbers are difficult for users to read. Conversely, if the user needs to enter a large number, commas help ensure accuracy.

Helping the procedure in JavaScript regular expressions is the `string.replace()` method (see Chapter 15, “The String Objects”). The method requires two parameters, a regular expression to search the string and a string to replace any match found in the string. The replacement string can be properties of the `RegExp` object as it stands after the most recent `exec()` method.

Listing 45-3 demonstrates how only a handful of script lines can do a lot of work when regular expressions handle the dirty work. The page contains three fields. Enter any number you want in the first one. A click of the Insert Commas button invokes the `commafy()` function in the page. The result is displayed in the second field. You can also enter a comma-filled number in the second field and click the Remove Commas button to see the inverse operation executed through the `decommafy()` function.

Specifications for the regular expression accept any positive or negative string of numbers. The keys to the action of this script are the parentheses around two segments of the regular expression. One set encompasses all characters not included in the second group: a required set of

three digits. In other words, the regular expression is essentially working from the rear of the string, chomping off three-character segments and inserting a comma each time a set is found.

A `while` repeat loop cycles through the string and modifies the string (in truth, the string object is not being modified, but, rather, a new string is generated and assigned to the old variable name). We use the `test()` method because we don't need the returned value of the `exec()` method. The `test()` method impacts the regular expression and `RegExp` object properties the same way as the `exec()` method, but more efficiently. The first time the `test()` method runs, the part of the string that meets the first segment is assigned to the `RegExp.$1` property; the second segment, if any, is assigned to the `RegExp.$2` property. Notice that we're not assigning the results of the `exec()` method to any variable, because for this application we don't need the array object generated by that method.

Next comes the tricky part. We invoke the `string.replace()` method, using the current value of the string (`num`) as the starting string. The pattern to search for is the regular expression defined at the head of the function. But the replacement string may look strange to you. The replacement string is replacing whatever the regular expression matches with the value of `RegExp.$1`, a comma, and the value of `RegExp.$2`. The `RegExp` object should not be part of the references used in the `replace()` method parameter. Because the regular expression matches the entire `num` string, the `replace()` method is essentially rebuilding the string from its components, plus adding a comma before the second component (the last freestanding three-digit section). Each `replace()` method invocation sets the value of `num` for the next time through the `while` loop and the `test()` method.

Looping continues until no matches occur — meaning that no more freestanding sets of three digits appear in the string. Then the results are written to the second field on the page.

LISTING 45-3

Replacing Strings via Regular Expressions

```

            var re = /(-?\d+)(\d{3})/;
            var num = form.entry.value;
```

continued

LISTING 45-3 *(continued)*

```
            while (re.test(num))
            {
               num = num.replace(re, "$1,$2");
            }
            form.commaOutput.value = num;
         }
         function decommafy(form)
         {
            var re = /,/g;
            form.plainOutput.value = form.commaOutput.value.replace(re,"");
         }
      </script>
   </head>
   <body>
      <span id="instructions">Use a regular expression to add/delete
                              commas from numbers:</span>
      <hr />
      <form>
         Enter a large number without any commas:<br />
         <input type="text" name="entry" size="15" />
         <p>
            <input type="button" value="Insert commas"
                   onclick="commafy(this.form)" />
         </p>
         <p>The comma version is:<br />
            <input type="text" name="commaOutput" size="20" />
         </p>
         <p>
            <input type="button" value="Remove commas"
                   onclick="decommafy(this.form)" />
         </p>
         <p>The un-comma version is:<br />
            <input type="text" name="plainOutput" size="15" />
         </p>
         <p><input type="reset" /></p>
      </form>
   </body>
</html>
```

Removing the commas is an even easier process. The regular expression is a comma with the global flag set. The `replace()` method reacts to the global flag by repeating the process until all matches are replaced. In this case, the replacement string is an empty string. For further examples of using regular expressions with string objects, see the discussions of the `string.match()`, `string.replace()`, and `string.split()` methods in Chapter 15.

Regular Expression Object

Properties	Methods	Event Handlers
`constructor`	`compile()`	
`global`	`exec()`	
`ignoreCase`	`test()`	
`lastIndex`		
`multiline`		
`source`		

Syntax

Accessing regular expression properties or methods:

```
regularExpressionObject.property | method([parameters])
```

Compatibility: WinIE4+, MacIE4+, NN4+, Moz1+, Safari1+, Opera+, Chrome+

About this object

The regular expression object is created on-the-fly by your scripts. Each regular expression object contains its own pattern and other properties. Deciding which object creation style to use depends on the way the regular expression will be used in your scripts.

When you create a regular expression with the literal notation (that is, with the two forward slashes), the expression is automatically compiled for efficient processing as the assignment statement executes. The same is true when you use the new `RegExp()` constructor and specify a pattern (and optional modifier flags) as a parameter. Whenever the regular expression is fixed in the script, use the literal notation; when some or all of the regular expression is derived from an external source (for example, user input from a text field), assemble the expression as a parameter to the new `RegExp()` constructor. A compiled regular expression should be used at whatever stage the expression is ready to be applied and reused within the script. Compiled regular expressions are not saved to disk or given any more permanence beyond the life of a document's script (that is, they die when the page unloads).

However, there may be times in which the specification for the regular expression changes with each iteration through a loop construction. For example, if statements in a `while` loop modify

the content of a regular expression, compile the expression inside the `while` loop, as shown in the following skeletal script fragment:

```
var srchText = form.search.value;
var re = new RegExp();  // empty constructor
while (someCondition)
{
   re.compile("\\s+" + srchText + "\\s+", "gi");
   statements that change srchText
}
```

Each time through the loop, the regular expression object is both given a new expression (concatenated with metacharacters for one or more white spaces on both sides of some search text whose content changes constantly) and compiled into an efficient object for use with any associated methods.

Properties

constructor

(See `string.constructor` in Chapter 15, "The String Object".)

global
ignoreCase

Value: Booleans Read-Only

Compatibility: WinIE5.5+, MacIE5+, NN4+, Moz1+, Safari1+, Opera+, Chrome+

These two properties reflect the regular expression `g` and `i` modifier flags, if any, associated with a regular expression. Settings are read-only and are determined as the object is created. Each property is independent of the other.

lastIndex

Value: Integer Read/Write

Compatibility: WinIE4+, MacIE4+, NN4+, Moz1+, Safari1+, Opera+, Chrome+

The `lastIndex` property indicates the index counter of the main string to be searched against the current regular expression object. When a regular expression object is created, this value is zero, meaning that there have been no searches with this object, and the default behavior of the first search is to start at the beginning of the string.

If the regular expression has the global modifier specified, the `lastIndex` property value advances to the next higher value, after the object is used in a method to match within a main string. The value is the position in the main string immediately after the previously matched string (and not including any character of the matched string). After locating the final match in a string, the method resets the `lastIndex` property to zero for the next time. You can also

influence the behavior of matches by setting this value on-the-fly. For example, if you want the expression to begin its search at the fourth character of a target string, you change the setting immediately after creating the object, as follows:

```
var re = /somePattern/;
re.lastIndex = 3;  // fourth character in zero-based index system
```

Related Items: Match result object index property

multiline

Value: Boolean Read-Only

Compatibility: WinIE5.5+, MacIE5, NN6+, Moz1+, Safari1+, Opera+, Chrome+

The `multiline` property reveals whether searches extend across multiple lines of a target string, as directed by the optional `m` modifier flag for a regular expression.

Related Items: `RegExp.multiline` property

source

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz1+, Safari1+, Opera+, Chrome+

The `source` property is simply the string representation of the regular expression used to define the object. This property is read-only.

Methods

compile("*pattern*", ["g" | "i" | "m"])

Returns: Regular expression object

Compatibility: WinIE4+, MacIE4+, NN4+, Moz1+, Safari+, Opera+, Chrome+

Use the `compile()` method to compile, on-the-fly, a regular expression whose content changes continually during the execution of a script. See the earlier discussion about this object for an example. Other regular expression creation statements (the literal notation and the `RegExp()` constructor that passes a regular expression) automatically compile their expressions.

exec("*string*")

Returns: Match array object or `null`

Compatibility: WinIE4+, MacIE4+, NN4+, Moz1+, Safari1+, Opera+, Chrome+

The `exec()` method examines the string passed as its parameter for at least one match of the specification defined for the regular expression object. The behavior of this method is similar to that of the `string.match()` method (although the `match()` method is more powerful in

completing global matches). Typically, a call to the `exec()` method is made immediately after the creation of a regular expression object, as in the following example:

```
var re = /somePattern/;
var matchArray = re.exec("someString");
```

Much happens as a result of the `exec()` method. Properties of both the regular expression object and the window's `RegExp` object are updated based on the success of the match. The method also returns an object that conveys additional data about the operation. Table 45-4 shows the properties of this returned object.

TABLE 45-4

Match Found Array Object Properties

Property	Description
`index`	Zero-based index counter of the start of the match inside the string
`input`	Entire text of original string
`[0]`	String of most recent matched characters
`[1],...[n]`	Parenthesized component matches

Some of the properties in this returned object echo properties in the `RegExp` object. The value of having them in the regular expression object is that their contents are safely stowed in the object, whereas the `RegExp` object and its properties may be modified soon by another call to a regular expression method. Items the two objects have in common are the `[0]` property (mapped to the `RegExp.lastMatch` property) and the `[1], ... [n]` properties (the first nine of which map to `RegExp.$1 ... RegExp.$9`). Although the `RegExp` object stores only nine parenthesized subcomponents, the returned array object stores as many as are needed to accommodate parenthesis pairs in the regular expression.

If no match turns up between the regular expression specification and the string, the returned value is `null`. See Listing 45-2 for an example of how this method can be applied. An alternate shortcut syntax may be used for the `exec()` method. Turn the regular expression into a function, as in

```
var re = /somePattern/;
var matchArray = re("someString");
```

Related Items: `string.match()` method

test("*string*")

Returns: Boolean

Compatibility: WinIE4+, MacIE4+, NN4+, Moz1+, Safari1+, Opera+, Chrome+

The most efficient way to find out if a regular expression has a match in a string is to use the `test()` method. Returned values are `true` if a match exists and `false` if not. In case you need more information, a companion method, `string.search()`, returns the starting index value of the matching string. See Listing 45-1 for an example of this method in action.

Related Items: `string.search()` method

```

Compatibility: WinIE4+, MacIE4+, NN4+, Moz1+, Safari+, Opera+, Chrome+

About this object

Beginning with version 4 browsers, the browser maintains a single instance of a `RegExp` object for each window or frame. The object oversees the action of all methods that involve regular expressions (including the few related string object methods). Properties of this object are exposed not only to JavaScript in the traditional manner, but also to a parameter of the method `string.replace()` for some shortcut access (see Listing 45-3).

With one `RegExp` object serving all regular expression-related methods in your document's scripts, you must exercise care in accessing or modifying this object's properties. You must make sure that the `RegExp` object has not been affected by another method. Most properties are subject to change as the result of any method involving a regular expression. This may be reason

enough to use the properties of the array object returned by most regular expression methods instead of the `RegExp` properties. The former stick with a specific regular expression object even after other regular expression objects are used in the same script. The `RegExp` properties reflect the most recent activity, irrespective of the regular expression object involved.

In the following listings, we supply the long, JavaScript-like property names. But each property also has an abbreviated, Perl-like manner to refer to the same properties. You can use these shortcut property names in the `string.replace()` method if you need the values. Also be aware that the `input`, `lastMatch`, `lastParen`, `leftContext`, `rightContext`, and `$1` through `$9` properties are deprecated in JavaScript 1.5.

Properties

input

Value: String Read/Write

Compatibility: WinIE4+, MacIE4+, NN4+, Moz-, Safari+, Opera-, Chrome+

The `RegExp.input` property is the main string against which a regular expression is compared in search of a match. In all of the example listings earlier in this chapter, the property was `null`. Such is the case when the main string is supplied as a parameter to the regular expression-related method.

But many text-related document objects have an unseen relationship with the `RegExp` object. If a `text`, `textarea`, `select`, or `link` object contains an event handler that invokes a function containing a regular expression, the `RegExp.input` property is set to the relevant textual data from the object. You don't have to specify any parameters for the event handler call or in the function called by the event handler. For `text` and `textarea` objects, the `input` property value becomes the content of the object; for the `select` object, it is the text (not the value) of the selected option; and for a link, it is the text highlighted in the browser associated with the link (and reflected in the link's `text` property).

Having JavaScript set the `RegExp.input` property for you may simplify your script. You can invoke either of the regular expression methods without having to specify the main string parameter. When that parameter is empty, JavaScript applies the `RegExp.input` property to the task. You can also set this property on-the-fly if you want. The short version of this property is `$_` (dollar sign underscore).

Related Items: Matching array object `input` property

multiline

Value: Boolean Read/Write

Compatibility: WinIE5.5+, MacIE5+, NN4+, Moz1+, Safari+, Opera-, Chrome+

The `RegExp.multiline` property determines whether searches extend across multiple lines of a target string. This property is automatically set to `true` when an event handler of a `textarea` triggers a function containing a regular expression. You can also set this property on-the-fly if

you want. The short version of this property is `$*`. This property (as distinct from the `multiline` property of an instance of a regular expression) is not defined in the ECMA-262 specification and is based on an early, incorrect implementation.

Related Items: Regular expression instance object `multiline` property

lastMatch

Value: String Read-Only

Compatibility: WinIE5.5+, MacIE5+, NN4+, Moz1+, Safari+, Opera-, Chrome+

After execution of a regular expression—related method, any text in the main string that matches the regular expression specification is automatically assigned to the `RegExp.lastMatch` property. This value is also assigned to the `[0]` property of the object array returned after the `exec()` and `string.match()` methods find a match. The short version of this property is `$&`.

Related Items: Matching array object `[0]` property

lastParen

Value: String Read-Only

Compatibility: WinIE5.5+, MacIE5+, NN4+, Moz1+, Safari+, Opera-, Chrome+

When a regular expression contains many parenthesized subcomponents, the `RegExp` object maintains a list of the resulting strings in the `$1,...$9` properties. You can also extract the value of the last matching parenthesized subcomponent with the `RegExp.lastParen` property, which is a read-only property. The short version of this property is `$+`.

Related Items: `RegExp.$1,...$9` properties

leftContext
rightContext

Value: String Read-Only

Compatibility: WinIE5.5+, MacIE5+, NN4+, Moz1+, Safari+, Opera+, Chrome+

After a match is found in the course of one of the regular expression methods, the `RegExp` object is informed of some key contextual information about the match. The `leftContext` property contains the part of the main string to the left of (up to but not including) the matched string. Be aware that the `leftContext` starts its string from the point at which the most recent search began. Therefore, for second or subsequent runs through the same string with the same regular expression, the `leftContext` substring varies widely from the first time through.

The `rightContext` consists of a string starting immediately after the current match and extending to the end of the main string. As subsequent method calls work on the same string and regular expression, this value obviously shrinks in length until no more matches are found. At this point, both properties revert to `null`. Note that Firefox in Windows returns a `null` for the `rightContext` property. The short versions of these properties are `` $` `` and `$'` for `leftContext` and `rightContext`, respectively.

prototype

(See `String.prototype` in Chapter 15, "The String Object".)

$1 ... $9

Value: String Read-Only

Compatibility: WinIE4+, MacIE4+, NN4+, Moz1+, Safari+, Opera+, Chrome+

As a regular expression method executes, any parenthesized results are stored in `RegExp`'s nine properties reserved for just that purpose (called backreferences). The same values (and any beyond the nine that `RegExp` has space for) are stored in the array object returned with the `exec()` and `string.match()` methods. Values are stored in the order in which the left parenthesis of a pair appears in the regular expression, regardless of nesting of other components. (Firefox in Windows returns a `null` for these properties.)

You can use these backreferences directly in the second parameter of the `string.replace()` method, without using the `RegExp` part of their address. The ideal situation is to encapsulate components that need to be rearranged or recombined with replacement characters. For example, the following script function turns a name that is last-name-first into first-name-last:

```
function swapEm()
{
   var re = /(\w+),\s*(\w+)/;
   var input = "Lincoln, Abraham";
   return input.replace(re,"$2 $1");
}
```

In the `replace()` method, the second parenthesized component (just the first name) is placed first, followed by a space and the first component. The original comma is discarded. You are free to combine these shortcut references as you like, including multiple times per replacement, if it makes sense to your application.

Data-Entry Validation

IN THIS CHAPTER

Validating data as it is being entered

Validating data immediately prior to submission

Organizing complex data-validation tasks

Give users a field in which to enter data and you can be sure that some users will enter the wrong kind of data. Often the mistake is accidental — a slip of the pinkie on the keyboard; other times, users intentionally type an incorrect entry to test the robustness of your application. Whether you solicit a user's entry for client-side scripting purposes or for input into a server-based CGI or database, you should use JavaScript on the client to handle validation of the user's entry. Even for a form connected to a server application, it's far more efficient (from the perspective of bandwidth, server load, and execution speed) to let client-side JavaScript get the data straight before your server program deals with it.

Real-Time Versus Batch Validation

You have two opportunities to perform data-entry validation in a form: as the user enters data into the form and just before the form is submitted. We recommend you take advantage of both of these opportunities.

Real-time validation triggers

The most convenient time to catch an error is immediately after the user makes it — especially for a long form that requests a wide variety of information. You can make the user's experience less frustrating if you catch an entry mistake just after the user enters the information: his or her attention is already focused on the nature of the content (or some paper source material may already be in front of the user). It is much easier for the user to address the same information right away.

A reasonable question for the page author is how to trigger the real-time validation. Your initial thought is probably to tie the validation to the `onchange` handler. The problem with using `onchange` as the validation trigger is that a user can defeat the validation. A change event occurs only when the text of a field indeed changes as the user tabs or clicks out of the field. If the user is alerted about some bad entry in a field and doesn't fix the error, the change event doesn't fire again. In some respects, this is good because a user may have a legitimate reason for passing by a particular form field initially, with the intention of returning to the entry later. Because a user can defeat the `onchange` event handler trigger, a reasonable solution is to perform batch validation prior to submission.

An even better approach, and a more effective real-time solution, is available to modern browsers. We're referring to the strategy of letting keyboard events trigger validations. This is most helpful when you want to prevent some character(s) from being entered into a field. For example, if a field is supposed to contain only a positive integer value, you can use the `onkeypress` event handler of the text box to verify that the character just typed is a number. If the character is not a number, the event is trapped and no character reaches the text box. You should also alert the user in some way about what's going on.

Listing 46-1 demonstrates a simplified version of this kind of keyboard trapping. The message to the user is displayed in the status bar. Displaying the message there has the advantage of being less intrusive than an alert dialog box (and keeps the text insertion cursor in the text box), but it also means that users might not see the message. (This is especially true in Chrome because that browser has a transient status bar.) Also, recall from Chapter 27, "Window and Frame Objects," that even browsers with a status bar might not support scripting a message to it. The `onsubmit` event handler in the listing prevents a press of the Enter key in this one-field form from reloading this sample page.

         Enter any positive integer:
         <input type="text" name="numeric"
                onkeypress="return checkIt(event)" />
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique used in this example and throughout this chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects."** ■

Aggressive keyboard event monitoring isn't practical for most validation actions, however. For example, if the user is supposed to enter an email address, you need to validate the complete entry for the presence of an @ symbol (through the `onchange` event handler). On the other hand, you can be granular about your validations and use both the `onchange` and `onkeypress` event handlers; you employ the latter for blocking invalid characters in email addresses (such as spaces).

Another interesting usage of keyboard event monitoring for validation is to offer helper messages in response to errant input, as opposed to preventing or rejecting the input outright. In this scenario, you typically place, beside the input control, a text label that will serve to display messages related to the validity of the input data. As the user enters information, the helper message dynamically updates in real time to provide input cues. You see this technique in action a bit later in the chapter, in Listing 46-8.

In the helper message approach to real-time validation, you aren't actually preventing any characters from being entered. For this reason, you may find the `onkeyup` event handler to be more direct than `onkeypress`; unlike `onkeypress`, `onkeyup` doesn't enable you to return `false` from the handler to prevent the entry of a character.

Batch mode validation

In all scriptable browsers, a form's `onsubmit` event handler cancels the submission if the handler evaluates to `return false`. Additional submission event cancellers include setting the IE4+

`event.returnValue` property to `false` and invoking the `evt.preventDefault()` method in Moz/W3C (see Chapter 32). You can see an example of the basic `return false` behavior in Listing 36-4 of Chapter 36. That example uses the results of a `window.confirm()` dialog box to determine the return value of the event handler. But you can also use a return value from a series of individual text box validation functions. If any one of the validations fails, the user is alerted and the submission is canceled.

Before you worry about two versions of validation routines loading down the scripts in your page, you'll be happy to know that you can reuse the same validation routines in both the real-time and batch validations. Later in this chapter, we demonstrate what we call industrial-strength data-entry validation, adapted from a real intranet application. But before you get there, you should learn about general validation techniques that you can apply to both types of validations.

Designing Filters

The job of writing data-validation routines essentially involves designing filters that weed out characters or entries that don't fit your programming scheme. Whenever your filter detects an incorrect entry, it should alert the user about the nature of the problem and enable the user to correct the entry.

Before you put a `text` or `textarea` object into your document that invites users to enter data, you must decide if any possible entry can disturb the execution of the rest of your scripts. For example, if your script must have a number from that field to perform calculations, you will need to filter out any entry that contains letters or punctuation — except for periods, if the program can accept floating-point numbers. Your task is to anticipate every possible entry users can make and allow only those entries your scripts can use.

Not every entry field needs a data-validation filter. For example, you may prompt a user for information that is eventually stored as a `document.cookie` or in a string database field on the server for future retrieval. If no further processing takes place on that information, you may not have to worry about the specific contents of the field.

One other design consideration is whether a text field is even the proper user interface element for the data required of the user. If the range of choices for a user entry is small (a dozen or fewer), a more sensible method is to avoid the data-entry problem altogether by turning that field into a `select` element. Your HTML attributes for the object ensure that you control the kind of entry made to that object. As long as your script knows how to deal with each of the options defined for that object, you're in the clear.

Building a Library of Filter Functions

A number of basic data-validation processes function repeatedly in form-intensive HTML pages. Filters for integers only, numbers only, empty entries, alphabet letters only, and the like are put to use every day. If you maintain a library of generalizable functions for each of your

data-validation tasks, you can drop these functions into your scripts at a moment's notice and be assured that they will work. You can also create the library of validation functions as a separate `.js` library file and link the scripts into any HTML file that needs them.

Making validation functions generalizable requires careful choice of wording and logic so that they return Boolean values that make syntactical sense when called from elsewhere in your scripts. As you see later in this chapter, when you build a larger framework around smaller functions, each function is usually called as part of an `if...else` conditional statement. Therefore, assign a name that fits logically as part of an `if` clause in plain language. For example, you can name a function that checks whether an entry is empty, `isEmpty()`. The calling statement for this function is

```
if (isEmpty(value)) { ... }
```

From a plain-language perspective, the expectation is that the function returns `true` if the passed value is empty. With this design, the statements nested in the `if` construction handle empty entry fields. We revisit this design later in this chapter when we start stacking multiple-function calls together in a larger validation routine.

To get you started with your library of validation functions, this chapter provides some building blocks that you can learn from and use as starting points for more specific filters of your own design. These functions utilize regular expressions, which are built into all modern JavaScript-powered browsers. Some of these functions are put to use in the JavaScript application in Chapter 53, "Application: A Lookup Table."

isEmpty()

The `isEmpty()` function, shown in Listing 46-2, checks to see whether an input value has been entered. Although you could design the function so that it checks for a null value, which would indicate emptiness, regular expressions provide an even cleaner solution. The regular expression approach examines whether the input string has one or more characters of any kind in it. This function returns `true` if the input is indeed empty, and `false` otherwise.

LISTING 46-2

Is an Entry Empty or Null?

```
// function to see if an input value has been
// entered at all
function isEmpty(inputStr)
{
   var re = /.+/;
      if (!inputStr.match(re))
      {
         return true;
      }
   return false;
}
```

isPosInteger()

The `isPosInteger()` function examines an input value to see if it is a positive integer, which includes only numbers from zero through nine, with no punctuation or other symbols. As Listing 46-3 reveals, regular expressions dramatically reduce the code in what would otherwise be a function that analyzes each character one at a time. The regular expression code simply checks to make sure that the string consists entirely of any number of numerals.

LISTING 46-3

Test for Positive Integers

```
// function to see if a suspected numeric input
// is a positive integer
function isPosInteger(inputStr)
{
   var re = /^\d*$/;
   inputStr = inputStr.toString();
      if (!inputStr.match(re))
      {
         return false;
      }
   return true;
}
```

isInteger()

The `isInteger()` function includes the entry of a negative integer value. Listing 46-4 shows that this function is identical to `isPosInteger()` except that the regular expression allows for one leading hyphen.

LISTING 46-4

Checking for Leading Minus Sign

```
// function to see if a suspected numeric input
// is a positive or negative integer
function isInteger(inputStr)
{
   var re = /^[-]?\d*$/;
   inputStr = inputStr.toString();
      if (!inputStr.match(re))
      {
         return false;
      }
   return true;
}
```

isNumber()

The isNumber() numeric filter function enables any integer or floating-point number to pass, while filtering out all others. All that distinguishes an integer from a floating-point number, for data-validation purposes, is the decimal point. A slight modification to the regular expression from Listing 46-4 — allowing a single decimal point between any number of numerals — turns the validation function into one that tests for any positive or negative number, with or without numbers to the right of the decimal, as shown in Listing 46-5.

LISTING 46-5

Testing for a Decimal Point

```
// function to see if a suspected numeric input
// is a positive or negative number
function isNumber(inputStr)
{
   var re = /^[-]?\d*\.?\d*$/;
   inputStr = inputStr.toString();
      if (!inputStr.match(re))
      {
         return false;
      }
   return true;
}
```

Custom validation functions

The listings shown so far in this chapter should give you plenty of source material to use in writing customized validation functions for your applications. Listing 46-6 shows an example of such an application-specific variation (extracted from the application in Chapter 53, "Application: A Lookup Table").

LISTING 46-6

A Custom Validation Function

```
// function to determine if value is in acceptable range
// for this application
function inRange(inputStr)
{
   num = parseInt(inputStr);
      if (num < 1 || num > 586 && num < 596 || num > 599 && num < 700 ||
          num > 728)
      {
         return false;
      }
   return true;
}
```

For this application, you need to verify if an entry falls within multiple ranges of acceptable numbers. The first statement of the `inRange()` function converts the incoming value to a number (through the `parseInt()` function) so that the value can be compared numerically against maximum and minimum values of several ranges within the database. The `if` condition then looks for values outside the acceptable range, so it can alert the user and return a `false` value.

The `if` condition is quite a long sequence of operators. As you noticed in the list of operator precedence (see Chapter 22, "JavaScript Operators"), the Boolean `and` operator (`&&`) has precedence over the Boolean `or` operator (`||`). Therefore, the `and` expressions evaluate first, followed by the `or` expressions. Using a "best practices" approach, otherwise unneeded parentheses may help you better visualize what's going on in that monster condition:

```
if (num < 1 || (num > 586 && num < 596) ||(num > 599 && num < 700) ||
    num > 728)
```

In other words, you exclude four possible ranges from consideration:

- Values less than 1
- Values between 586 and 596
- Values between 599 and 700
- Values greater than 728

Any value for which any one of these tests is true yields a Boolean `false` from this function. Combining all these tests into a single condition statement eliminates the need to construct an otherwise complex series of nested `if` conditions.

Combining Validation Functions

When you design a page that requests a particular kind of text input from a user, you often need to call more than one data-validation function to handle the entire job. For example, if you merely want to test for a positive integer entry, your validation should test for the presence of any entry, as well as the validation as an integer.

After you know the kind of permissible data that your script will use after validation, you're ready to plot the sequence of data validation. Because each page's validation task is different, we supply some guidelines to follow in your planning rather than prescribe a fixed route for all to take.

Our preferred sequence is to start with examinations that require less work, and increase the intensity of validation detective work with succeeding functions. We borrow this tactic from real life: When a lamp fails to turn on, we look for a pulled plug or a burned-out lightbulb before tearing the lamp's wiring apart to look for a short.

Using the data-validation sequence from the data-entry field (which must be a three-digit number within a specified range) in Chapter 53, we start with the test that requires the least amount of work: Is there an entry at all? After our script has ensured that an entry of some kind exists, it then checks whether that entry is "all numbers as requested of the user." If so, the script compares the number against the ranges of numbers in the database.

To make this sequence work efficiently, we create a master validation function consisting of nested `if...else` statements. Each `if` condition calls one of the generalized data-validation functions. Listing 46-7 shows the master validation function.

LISTING 46-7

Master Validation Function

```
// Master value validator routine
function isValid(inputStr)
{
  if (isEmpty(inputStr))
  {
     alert("Please enter a number into the field before clicking the button.");
     return false;
  }
  else
  {
     if (!isNumber(inputStr))
     {
       alert("Please make sure entries are numbers only.");
       return false;
     }
     else
     {
       if (!inRange(inputStr))
       {
         var msg = "Sorry, the number you entered is not part of our database.";
         msg += "Try another three-digit number.";
         alert(msg);
         return false;
       }
     }
   }
   return true;
}
```

This function, in turn, is called by the function that controls most of the work in this application. All that the main function wants to know is whether the entered number is valid. The details of validation are handed off to the `isValid()` function and its special-purpose validation testers.

We construct the logic in Listing 46-7 so that if the input value fails to be valid, the `isValid()` function alerts the user to the problem and returns `false`. That means we have to watch our `true` and `false` returns very carefully.

In the first validation test, an empty value is a bad thing; thus, when the `isEmpty()` function returns `true`, the `isValid()` function returns `false` because an empty string is not a valid entry. In the second test, a number value is good, so the logic has to flip 180 degrees. The `isValid()` function returns `false` only if the `isNumber()` function returns `false`. But

because `isNumber()` returns `true` when the value is a number, we switch the condition to test for the opposite results of the `isNumber()` function by negating the function name (preceding the function with the Boolean `not` (`!`) operator). This operator works only with a value that evaluates to a Boolean expression — which the `isNumber()` function always does. The final test for being within the desired range works on the same basis as `isNumber()`, using the Boolean `not` operator to turn the results of the `inRange()` function into the method that works best for this sequence.

Finally, if all validation tests fail to find bad or missing data, the entire `isValid()` function returns `true`. The statement that calls this function can now proceed, assured that the value entered by the user will work.

There is one additional point worth reinforcing, especially for newcomers. Although all these functions seem to be passing around the same input string as a parameter, notice that any changes made to the value (such as converting it to a string or number) are kept private to each function. These subfunctions never touch the original value in the calling function — they work only with copies of the original value. Therefore, even after the data validation takes place, the original value is in its original form and ready to go.

Date and Time Validation

You can scarcely open a bigger can of cultural worms than trying to program around the various date and time formats in use around the world. If you have ever looked through the possible settings in your computer's operating system, you can begin to understand the difficulty of this issue.

Trying to write JavaScript that accommodates all of the world's date and time formats for validation is an enormous, if not wasteful, challenge. It's one thing to check that a text box contains data in the form `xx/xx/xxxx`, but there are also valid value concerns that can get very messy on an international basis. For example, whereas North America typically uses the `mm/dd/yyyy` format, a large portion of the rest of the world uses `dd/mm/yyyy` (with different delimiter characters, as well). Therefore, how should your validation routine treat the entry `20/03/2002`? Is it incorrect because there are not 20 months in a year? Or is it correct as March 20th? To query a user for this kind of information, we suggest you divide the components into individually validated fields (separate text objects for hours and minutes), or make `select` element entries whose individual values can be assembled at submit time into a hidden date field, for processing by the database that needs the date information. (Alternately, you can let your server application handle the conversion.) Or you can provide helper text to clarify what format you're expecting (more on this in a moment).

Despite our encouragement to "divide and conquer" date entries, there may be situations in which you feel it's safe to provide a single text box for date entry (perhaps for a form that is used on a corporate intranet, strictly by users in one country). You see some more sophisticated code later in this chapter, but a quick-and-dirty solution runs along these lines:

1. Use the entered data (for example, in `mm/dd/yyyy` format) as a value passed to the `new Date()` constructor function.

2. From the newly created date object, extract each of the three components (month, day, and year) into separate numeric values (with the help of `parseInt()`).
3. Compare each of the extracted values against the corresponding date, month, and year values returned by the date object's `getDate()`, `getMonth()`, and `getFullYear()` methods (adjusting for zero-based values of `getMonth()`).
4. If all three pairs of values match, the entry is apparently valid.

Listing 46-8 puts this action sequence to work in such a way as to make the user interface highly intuitive. The `validDate()` function receives a reference to the field being checked. A copy of the field's value is made into a date object, and its components are read. If any part of the date conversion or component extraction fails (because of improperly formatted data or unexpected characters), a helper message is displayed next to the input box. This code assumes that the user enters a date in the `mm/dd/yyyy` format, which is the sequence in which the `Date` object constructor expects its data. If the user enters `dd/mm/yyyy`, the validation fails for any day beyond the twelfth.

LISTING 46-8

Simple Date Validation

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Simple Date Validation</title>
      <style type="text/css">
         .vm_invalid
         {
            font-style:italic;
            color:red;
         }
         .vm_valid
         {
            font-style:italic;
            color:green;
         }
      </style>
      <script type="text/javascript">
         function validDate(fld)
         {
            var testMo, testDay, testYr, inpMo, inpDay, inpYr, msg;
            var inp = fld.value;
            status = "";
            var re = /\b\d{1,2}[\/-]\d{1,2}[\/-]\d{4}\b/;
               if (re.test(inp))
               {
```

```
         var delimChar = (inp.indexOf("/") != -1) ? "/" : "-";
         var delim1 = inp.indexOf(delimChar);
         var delim2 = inp.lastIndexOf(delimChar);
         mo = parseInt(inp.substring(0, delim1), 10);
         day = parseInt(inp.substring(delim1+1, delim2), 10);
         yr = parseInt(inp.substring(delim2+1), 10);
         var testDate = new Date(yr, mo-1, day);
         if (testDate.getDate() == day)
         {
             if (testDate.getMonth() + 1 == mo)
             {
                 if (testDate.getFullYear() == yr)
                 {
                     msg = "";
                 }
                 else
                 {
                     msg = "Invalid year.";
                 }
             }
             else
             {
                 msg = "Invalid month.";
             }
         }
         else
         {
             msg = "Invalid date.";
         }
      }
      else
      {
         msg = "Enter as mm/dd/yyyy.";
      }
   var validateMsg = document.getElementById("validateMsg");
      if (msg)
      {
         // there's a message, so something failed
         // change the validation message style and content
         validateMsg.className = "vm_invalid";
         validateMsg.innerHTML = msg;
         while(validateMsg.firstChild)
         {
            validateMsg.removeChild(validateMsg.firstChild);
         }
         validateMsg.appendChild(document.createTextNode(msg));
         // make sure focus stays with the input control
         fld.focus();
      }
      else
```

continued

LISTING 46-8 *(continued)*

    <hr />
    <form name="entryForm" onsubmit="return false">
      Enter any date (mm/dd/yyyy):
      <input type="text" id="test" name="startDate" onkeyup="validDate(this)" />
       <span id="validateMsg"></span>
    </form>
   </body>
</html>
```

Note

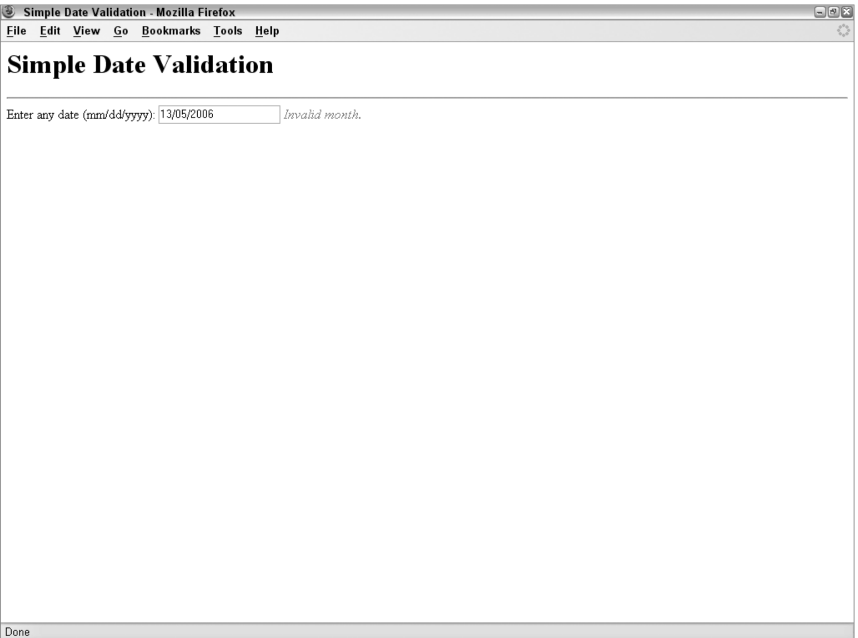
As handy as it may be, in a strict W3C approach to JavaScript, you wouldn't use the `innerHTML` property since it isn't officially part of the W3C standard. However, it is often too powerful a convenience property to ignore, as much of the code throughout this book is a testament. The book shows the W3C node manipulation alternative to `innerHTML` in some examples. Refer to Chapter 29, "Document and Body Objects," for a thorough explanation, and examples of the W3C alternative to `innerHTML`. ■

Although Figure 46.1 reveals the helper text next to the text input box, it doesn't show the effectiveness of real-time data validation. Note in the code how the `validDate()` function is tied to the `onkeyup` event, which causes the function to be called in response to every key press (key release, actually). The net effect is that the input is checked continuously as the date is entered, with helper text reflecting any problems along the way.

If this real-time validation approach has a familiar feel to it, then you're probably thinking about any of several modern applications that use Ajax, and similar validation techniques, to provide a richer data entry experience. In the case of Ajax, the real-time validation involves checking user input against data obtained from a server in an XML format, as opposed to simply performing client-side validity checks, as in this example.

FIGURE 46-1

Real-time data validation can dramatically improve any user interface.



Cross-Reference

For more on Ajax, check out Chapter 39, "Ajax, E4X, and XML Objects." ■

During batch validations, it is especially helpful to the user if your code — upon discovering an invalid entry — not only brings focus to the subject text field, but also selects the content for the user. By preselecting the entire field, you make it easy for the user to just retype the data into the field for another attempt (or to begin using the left and right arrow keys to move the insertion cursor for editing). The reverse type on the field text also helps bring attention to the field. (Not all operating systems display a special rectangle around a focused text field.) Form fields have both `focus()` and `select()` methods, which you should invoke for the subject field in that order.

In the case of real-time validation — which means you're validating user input literally as it is being entered — it is only necessary to keep the input control focused. Forcing the selection of the control wouldn't work because each subsequent key press would overwrite the previously entered text. The example in Listing 46-8 uses the focus-only technique to make sure the text input control retains focus as the text within it is validated in real time.

An Industrial-Strength Validation Solution

I had the privilege of working on a substantial intranet project that included dozens of forms, often with two or three different kinds of forms displayed simultaneously within a frameset. Data-entry accuracy was essential to the validity of the entire application. My task was to devise a data-entry validation strategy that not only ensured accurate entry of data types for the underlying (SQL) database, but also intelligently prompted users who made mistakes in their data entry.

Structure

From the start, the validation routines were to be in a client-side library linked in from an external `.js` file that would allow all forms to share the validation functions. Because there were multiple forms displayed in a frameset, it would prove too costly in download time and memory requirements to include the `validations.js` file in every frame's document. Therefore, the library was moved, to load in with the frameset. The `<script src="validations.js"></script>` tag set went in the Head portion of the framesetting document.

This logical placement presented a small challenge for the workings of the validations because there had to be two-way conversations between a validation function (in the frameset) and a form element (nested in a frame). The mechanism required that a reference to the frame containing the form element be passed as part of the validation routine so that the validation script could make corrections, automatic formatting, and erroneous field selections from the frameset document's script. (In other words, the frameset script needed a path back to the form element making the validation call.)

Dispatch mechanism

From the specification drawn up for the application, it is clear that there are more than two dozen specific types of validations across all the forms. Moreover, multiple programmers work on different forms. It is helpful to standardize the way validations are called, regardless of the validation type (number, string, date, phone number, and so on).

My idea was to create one `validate()` function that contained parameters for the current frame, the current form element, and the type of validation to perform. This would make it clear to anyone reading the code later that an event handler calling `validate()` performed validation, and that the details of the code were in the `validations.js` library file.

In `validations.js`, I converted the string name of a validation type into the name of the function that performs the validation, in order to make this idea work. As a bridge between the two, I created what I called a *dispatch lookup table* for all the primary validation routines that would be called from the forms. Each entry of the lookup table had a label consisting of the name of the validation and a method that invoked the function. Listing 46-9 shows an excerpt of the entire lookup table creation mechanism.

LISTING 46-9

Creating the Dispatch Lookup Table

```
/*
   Begin validation dispatching mechanism
*/
function dispatcher(validationFunc)
{
   this.doValidate = validationFunc;
}
var dispatchLookup = new Array();
dispatchLookup["isNotEmpty"] = new dispatcher(isNotEmpty);
dispatchLookup["isPositiveInteger"] = new dispatcher(isPositiveInteger);
dispatchLookup["isDollarsOnly8"] = new dispatcher(isDollarsOnly8);
dispatchLookup["isUSState"] = new dispatcher(isUSState);
dispatchLookup["isZip"] = new dispatcher(isZip);
dispatchLookup["isExpandedZip"] = new dispatcher(isExpandedZip);
dispatchLookup["isPhone"] = new dispatcher(isPhone);
dispatchLookup["isConfirmed"] = new dispatcher(isConfirmed);
dispatchLookup["isNY"] = new dispatcher(isNY);
dispatchLookup["isNum16"] = new dispatcher(isNum16);
dispatchLookup["isM90_M20Date"] = new dispatcher(isM90_M20Date);
dispatchLookup["isM70_0Date"] = new dispatcher(isM70_0Date);
dispatchLookup["isM5_P10Date"] = new dispatcher(isM5_P10Date);
dispatchLookup["isDateFormat"] = new dispatcher(isDateFormat);
```

Each entry of the array is assigned a `dispatcher` object, whose custom object constructor assigns a function reference to the object's `doValidate()` method. For these assignment statements to work, their corresponding functions must be defined earlier in the document. You can see some of these functions later in this section.

The link between the form elements and the dispatch lookup table is the `validate()` function, shown in Listing 46-10. A call to `validate()` requires a minimum of three parameters, as shown in the following example:

```
<input type="text" name="phone" size="10"
       onchange="parent.validate(window, this, 'isPhone')" />
```

The first parameter is a reference to the frame containing the document that is calling the function (passed as a reference to the current window). The second is a reference to the form control element itself (using the `this` operator). After that, you see one or more individual validation function names as strings. This design allows more than one type of validation to take place with each call to `validate()`. (For example, in case a field must check both for a data type and that the field is not empty.)

LISTING 46-10

Main Validation Function

```
// main validation function called by form event handlers
function validate(frame, field, method)
{
   gFrame = frame;
   gField =  window.frames[frame.name].document.forms[0].elements[field.name];
   var args = validate.arguments;
   for (i = 2; i < args.length; i++)
   {
      if (!dispatchLookup[args[i]].doValidate())
      {
         return false;
      }
   }
   return true;
}
```

In the `validate()` function, the frame reference is assigned to a global variable that is declared at the top of the `validations.js` file. Validation functions in this library need this information to build a reference back to a companion field required of some validations (explained later in this section). A second global variable contains a reference to the calling form element. Because the form element reference by itself does not contain information about the frame in which it lives, the script must build a reference out of the information passed as parameters. The reference must work from the framesetting document down to the frame, its form, and form element name. Therefore, I use the `frame` and `field` object references to get their respective names (within the `frames` and `elements` arrays) to assemble the text field's object reference; the resulting value is assigned to the `gField` global variable. I choose to use global variables in this case because passing these two values to numerous nested validation functions could be difficult to track reliably. Instead, the only parameter passed to specific validation functions is the value under test.

Next, the script creates an array of all arguments passed to the `validate()` function. A `for` loop starts with an index value of `2`, the third parameter containing the first validation function name. For each one, the named item's `doValidate()` method is called. If the validation fails, this function returns `false`; but if all validations succeed, this function returns `true`. Later you see that this function's returned value is the one that allows or disallows a form submission.

Sample validations

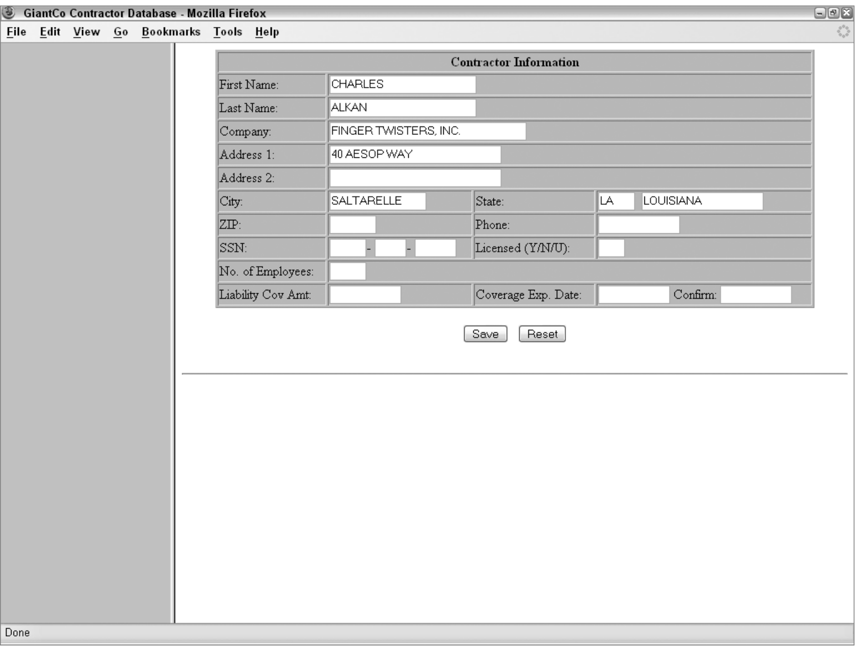
Above the dispatching mechanism in the `validations.js` are the validation functions themselves. Many of the named validation functions have supporting utility functions that other named validation functions often use. Because of the eventual large size of this library file (the production version was about 40KB), I organized the functions into two groups: the named

functions first, and the utility functions below them (but still before the dispatching mechanism at the bottom of the document).

To demonstrate how some of the more common data types are validated for this application, I show several validation functions and, where necessary, their supporting utility functions. Figure 46.2 shows a sample form that takes advantage of these validations. (You have a chance to try it later in this chapter.) When you are dealing with critical corporate data, you must go to extreme lengths to ensure valid data. And to help users see their mistakes quickly, you need to build some intelligence into validations where possible.

FIGURE 46-2

Sample form for industrial-strength validations.



U.S. state name

The design specification for forms that require entry of a U.S. state calls for entry of the state's two-character abbreviation. A companion field to the right displays the entire state name as user feedback verification. The `onchange` event handler not only calls the validation, but also feeds the focus to the field following the expanded state field, so users are less likely to type into it.

Before the validation can even get to the expansion part, it must first check that the entry is a valid, two-letter abbreviation. Because we need both the abbreviation and the full state name for this validation, we create an array of all the states, using each state abbreviation as the index label for each entry. Listing 46-11 shows that array creation.

LISTING 46-11

Creating a U.S. States Array

```
// States array
var USStates = new Array(51);
USStates["AL"] = "ALABAMA";
USStates["AK"] = "ALASKA";
USStates["AZ"] = "ARIZONA";
USStates["AR"] = "ARKANSAS";
USStates["CA"] = "CALIFORNIA";
USStates["CO"] = "COLORADO";
USStates["CT"] = "CONNECTICUT";
USStates["DE"] = "DELAWARE";
USStates["DC"] = "DISTRICT OF COLUMBIA";
USStates["FL"] = "FLORIDA";
USStates["GA"] = "GEORGIA";
USStates["HI"] = "HAWAII";
USStates["ID"] = "IDAHO";
USStates["IL"] = "ILLINOIS";
USStates["IN"] = "INDIANA";
USStates["IA"] = "IOWA";
USStates["KS"] = "KANSAS";
USStates["KY"] = "KENTUCKY";
USStates["LA"] = "LOUISIANA";
USStates["ME"] = "MAINE";
USStates["MD"] = "MARYLAND";
USStates["MA"] = "MASSACHUSETTS";
USStates["MI"] = "MICHIGAN";
USStates["MN"] = "MINNESOTA";
USStates["MS"] = "MISSISSIPPI";
USStates["MO"] = "MISSOURI";
USStates["MT"] = "MONTANA";
USStates["NE"] = "NEBRASKA";
USStates["NV"] = "NEVADA";
USStates["NH"] = "NEW HAMPSHIRE";
USStates["NJ"] = "NEW JERSEY";
USStates["NM"] = "NEW MEXICO";
USStates["NY"] = "NEW YORK";
USStates["NC"] = "NORTH CAROLINA";
USStates["ND"] = "NORTH DAKOTA";
USStates["OH"] = "OHIO";
USStates["OK"] = "OKLAHOMA";
USStates["OR"] = "OREGON";
USStates["PA"] = "PENNSYLVANIA";
USStates["RI"] = "RHODE ISLAND";
USStates["SC"] = "SOUTH CAROLINA";
USStates["SD"] = "SOUTH DAKOTA";
USStates["TN"] = "TENNESSEE";
```

```
USStates["TX"] = "TEXAS";
USStates["UT"] = "UTAH";
USStates["VT"] = "VERMONT";
USStates["VA"] = "VIRGINIA";
USStates["WA"] = "WASHINGTON";
USStates["WV"] = "WEST VIRGINIA";
USStates["WI"] = "WISCONSIN";
USStates["WY"] = "WYOMING";
```

The existence of this array comes in handy in determining if the user enters a valid, two-letter abbreviation. Listing 46-12 shows the actual `isUSState()` validation function that puts this array to work.

The function's first task is to assign an uppercase version of the entered value to a local variable (`inputStr`), which is the value being analyzed throughout the rest of the function. If the user enters something in the field (`length > 0`), but no entry in the `USStates` array exists for that value, the entry is not a valid state abbreviation. Time to go to work to help out the user.

LISTING 46-12

Validation Function for U.S. States

```
// input value is a U.S. state abbreviation; set entered value to all uppercase
// also set companion field (NAME="<xxx>_expand") to full state name
function isUSState()
{
   var inputStr = gField.value.toUpperCase();
     if (inputStr.length > 0 && USStates[inputStr] == null)
     {
       var msg = "";
       var firstChar = inputStr.charAt(0);
         if (firstChar == "A")
         {
            msg += "\n(Alabama = AL; Alaska = AK; Arizona = AZ; Arkansas = AR)";
         }
         if (firstChar == "D")
         {
            msg += "\n(Delaware = DE; District of Columbia = DC)";
         }
         if (firstChar == "I")
         {
            msg += "\n(Idaho = ID; Illinois = IL; Indiana = IN; Iowa = IA)";
         }
         if (firstChar == "M")
         {
            msg += "\n(Maine = ME; Maryland = MD; Massachusetts = MA;  " +
                   "Michigan = MI; Minnesota = MN; Mississippi = MS; " +
                   "Missouri = MO; Montana = MT)";
```

continued

LISTING 46-12 *(continued)*

```
         }
         if (firstChar == "N")
         {
            msg += "\n(Nebraska = NE; Nevada = NV)";
         }
      alert("Check the spelling of the state abbreviation." + msg);
      gField.focus();
      gField.select();
      return false;
   }
   gField.value = inputStr;
   var expandField =
      window.frames[gFrame.name].document.forms[0].elements[gField.name +
      "_expand"];
   expandField.value = USStates[inputStr];
   return true;
}
```

The function assumes that the user tried to enter a valid state abbreviation but either had incorrect source material or momentarily forgot a particular state's abbreviation. Therefore, the function examines the first letter of the entry. If that first letter is any one of the five identified as causing the most difficulty, a legend for all states beginning with that letter is assigned to the `msg` variable (for running on newer browsers only, a `switch` construction is preferred). An alert message displays the generic alert, plus any special legend, if one is assigned to the `msg` variable. When the user closes the alert, the field has focus and its text is selected. The function returns `false` at this point.

If, on the other hand, the abbreviation entry is a valid one, the field is handed the uppercase version of the entry. The script then uses the two global variables set in `validate()` to create a reference to the expanded display field (whose name must be the same as the entry field, plus `"_expand"`). That expanded display field is then supplied the `USStates` array entry value corresponding to the abbreviation label. All is well with this validation, so it returns `true`.

You can see here that the so-called validation routine is doing far more than simply checking the validity of the data. By communicating with the field, converting its contents to uppercase, and talking to another field in the form, a simple call to the validation function yields a lot of mileage.

Date validation

Many of the forms in this application have date fields. In fact, dates are an important part of the data maintained in the database behind the forms. All users of this application are familiar with standard date formats in use in the United States, so I don't have to worry about the possibility of cultural variations in date formats. Even so, I want the date entry to accommodate the common date formats, such as `mmddyyyy`, `mm/dd/yyyy`, and `mm-dd-yyyy` (as well as accommodate two-digit year entries spanning 1930 to 2029).

The plan also calls for going further in helping users enter dates within certain ranges. For example, a field used for a birth date (the listings are for medical professionals) should recommend dates starting no more than 90 years, and no less than 20 years, from the current date. And to keep this application running well into the future, the ranges should be on a sliding scale from the current year, no matter when it might be. Whatever the case, the date range validation is only a recommendation and not a transaction stopper.

Rather than create separate validation functions for each date field, I create a system of reusable validation functions for each date range (several fields on different forms require the same date ranges). Each one of these individual functions calls a single, generic date-validation function that handles the date-range checking. Listing 46-13 shows a few examples of these individual range-checking functions.

LISTING 46-13

Date Range Validations

```
// Date Minus 90/Minus 20
function isM90_M20Date()
{
   if (gField.value.length == 0)
   {
      return true;
   }
   var thisYear = getTheYear();
   return isDate((thisYear - 90),(thisYear - 20));
}

// Date Minus 70/Minus 0
function isM70_0Date()
{
   if (gField.value.length == 0)
   {
      return true;
   }
   var thisYear = getTheYear();
   return isDate((thisYear - 70),(thisYear));
}

// Date Minus 5/Plus 10
function isM5_P10Date()
{
   if (gField.value.length == 0)
   {
      return true;
   }
   var thisYear = getTheYear();
   return isDate((thisYear - 5),(thisYear + 10));
}
```

The naming convention I create for the functions includes the two range components relative to the current date. A letter “M” means the range boundary is minus a number of years from the current date; “P” means the range is plus a number of years. If the boundary should be the current year, a zero is used. Therefore, the `isM5_P10Date()` function performs range checking for boundaries between five years before and 10 years after the current year.

Before performing any range checking, each function makes sure there is some value to validate. If the field entry is empty, the function returns `true`. This is fine here because dates are not required when the data is unknown.

Next, the functions get the current four-digit year. The code here had to work originally with browsers that did not have the `getFullYear()` method available yet. Therefore, the Y2K fix described in Chapter 17, “The Date Object,” was built into the application:

```
function getTheYear()
{
   var thisYear = (new Date()).getYear();
   thisYear = (thisYear < 100) ? thisYear + 1900 : thisYear;
   return thisYear;
}
```

The final call from the range validations is to a common `isDate()` function, which handles not only the date range validation but also the validation for valid dates (for example, making sure that September has only 30 days). Listing 46-14 shows this monster-sized function. Because of the length of this function, I interlace commentary within the code listing.

LISTING 46-14

Primary Date Validation Function

```
// date field validation (called by other validation functions that specify
// minYear/maxYear)
function isDate(minYear,maxYear,minDays,maxDays)
{
   var inputStr = gField.value;
```

To make it easier to work with dates supplied with delimiters, I first convert hyphen delimiters to slash delimiters. The pre-regular expression `replaceString()` function is the same one described in Chapter 15; it is located in the utility functions part of the `validations.js` file.

```
   // convert hyphen delimiters to slashes
   while (inputStr.indexOf("-") != -1)
   {
      inputStr = replaceString(inputStr,"-","/");
   }
```

For validating whether the gross format is OK, I check whether zero or two delimiters appear. If the value contains only one delimiter, the overall formatting is not acceptable. The error alert shows models for acceptable date-entry formats.

```
    var delim1 = inputStr.indexOf("/");
    var delim2 = inputStr.lastIndexOf("/");
       if (delim1 != -1 && delim1 == delim2)
       {
         // there is only one delimiter in the string
         alert("The date entry is not in an acceptable format.\n\nYou can
  enter dates in the following formats: mmddyyyy, mm/dd/yyyy, or mm-dd-yyyy.
  (If the month or date data is not available, enter \'01\' in the
  appropriate location.)");
         gField.focus();
         gField.select();
         return false;
       }
```

If there are two delimiters, I tear apart the string into components for month, day, and year. Because two-digit entries can begin with zeros, I make sure the `parseInt()` functions specify base-10 conversions.

```
       if (delim1 != -1)
       {
         // there are delimiters; extract component values
         var mm = parseInt(inputStr.substring(0,delim1),10);
         var dd = parseInt(inputStr.substring(delim1 + 1,delim2),10);
         var yyyy = parseInt(inputStr.substring(delim2 + 1, inputStr.length),10);
```

For no delimiters, I tear apart the string and assume two-digit entries for the month and day, and two or four digits for the year.

```
       }
       else
       {
          // there are no delimiters; extract component values
          var mm = parseInt(inputStr.substring(0,2),10);
          var dd = parseInt(inputStr.substring(2,4),10);
          var yyyy = parseInt(inputStr.substring(4,inputStr.length),10);
       }
```

The `parseInt()` functions reveal whether any entry is not a number by returning `NaN`, so I check whether any of the three values is not a number. If so, an alert signals the formatting problem and supplies acceptable models.

```
          if (isNaN(mm) || isNaN(dd) || isNaN(yyyy))
          {
            // there is a non-numeric character in one of the component values
            alert("The date entry is not in an acceptable format.\n\nYou can
                   enter dates in the following formats: mmddyyyy, mm/dd/yyyy, or

                   mm-dd-yyyy.");
            gField.focus();
            gField.select();
            return false;
          }
```

Next, I perform some gross range validation on the month and date to make sure that months are entered from 1 to 12 and dates from 1 to 31. I take care of aligning exact month lengths later.

```
        if (mm < 1 || mm > 12)
        {
           // month value is not 1 thru 12
           alert("Months must be entered between the range
                  of 01 (January) and 12 (December).");
           gField.focus();
           gField.select();
           return false;
        }
        if (dd < 1 || dd > 31)
        {
           // date value is not 1 thru 31
           alert("Days must be entered between the range of 01 and a
                  maximum of 31 (depending on the month and year).");
           gField.focus();
           gField.select();
           return false;
        }
```

Before getting too deep into the year validation, I convert any two-digit year within the specified range to its four-digit equivalent.

```
        // validate year, allowing for checks between year ranges
        // passed as parameters from other validation functions
        if (yyyy < 100)
        {
           // entered value is two digits, which we allow for 1930-2029
           if (yyyy >= 30)
           {
              yyyy += 1900;
           }
           else
           {
              yyyy += 2000;
           }
        }

  var today = new Date();
```

I designed this function to work with a pair of year ranges or date ranges (so many days before and/or after today). If the function is passed date ranges, the first two parameters must be passed as `null`. This first batch of code works with the date ranges (because the `minYear` parameter is `null`).

```
  if (!minYear)
  {
     // function called with specific day range parameters
     var dateStr = new String(monthDayFormat(mm) +
                              "/" + monthDayFormat(dd) +
```

```
                            "/" + yyyy);
      var testDate = new Date(dateStr);
         if (testDate.getTime() < (today.getTime() +
            (minDays * 24 * 60 * 60 * 1000)))
         {
            alert("The most likely range for this entry begins " + minDays +
                  " days from today.");
         }
         if (testDate.getTime() > today.getTime() +
             (maxDays * 24 * 60 * 60 * 1000))
         {
            alert("The most likely range for this entry ends " + maxDays +
                  " days from today.");
         }
   }
```

You can also pass hard-wired, four-digit years as parameters. The following branch compares the entered year against the range specified by those passed year values.

```
   else if (minYear && maxYear)
   {
      // function called with specific year range parameters
      if (yyyy < minYear || yyyy > maxYear)
      {
         // entered year is outside of range passed from calling function
         alert("The most likely range for this entry is between the years " +
               minYear + " and " + maxYear +
               ".  If your source data indicates a date outside
                   this range, then enter that date.");
      }
   }
   else
```

For year parameters passed as positive or negative year differences, I begin processing by getting the four-digit year for today's date. Then I compare the entered year against the passed range values. If the entry is outside the desired range, an alert reveals the preferred year range within which the entry should fall. But the function does not return any value here because an out-of-range value is not critical for this application.

```
   {
      // default year range (now set to (this year - 100) and (this year + 25))
      var thisYear = today.getYear();
         if (thisYear < 100)
         {
            thisYear += 1900;
         }
      if (yyyy < minYear || yyyy > maxYear)
      {
         alert("It is unusual for a date entry to be before " + minYear +
               " or after " + maxYear + ". Please verify this entry.");
      }
   }
```

One more important validation is to make sure that the entered date is valid for the month and year. Therefore, the various date components are passed to functions to check against month lengths, including the special calculations for the varying length of February. Listing 46-15 shows these functions. The alert messages they display are smart enough to inform the user what the maximum date is for the entered month and year.

```
if (!checkMonthLength(mm,dd))
{
   gField.focus();
   gField.select();
   return false;
}
if (mm == 2)
{
   if (!checkLeapMonth(mm,dd,yyyy))
   {
      gField.focus();
      gField.select();
      return false;
   }
}
```

The final task is to reassemble the date components into a format that the database wants for its date storage, and stuff it into the form field. If the user enters an all-number or hyphen-delimited date, it is automatically reformatted and displayed as a slash-delimited, four-digit-year date.

```
   // put the Informix-friendly format back into the field
   gField.value = monthDayFormat(mm) + "/" + monthDayFormat(dd) + "/" + yyyy;
   return true;
}
```

A utility function, invoked multiple times in the previous function, converts a single-digit month or day number to a string that might have a leading zero:

```
// convert month or day number to string,
// padding with leading zero if needed
function monthDayFormat(val)
{
   if (isNaN(val) || val == 0)
   {
      return "01";
   }
   else if (val < 10)
   {
      return "0" + val;
   }
   return "" + val;
}
```

LISTING 46-15

Functions to Check Month Lengths

```
// check the entered month for too high a value
function checkMonthLength(mm,dd)
{
   var months = new
Array("","January","February","March","April","May","June","July",
         "August","September","October","November","December");
   if ((mm == 4 || mm == 6 || mm == 9 || mm == 11) && dd > 30)
   {
      alert(months[mm] + " has only 30 days.");
      return false;
   }
   else if (dd > 31)
   {
      alert(months[mm] + " has only 31 days.");
      return false;
   }
   return true;
}

// check the entered February date for too high a value
function checkLeapMonth(mm,dd,yyyy)
{
   if (yyyy % 4 > 0 && dd > 28)
   {
      alert("February of " + yyyy + " has only 28 days.");
      return false;
   }
   else if (dd > 29)
   {
      alert("February of " + yyyy + " has only 29 days.");
      return false;
   }
   return true;
}
```

This is a rather extensive date-validation routine, but it demonstrates how thorough you must be when a database relies on accurate entries. The more prompting and assistance you can give to users to ferret out problems with invalid entries, the happier those users will be.

Cross-confirmation fields

The final validation type covered here is probably not a common request, but it demonstrates how the dispatch mechanism, created at the outset, expands so easily to accommodate this enhanced client request. The situation is that some fields (mostly dates in this application) are deemed critical pieces of data because this data triggers other processes from the database. As

a further check to ensure entry of accurate data, a number of values are set up for entry twice in separate fields — and the fields have to match exactly. In many ways, this mirrors the two passes you are often requested to make when you set a password: enter two copies and let the computer compare them to make sure you typed what you intended to type.

I established a system that places only one burden on the many programmers working on the forms: although you can name the primary field anything you want (to help alignment with database column names, for example), you must name the secondary field the same plus `"_xcfm"` — which stands for *cross-confirm*. Then, pass the `isConfirmed` validation name to the `validate()` function after the date range validation name, as follows:

```
onchange="parent.validate(window, this, 'isM5_P10Date','isConfirmed')"
```

In other words, after the entered value is initially checked against a required date range, the `isConfirmed()` validation function compares the fully vetted, properly formatted date in the current field against its parallel entry.

Listing 46-16 shows the one function in `validations.js` that handles the confirmation in both directions. After assigning a copy of the entry field value to the `inputStr` variable, the function next sets a Boolean flag (`primary`) that lets the rest of the script know if the entry field is the primary or secondary field. If the string `"_xcfm"` is missing from the field name, the entry field is the primary field.

For the primary field branch, the script assembles the name of the secondary field and compares the content of the secondary field's value against the `inputStr` value. If they are not the same, the user is entering a new value into the primary field, and the script empties the secondary field to force reentry to verify that the user enters the proper data.

For the secondary field entry branch, the script assembles a reference to the primary field by stripping away the final five characters of the secondary field's name. (I could use the `lastIndexOf()` string method, instead of the longer way involving the string's length; but after experiencing so many platform-specific problems with `lastIndexOf()` in earlier browsers, I decided to play it safe.) Finally, the two values are compared, with an appropriate alert displayed if they don't match.

LISTING 46-16

Cross-Confirmation Validation

```
// checks an entry against a parallel, duplicate entry to
// confirm that correct data has been entered
// Parallel field name must be the main field name plus "_xcfm"
function isConfirmed()
{
   var inputStr = gField.value;
   // flag for whether field under test is primary (true) or confirmation field
   var primary = (gField.name.indexOf("_xcfm") == -1);
      if (primary)
```

```
      {
         // clear the confirmation field if primary field is changed
         var xcfmField =
 window.frames[gFrame.name].document.forms[0].elements[gField.name + "_ xcfm"];
         var xcfmValue = xcfmField.value;
            if (inputStr != xcfmValue)
            {
               xcfmField.value = "";
               return true;
            }
      }
      else
      {
         var xcfmField =
 window.frames[gFrame.name].document.forms[0].elements[gField.name.substring(0,
(gField.name.length-5))];
         var xcfmValue = xcfmField.value;
            if (inputStr != xcfmValue)
            {
               alert("The main and confirmation entry field contents do not
                     match. Both fields must have EXACTLY the same content to
                     be accepted by the database.");
               gField.focus();
               gField.select();
               return false;
            }
      }
   return true;
}
```

Last-minute check

Every validation event handler is designed to return `true` if the validation succeeds. This comes in handy for the batch validation that performs one final check of the entries triggered by the form's `onsubmit` event handler. This event handler calls a `checkForm()` function and passes the form control object as a parameter. That parameter helps create a reference to the form element that is passed to each validation function.

Because successful validations return `true`, you can nest consecutive validation tests so that the most nested statement of the construction is `return true` after all validations have succeeded. The form's `onsubmit` event handler is as follows:

```
onsubmit="return checkForm(this)"
```

The following code fragment is an example of a `checkForm()` function. A separate `isDateFormat()` validation function, called here, checks whether the field contains an entry in the proper format — meaning that it has likely survived the range checking and format shifting of the real-time validation check.

```
function checkForm(form)
{
   if (parent.validate(window, form.birthdate, "isDateFormat"))
   {
      if (parent.validate(window, form.phone, "isPhone"))
      {
         if (parent.validate(window, form.name, "isNotEmpty"))
         {
            return true;
         }
      }
   }
   return false;
}
```

If any one validation fails, the field is given focus, and its content is selected (controlled by the individual validation function). In addition, the `checkForm()` function returns `false`. This, in turn, cancels the form submission.

Try it out

Listing 46-17 is a definition for a frameset that not only loads the validation routines described in this section, but also loads a page with a form that exercises the validations in real-time and batch mode, just prior to submission. The form appears earlier in this chapter in Figure 46.2.

LISTING 46-17

Frameset for Trying validation.js

```
<html>
   <head>
      <title>GiantCo Contractor Database</title>
      <script type="text/javascript" src="validation.js">
      </script>
      <script type="text/javascript">
         function blank()
         {
            return "<html><body bgcolor='lightsteelblue'><\/body><\/html>";
         }
      </script>
   </head>
   <frameset frameborder="" cols="20%,80%">
      <frame name="toc" src="javascript:parent.blank()" />
      <frame name="entries" src="jsb46-18.html" />
   </frameset>
</html>
```

The application scenario for the form is the entry of data into a company's contractor database. Some fields are required, and the date field must be cross-confirmed with a second entry of the same data. If the form passes its final validation prior to submission, the form reloads, and you see a readout of the form data that would have been submitted from the previous form, had the `action` been set to a server application URI.

Plan for Data Validation

We devoted this entire chapter to the subject of data validation because it represents the one area of error-checking that almost all JavaScript authors should be concerned with. If your scripts (client-side or server-side) perform processing on user entries, you want to prevent script errors at all costs.

CHAPTER

Scripting Java Applets and Plug-Ins

IN THIS CHAPTER

Communicating with Java applets from scripts

Accessing scripts and objects from Java applets

Controlling scriptable plug-ins

Netscape was the first to implement the facility enabling JavaScript scripts, Java applets, and plug-ins to communicate with each other under one technology umbrella, called the NPAPI (Netscape Plugin Application Programming Interface). Microsoft met the challenge and implemented a large part of that technology for WinIE4, but of course without using the Netscape-trademarked name for the technology. The name is a convenient way to refer to the capability, so you find it used throughout this chapter, applying to any browser that supports such facilities. This chapter focuses on the scripting side of the NPAPI: approaching applets and plug-ins from scripts and accessing scripts from Java applets.

Except for the part about talking to scripts from inside a Java applet, we don't assume you have any knowledge of Java programming. The primary goal here is to help you understand how to control applets and plug-ins (including ActiveX controls in WinIE) from your scripts. If you're in a position to develop specifications for applets, you learn what to ask of your Java programmers. But if you are also a Java applet programmer, you learn the necessary skills to get your applets in touch with HTML pages and scripts.

NPAPI Overview

Before you delve too deeply into the subject, you should be aware that NPAPI features are not available in Internet Explorer for Macintosh and early versions of Safari. Although unfortunate, this shouldn't prove to be an enormous hindrance as you contemplate a cross-browser application that utilizes the NPAPI. The bigger issue that emerges is between Internet Explorer and Mozilla, as the former prefers ActiveX controls, whereas the latter leans toward Java applets for similar functionality.

Whether you use the NPAPI to communicate with a Java applet or an ActiveX control, the advantage to you as an author is that the NPAPI extends the document object model to include objects and data types that are not a part of the HTML world. HTML, for example, does not have a form control element that displays real-time stock ticker data; nor does HTML have the capability to treat a sound file like anything more than a URL to be handed off to a helper application. With the NPAPI, however, your scripts can treat the applet that displays the stock ticker as an object whose properties and methods can be modified after the applet loads; scripts can also tell an audio clip when to play or pause by controlling the plug-in that manages the incoming sound file.

Why Control Java Applets?

A question we often hear from experienced Java programmers is, "Why bother controlling an applet via a script when you can build all the interactivity you want into the applet itself?" This question is valid if you come from the Java world, but it takes a viewpoint from the HTML and scripting world to fully answer it.

Java applets exist in their own private rectangles, remaining largely oblivious to the HTML surroundings on the page. Applet designers who don't have extensive web page experience tend to regard their applets as the center of the universe rather than as components of HTML pages.

As a scripter, on the other hand, you may want to use those applets as powerful components to spiff up the overall presentation. Using applets as prewritten objects enables you to make simple changes to the HTML pages — including the geographic layout of elements and images — at the last minute, without having to rewrite and recompile Java program code. If you want to update the look with an entirely new graphical navigation or control bar, you can do it directly via HTML and scripting.

When it comes to designing or selecting applets for inclusion into our scripted page, we prefer using applet interfaces that confine themselves to data display, putting any control of the data into the hands of the script, rather than using onscreen buttons in the applet rectangle. We believe this setup enables much greater last-minute flexibility in the page design — not to mention consistency with HTML form element interfaces — than putting everything inside the applet rectangle.

A Little Java

If you plan to look at a Java applet's scripted capabilities, you can't escape the need to know a little about Java applets and some terminology. The discussion goes more deeply into object orientation than you have seen with JavaScript, but we'll try to be gentle.

Java building blocks classes

One part of Java that closely resembles JavaScript is that Java programming deals with objects, much the way JavaScript deals with a page's objects. Java objects, however, are not the familiar HTML objects, but rather more basic building blocks, such as tools that draw to the screen and data streams. But both languages also have some non-HTML kinds of objects in common: strings, arrays, numbers, and so on.

While not technically correct, we can say that every Java object is known as a *class* — a term from the object-oriented world. When you use a Java compiler to generate an applet from its source code, a `.class` file is generated, which happens to incorporate many Java classes, such as strings, image areas, font objects, and the like. This file is the one you specify for the `code` attribute of the `<object>` tag (the `<applet>` tag was used in older browsers but is now deprecated).

Java methods

Most JavaScript objects have methods attached to them that define what actions the objects are capable of performing. A string object, for instance, has the `toUpperCase()` method that converts the string to all uppercase letters. Java classes also have methods. Many methods are predefined in the base Java classes embedded inside the virtual machine. But inside a Java applet, the author can write methods that either override the base method or are used exclusively in the applet's class. These methods are, in a way, like the functions you write in JavaScript for a page.

Not all methods, however, are created the same. Java lets authors determine how visible a method is to outsiders. The types of methods that you, as a scripter, are interested in are the ones declared as public methods. You can access such methods from JavaScript via a syntax that falls very much in line with what you already know. For example, a common public method in applets stops an applet's main process. Such a Java method may look like this:

```
@Override
public void stop() {
   if(thread != null) {
      thread = null;
   }
}
```

The `void` keyword simply means that this method does not return any values (compilers need to know this stuff). Assuming that you have one applet loaded in your page, the JavaScript call to this applet method is

```
document.applets[0].stop();
```

Listing 47-1 shows how all this works with the `<object>` tag for a scriptable digital clock applet example. The script includes calls to two of the applet's methods: to stop and to start the clock.

The syntax for accessing the method (in the two functions) is just like JavaScript in that the references to the applet's methods include the applet object (`clock1` in the example), which is contained by the `document` object.

LISTING 47-1

Stopping and Starting an Applet (XHTML)

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>A Script That Could Stop a Clock</title>
      <script type="text/javascript">
         function pauseClock()
         {
            // get ref to second object for non-WinIE
            var applet = (document.clock1.length) ? document.clock1[1] :
                           document.clock1;
            applet.stop();
         }
         function restartClock()
         {
            var applet = (document.clock1.length) ? document.clock1[1] :
                           document.clock1;
            applet.start();
         }
      </script>
   </head>
   <body>
      <h1>Simple control over an applet</h1>
      <hr />

LISTING 47-1 *(continued)*

```
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique employed throughout the code in this chapter and much of the book is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects."** ■

Even though the `<object>` tag is supported by all modern browsers, its specific usage across browsers isn't exactly standard. It's necessary to work a little markup magic to use modern `<object>` tags that operate in IE, Mozilla-based, and WebKit-based browsers. The difficulty arises in the way the browsers specify some attribute or parameter values for Java applets. Listing 47-1 reveals how to embed an applet into a document with the `<object>` tag that works simultaneously in the different browsers.

An important feature of the listing is a Microsoft proprietary markup feature called *conditional comments* (`http://msdn.microsoft.com/en-us/library/ms537512%28VS.85%29.aspx`). These HTML comment tags, with their special comment text, allow IE to skip over HTML markup (although if the Microsoft conditional comments are not used, IE will still render correctly; this is just a cleaner, best practices, approach). In the listing, only the first `<object>` tag is rendered in WinIE; other browsers load both, but do not load the applet in the first tag because the attribute and parameter values are not in the format that they require for loading a Java applet. In addition to the tag markup differences, note that the functions controlling the applet create references to the applet object differently. Browsers other than IE have two `object` elements with the same name to deal with, meaning that there is an array of objects with that name; thus the script pulls a reference to the second one when two are detected.

Java applet "properties"

The Java equivalents of JavaScript object properties can be called properties in Java as well, but in reality are public accessor and mutator methods, commonly called *getters* and *setters*. These methods allow for reading and writing the corresponding private attribute of the class. If you have access to some Java source code, you can recognize these getters and setters by their names:

```
private String fontName;
...
public String getFontName() {
   return fontName;
}

public void setFontName(String fontName) {
   this.fontName = fontName;
}
```

In the preceding code, you'll notice that the private attribute `fontName` is associated with its corresponding getters and setters via a standard JavaBean naming convention: camel case. As a JavaScript programmer, you would be using these methods to indirectly access the corresponding private attribute. Getters and setters are used because the use of public instance attributes is considered a violation of object encapsulation and is seriously frowned upon by the Java programmer.

Java authors must specify a method's data type when declaring any method that returns a value. That's why the `String` data type appears in the preceding example.

Your scripts can access these variables with the same kind of syntax that you use to access JavaScript object properties. In order to access the `fontName` field, you would execute its corresponding getter and setter, as shown in the following example:

```
var theFont = document.applets[0].getFontName();
document.applets[0].setFontName("courier");
```

Scripting Applets in Real Life

Because the purpose of scripting an applet is to gain access to the inner sanctum of a compiled program, the program should be designed to handle such rummaging around by scripters. If you can't acquire a copy of the source code or don't have any other documentation about the scriptable parts of the applet, you may have a difficult time knowing what to script and how to do it.

Getting to scriptable methods

If you write your own applets or are fortunate enough to have the source code for an existing applet, the safest way to modify the applet variable settings or the running processes is through applet methods. An applet designed for scriptability should have a number of methods defined that enable you to make scripted changes to private variable values.

To view a sample of an applet designed for scriptability, open the Java source code file for Listing 47-2 from the CD-ROM. A portion of that program listing is shown in the following example.

LISTING 47-2

}
```

The methods shown in Listing 47-2 are defined specifically for scripted access. In this case, they safely stop the applet thread before changing any values. The last method is one we recommend to applet authors. The method returns a small bit of documentation containing information about the kind of methods that the applet likes to have scripted and what you can have as the passed parameter values.

Now that you see the amount of scriptable information in this applet, look at Listing 47-3, which takes advantage of that scriptability by providing several HTML form elements as user controls for the clock. The results are shown in Figure 47-1.

LISTING 47-3

A More Fully Scripted Clock

```
<!DOCTYPE html>
<html>
   <head>
     <meta http-equiv="content-type" content="text/html;charset=utf-8">
     <title>Clock with Lots o' Widgets</title>
     <script type="text/javascript">
       function setTimeZone(popup)
       {
          var choice = popup.options[popup.selectedIndex].value;
          var applet = (document.clock2.length) ? document.clock2[1] :
                        document.clock2;
          applet.setTimeZone(choice);
       }

       function setColor(form)
       {
          var bg =
form.backgroundColor.options[form.backgroundColor.selectedIndex].value;
          var fg =
form.foregroundColor.options[form.foregroundColor.selectedIndex].value;
          var applet = (document.clock2.length) ? document.clock2[1] :
document.clock2;
          applet.setColor(bg, fg);
       }

       function setFont(form)
       {
          var fontName = form.theFont.options[form.theFont.selectedIndex].value;
          var fontStyle =
 form.theStyle.options[form.theStyle.selectedIndex].value;
          var fontSize = form.theSize.options[form.theSize.selectedIndex].value;
          var applet = (document.clock2.length) ? document.clock2[1] :
 document.clock2;
          applet.setFont(fontName, fontStyle, fontSize);
       }
       function getAppletInfo(form)
       {
          var applet = (document.clock2.length) ? document.clock2[1] :
document.clock2;
          form.details.value = applet.getInfo();
       }

       function showSource()
       {

Very little of the code here controls the applet — only the handful of functions near the top. The rest of the code makes up the HTML user interface for the form element controls. After you open this document from the CD-ROM, be sure to click the Applet Info button to see the methods that you can script and the way that the parameter values from the JavaScript side match up with the parameters on the Java method side.

Applet limitations

Because of concerns about security breaches via the NPAPI, Mozilla clamps down on some powers that would be nice to have via a scripted applet. The most noticeable barrier is the one that prevents applets from accessing the network under scripted control. Therefore, even though a Java applet has no difficulty reading or writing text files from the server, such capabilities — even if built into an applet of your own design — won't be carried out if triggered by a JavaScript call to the applet. However, signed scripts (see Chapter 49) and applets can break through these security barriers after the user has given explicit permission for them to do so.

FIGURE 47-1

Scripting more of the ScriptableClock applet.

Faceless applets

Until the NPAPI came along, Java applets were generally written to show off data and graphics — to play a big role in the presentation on the page. But if you prefer to let an applet do the heavy algorithmic lifting for your pages, while the HTML form elements and images (or Dynamic HTML facilities) do the user interface, you essentially need what we call a *faceless applet*.

The method for embedding a faceless applet into your page is the same as embedding any applet: Use the `<object>` tag. For a faceless applet, specify only 1 pixel for both the `height` and `width` attributes (0 has strange side effects). This setting creates a dot on the screen, which, depending on your page's background color, may be completely invisible to page visitors. Place it at the bottom of the page, if you like.

To show how nicely this method can work, Listing 47-4 provides the Java source code for a simple applet that retrieves a specific text file, and stores the results in a Java variable available for fetching by the JavaScript shown in Listing 47-5. The HTML even automates the loading process by triggering the retrieval of the Java applet's data from an `onload` event handler.

LISTING 47-4

Java Applet Source Code

```
import java.net.*;
import java.io.*;

public class FileReader extends java.applet.Applet implements Runnable {

   private Thread thread;
   private URL url;
   private String output;
   private String fileName = "Bill of rights.txt";

   public void getFile(String fileName) throws IOException {
      String result = null;
      String line = null;
      InputStream connection = null;
      DataInputStream dataStream = null;
      StringBuffer buffer = new StringBuffer();

      try {
         url = new URL(getDocumentBase(), fileName);
         connection = url.openStream();
         dataStream = new DataInputStream(new BufferedInputStream(connection));

         while ((line = dataStream.readLine()) != null) {
            buffer.append(line + "\n");
         }
         result = buffer.toString();
      } catch (MalformedURLException e) {
         result = "AppletError " + e;
      } catch (IOException e) {
         result = "AppletError: " + e;
      } finally {
         if (dataStream != null) {
            dataStream.close();
         }
         if (connection != null) {
            connection.close();
         }
      }
      output = result;
   }

   public String fetchText() {
      return output;
   }

   @Override
   public void init() {
   }
```

```
    @Override
    public void start() {
       if (thread == null) {
          thread = new Thread(this);
          thread.start();
       }
    }

    @Override
    public void stop() {
       if (thread != null) {
          thread = null;
       }
    }

    public void run() {
       try {
          getFile(fileName);
       } catch (IOException e) {
          output = "AppletError: " + e;
       }
    }
}
```

All the work of actually retrieving the file is performed in the `getFile()` method (which runs immediately after the applet loads). Notice that the name of the file to be retrieved, `Bill of Rights.txt`, is stored as a variable near the top of the code, making it easy to change for a recompilation, if necessary. You can also modify the applet to accept the filename as an applet parameter, specified in the HTML code. Meanwhile, the only hook that JavaScript needs is the one public method called `fetchText()`, which merely returns the value of the output variable, which in turn holds the file's contents.

This Java source code must be compiled into a Java class file (already compiled and included on the CD-ROM as `FileReader.class`) and placed in the same directory as the HTML file that loads this applet. Also, no explicit pathname for the text file is supplied in the source code, so the text file is assumed to be in the same directory as the applet.

LISTING 47-5

HTML Asking Applet to Read Text File

```

     <script type="text/javascript">
       function getFile(form)
```

continued

LISTING 47-5 *(continued)*

```
        {
         var applet = (document.readerApplet.length) ?
                        document.readerApplet[1] : document.readerApplet;
         var output = applet.fetchText();
           form.fileOutput.value = output;
        }
        function autoFetch()
        {
         var applet = (document.readerApplet.length) ? document.readerApplet[1] :
                        document.readerApplet;
         var output = applet.fetchText();
              if (output != null)
              {
                 document.forms[0].fileOutput.value = output;
                 return;
              }
         var t = setTimeout("autoFetch()",1000);
        }
       </script>
    </head>
    <body onload="autoFetch()">
       <h1>Text from a text file...</h1>
       <form name="reader">
          <input type="button" value="Get File" onclick="getFile(this.form)" />
          <p>
             <textarea name="fileOutput" rows="10" cols="60" wrap="hard">
             </textarea>
          </p>
          <p>
             <input type="Reset" value="Clear" />
          </p>
       </form>
       <object name="readerApplet"
 classid="clsid:8AD9C840-044E-11D1-B3E9-00805F499D93"
              codebase=
       "http://java.sun.com/update/1.5.0/jinstall-1_5_0-windows-i586.cab"
              width="1" height="1">
          <param name="code" value="FileReader.class" />
          <!--[if !IE]> Non-WinIE Browsers -->
             <object name="readerApplet" classid="java:FileReader.class"
                     type="application/x-java-applet"
                     width="1" height="1">
             </object>
          <!-- <![endif]-->
       </object>
    </body>
 </html>
```

Because an applet is usually the last detail to finish loading in a document, you can't use an applet to generate the page immediately. At best, an HTML document can display a pleasant welcome screen while the applet finishes loading and running whatever it does to prepare data for the page's form elements. Fortunately for modern browsers, the page can then be dynamically constructed out of the retrieved data. Notice in Listing 47-5 that the `onload` event handler calls a function that checks whether the applet has supplied the requested data. If not, the same function is called repeatedly in a timer loop, until the data is ready and the textarea can be set. The `<object>` tag is located at the bottom of the Body, set to 1 pixel square — invisible to the user. No user interface exists for this applet, so you have no need to clutter up the page with any placeholders or bumper stickers.

Figure 47-2 shows the page generated by the HTML and the applet working together. The Get File button is merely a manual demonstration of calling the same applet method that the `onload` event handler calls.

FIGURE 47-2

The page with text retrieved from a server file.

A faceless applet may be one way for web authors to hide what may otherwise be JavaScript code that is open to any visitor's view. For example, if you want to deliver a small data collection lookup with a document, but don't want the array of data to be visible in the JavaScript code, you can create the array and lookup functionality inside a faceless applet. Then, use form controls and JavaScript to act as query entry and output display devices (or to dynamically generate a table). Because the parameter values passed between JavaScript and Java applets must be string, numeric, or Boolean values, you won't be able to pass arrays without performing some amount

of conversion within either the applet or the JavaScript code (JavaScript's `string.split()` and `array.join()` methods help a great deal here).

Data type conversions

The example in this chapter does not pass any parameters to the applet's methods, but you are free to do so. You need to pay attention to the way in which values are converted to Java data types. JavaScript strings and Boolean values are converted to Java String and Boolean objects. All JavaScript numbers, regardless of their subtype (that is, integer or floating-point number), are converted to `Float` objects. Therefore, if a method must accept a numeric parameter from a script, the parameter variable in the Java method must be defined as a `Float` type.

The distinction between JavaScript string values and string objects can impact data being passed to an applet. If an applet method requires a string object as a parameter, you may have to explicitly convert a JavaScript string value (for example, a string from a text field) to a string object via the `new String()` constructor (see Chapter 15).

You can also pass references to objects, such as form control elements. Such objects get wrapped with a `JSObject` type (see the discussion about this class later in the chapter). Therefore, parameter variables must be established as type `JSObject` (and the `netscape.javascript.JSObject` class must be imported into the applet).

Applet-to-Script Communication

The flip side of scripted applet control is having an applet control both script and HTML content in the page. Before you undertake this avenue in page design, you must bear in mind that any calls made from the applet to the page are hard-wired for the specific scripts and HTML elements in the page. If this level of tight integration and dependence suits the application, the link up will be successful.

Note

The discussion of applet-to-script communication assumes you have experience writing Java applets. We use Java jargon quite freely in this discussion. ■

What your applet needs

Most modern browsers come with a zipped set of special class files tailored for use in the NPAPI. For Mozilla, the class files are located in an archive called `-plugin.jar` (Windows) or `JavaPluginCocoa.bundle` (Mac). Use the file search facility of the OS to locate the relevant file on your system. Microsoft versions of these class files are usually located in `C:\Program Files\Java\jre6\lib`. If you don't find `jre6`, look for `jre5`. The browser must see these class files (and have both Java and JavaScript enabled in the preferences screens) for the NPAPI to work.

You then need to add the `plugin.jar` file to the Java `classpath` environment variable. Following is an example of how this is accomplished at the command line:

```
set CLASSPATH= C:\jdk1.6.0\jre\lib\plugin.jar
```

Of course, your specific Java SDK installation may be different in terms of version numbering, but the command should be very similar. With the `plugin.jar` file available in the `classpath`, you're ready to use the NPAPI objects in Java code, and build an applet.

Following are the two vital classes in the `netscape` package (yes, even for IE), which is the Java package made available in the NPAPI ZIP file (`-plugin.jar`):

```
netscape.javascript.JSObject
netscape.javascript.JSException
```

Both classes must be imported into your applet via the Java `import` compiler directive:

```
import netscape.javascript.*;
```

When the applet runs, the NPAPI-aware browser knows how to find the two classes, so that the user doesn't have to do anything special as long as the supporting files are in their default locations.

What your HTML needs

As a security precaution, an `<object>` tag requires one extra parameter to give the applet permission to access the HTML and scripting inside the document. That parameter is `mayscript`, and it can go anywhere inside the `<object>` tag, as follows:

```
<param name="mayscript" value="true" />
```

Permission is not required for JavaScript to access an applet's methods or properties, but if the applet initiates contact with the page, this attribute is required.

About the JSObject class

The portal between the applet and the HTML page that contains it is the `netscape.javascript.JSObject` class. This object's methods allow the applet to contact document objects and invoke JavaScript statements. Table 47-1 shows the object's methods and one static method.

Just as the `window` object is the top of the document object hierarchy for JavaScript references, the `window` object is the gateway between the applet code and the scripts and document objects. To open that gateway, use the `JSObject.getWindow()` method to retrieve a reference to the document window. Assign that object to a variable that you can use throughout your applet code. The following code fragment shows the start of an applet that assigns the window reference to a variable named `mainwin`:

```
import netscape.javascript.*;

public class myClass extends java.applet.Applet {
   private JSObject mainwin;

   @Override
```

```
      public void init() {
         mainwin = JSObject.getWindow(this);
      }
   }
```

TABLE 47-1

JSObject Class Methods

Method	Description
`call(String functionName, arrayObject args[])`	Invokes JavaScript function; argument(s) passed as an array
`eval(String expression)`	Invokes a JavaScript statement
`getMember(String elementName)`	Retrieves a named object belonging to a container
`getSlot(Int index)`	Retrieves indexed object belonging to a container
`getWindow(Applet applet)`	Static method retrieves applet's containing window
`removeMember(String elementName)`	Removes a named object belonging to a container
`setMember(String elementName, Object value)`	Sets value of a named object belonging to a container
`setSlot(int index, Object value)`	Sets value of an indexed object belonging to a container
`toString()`	Returns string version of JSObject

If your applet will be making frequent trips to a particular object, you may want to create a variable holding a reference to that object. To accomplish this, the applet needs to make progressively deeper calls into the document object hierarchy with the `getMember()` method. For example, the following sequence assumes `mainwin` is a reference to the applet's document window. Eventually, the statements set a form's field object to a variable for use elsewhere in the applet:

```
JSObject doc = (JSObject) mainwin.getMember("document");
JSObject form = (JSObject) doc.getMember("entryForm");
JSObject phonefld = (JSObject) form.getMember("phone");
```

Another option is to use the Java `eval()` method to execute an expression from the point of view of any object. For example, the following statement gets the same field object as the preceding fragment:

```
JSObject phonefld = mainwin.eval("document.entryForm.phone");
```

As soon as you have a reference to an object, you can access its properties via the `getMember()` method, as shown in the following example, which reads the `value` property of the text box, and casts the value into a Java `String` object:

```
String phoneNum = (String) phonefld.getMember("value");
```

Two `JSObject` class methods let your applet execute arbitrary JavaScript expressions, and invoke object methods: the `eval()` and `call()` methods. Use these methods with any `JSObject`. If a value is to be returned from the executed statement, you must cast the result into the desired object type. The parameter for the `eval()` method is a string of the expression to be evaluated by JavaScript. Scope of the expression depends on the object attached to the `eval()` method. If you use the `window` object, the expression would exist as if it were a statement in the document script (not defined inside a function).

Using the `call()` method is convenient for invoking JavaScript functions in the document, although it requires a little more preparation. The first parameter is a string of the function name. The second parameter is an array of arguments for the function. Parameters can be of mixed data types, in which case the array would be of type `Object`. If you don't need to pass a parameter to the function call, you can define an array of a single empty string value (for example, `String arg[] = {""}`) and pass that array as the second parameter.

Data type conversions

The strongly-typed Java language is a mismatch for loosely-typed JavaScript. As a result, with the exception of Boolean and string objects (which are converted to their respective JavaScript objects), you should be aware of the way the NPAPI adapts data types to JavaScript.

Any Java object that contains numeric data is converted to a JavaScript number value. Because JavaScript numbers are `IEEE` doubles, they can accommodate just about everything Java can throw their way.

If the applet extracts an object from the document, and then passes that `JSObject` type back to JavaScript, that passed object is converted to its original JavaScript object type. But objects of other classes are passed as their native objects wrapped in JavaScript "clothing." JavaScript can access the applet object's methods as if the object were a JavaScript object. Finally, Java arrays are converted to the same kind of JavaScript array created via the `new Array()` constructor. Elements can be accessed by integer index values (not named index values). All other JavaScript array properties and methods apply to this object as well.

Example applet-to-script application

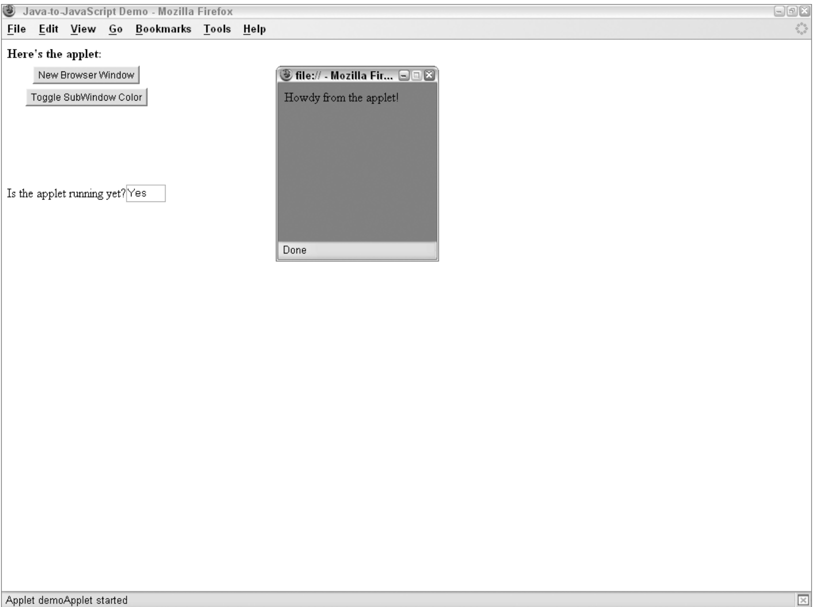
To demonstrate several techniques for communicating from an applet to both JavaScript scripts and document objects, we present an applet that displays two simple buttons (see Figure 47-3). One button generates a new window, spawned from the main window, and fills the window with dynamically-generated content from the applet.

Note

Be sure to turn off pop-up window blocking temporarily to run this example. WebKit-based browsers do not handle pop-up windows in the same way as IE, Opera, and Mozilla-based browsers, so you will have problems when running this example. ■

FIGURE 47-3

The applet displays two buttons seamlessly on the page.



The second button communicates from the applet to that second window by invoking a JavaScript function in the document. The last part of the demonstration shows the applet changing the value of a text box when the applet starts up.

Listing 47-6 shows the source code for the Java applet. Because the applet generates two buttons, the code begins by importing the `AWT` interface builder classes. We also import the `netscape.javascript` package to get the `JSObject` class. The name of this sample class is `JtoJSDemo`. We declare four global variables: two for the windows, two for the applet button objects.

LISTING 47-6

Java Applet Source Code

```
import java.awt.*;
import java.awt.event.*;
import netscape.javascript.*;

public class JtoJSDemo extends java.applet.Applet implements ActionListener {
   private JSObject mainwin, subwin;
   private Button newWinButton, toggleButton;
```

The applet's `init()` method establishes the user interface elements for this simple applet. A white background is matched in the HTML with a white document background color, making the applet appear to blend in with the page. We use this opportunity to set the `mainwin` variable to the browser window that contains the applet.

```
@Override
public void init() {
   setBackground(Color.white);
   newWinButton = new Button("New Browser Window");
   toggleButton = new Button("Toggle SubWindow Color");
   this.add(newWinButton);
   this.add(toggleButton);
   newWinButton.addActionListener(this);
   toggleButton.addActionListener(this);
   mainwin = JSObject.getWindow(this);
}
```

As soon as the applet starts, it changes the `value` property of a text box in the HTML form. Because this is a one-time access to the field, we elected to use the `eval()` method from the point of view of the main window, rather than build successive object references through the object hierarchy with the `getMember()` method.

```
@Override
public void start() {
   mainwin.eval("document.indicator.running.value = 'Yes'");
}
```

Event handling is quite simple in this application. A click of the first button invokes `doNewWindow()`; a click of the second invokes `toggleColor()`. Both methods are defined later in the applet.

```
public void actionPerformed(ActionEvent evt) {
   Button source = (Button)evt.getSource();
   if (source == newWinButton) {
      doNewWindow();
   } else if (source == toggleButton) {
      toggleColor();
   }
}
```

One of the applet's buttons calls the `doNewWindow()` method defined here. We use the `eval()` method to invoke the JavaScript `window.open()` method. The string parameter of the `eval()` method is exactly like the statement that appears in the page's JavaScript to open a new window. The `window.open()` method returns a reference to that subwindow, so that the statement here captures the returned value, casting it as a `JSObject` type for the `subwin` variable. That `subwin` variable can then be used as a reference for another `eval()` method that writes to that second window. Notice that the object to the left of the `eval()` method governs the recipient of the `eval()` method's expression. The same is true for closing the writing stream to the subwindow.

Note

Unfortunately, earlier IE implementations of `JSObject` do not provide a suitable reference to the external window after it is created. Therefore, the window neither receives its content nor responds to color changes in this example. Due to other anomalies with subwindows, we advise against using NPAPI powers with multiple windows in older versions of IE. ■

LISTING 47-6 *(continued)*

Java Applet Source Code

```
   void doNewWindow() {
      subwin = (JSObject) mainwin.eval(
         "window.open('','fromApplet','height=200,width=200')");
      subwin.eval("document.write('<html><body bgcolor=white>Howdy from the
         applet!</body></html>')");
      subwin.eval("document.close()");
   }
```

The second button in the applet calls the `toggleColor()` method. In the HTML document, a JavaScript function named `toggleSubWindowColor()` takes a `window` object reference as an argument. Therefore, we first assemble a one-element array of type `JSObject`, consisting of the `subwin` object. That array is the second parameter of the `call()` method, following a string version of the JavaScript function name being called.

```
         void toggleColor() {
            if (subwin != null) {
               JSObject arg[] = {subwin};
               mainwin.call("toggleSubWindowColor", arg);
            }
         }
      }
```

Now onto the HTML that loads the preceding applet class and receives its calls. The document is shown in Listing 47-7. One function is called by the applet. A text box in the form is initially set to "No" but gets changed to "Yes" by the applet after it has finished its initialization. The only other item of note is that the `<object>` tag includes a `mayscript` parameter to allow the applet to communicate with the page.

LISTING 47-7

HTML Document Called by Applet

```

```

Scripting Plug-Ins

Controlling a plug-in (or Windows ActiveX control in IE) from JavaScript is much like controlling a Java applet, but with more browser-specific concerns to worry about, even at the HTML level. Not all plug-ins are scriptable, of course, nor do all browsers permit such scripting, as mentioned at the start of this chapter. Yet even when you have found the right combination of

browser version(s) and plug-in(s), you must also learn what the properties and/or methods of the plug-in are, so that your scripts can control them. Take a common plug-in duty, such as playing audio: the likelihood that all users will have the same audio playback plug-in installed in a particular browser brand and operating system is perhaps too small to entrust your programming to a single plug-in. If, on the other hand, you are using a plug-in that works only with a special data type, your page just needs to check that the plug-in is installed (and that it is the desired minimum version).

In this section of the chapter, you'll begin to understand the HTML issues, and then examine two separate audio playback examples. One example lets users change tunes being played back; the other arrives with five sounds, each of which is controlled by a different onscreen interface element. Both of these audio playback examples employ a library that has been designed to provide basic audio playback interfaces to the most popular scriptable audio playback plug-in, Windows Media Player, running in Internet Explorer for Windows.

The main goal of the library is to act as an API (Application Programming Interface) between your scripts and the player. The API presents a simple vocabulary to let your scripts control the Windows Media Player. If you want to control an older version of the player, you can modify the details to accommodate that player's API, while leaving your other interface code untouched.

The HTML side

Although several tags have been used in the past to embed plug-ins in web pages, the modern approach involves a single tag only. With the plug-in embedded within the page (even if you don't see it), the plug-in becomes part of the document's object model, which means that your scripts can address it.

The modern and now preferred way to get external media into the document is to load the plug-in as an object through the `<object>` tag. The `object` element is endorsed by the W3C HTML standard, and has been supported in Internet Explorer since IE4. In many ways the `<object>` tag works like the legacy `<applet>` tag, in that aside from specifying attributes that load the plug-in, additional nested `param` elements enable you to make numerous settings to the plug-in while it loads, including the name of the file to pre-load. As with a plug-in's attributes, an object's parameters are unique to the object and are documented (somewhere) for every object intended to be put into an HTML page.

The Windows operating system has a special (that is, far from intuitive) way it refers to the plug-in program (otherwise known in Windows as an ActiveX control): through its class `id` (also known as a `guid`). You must know this long string of numbers and letters in order to embed the object into your page.

The following example is an `object` element that loads the Windows Media Player 9.*x* plug-in (ActiveX control) into a page:

```
<object id="jukebox" width="1" height="1"
        classid="CLSID:6BF52A52-394A-11d3-B153-00C04F79FAA6"
   <param name="URL" value="Beethoven.aif" />
   <param name="autoStart" value="false" />
</object>
```

As compared to older approaches to embedded media objects, the `object` approach has many similar properties and values, which are just expressed differently (for example, `param` elements versus attributes). If you've embedded objects using one of the older techniques, the `object` approach should still be somewhat familiar.

The API approach

In this section, you see one version of an API that is tailor-made for the Windows Media Player. The API has its own initialization routine, which alerts users of ill-equipped browsers with a relevant message about why their browser can't get the most out of the page.

This API is far from the be-all, end-all library, although you will see that it does quite a bit as-is. The code is offered as a starting point for your further development. Such development may take the shape of adding more operations to the API or adding capabilities for additional scriptable plug-ins. For example, although the API as shown supports the newer Windows Media Player versions 9 and up, Microsoft continues to upgrade the Player to new versions (with new `guid`s for your `object` tags) that have new command vocabularies. There is no reason that the API cannot be extended for new generations of Windows Media Player, while maintaining backward compatibility for the version 9 and 10 generation.

You can find the complete API code on the CD-ROM, within the folder of example listings for this chapter. The API file is named `MPAudioAPI.js`. Check out the following high points of this library.

Loading the library

Adding the library to your page is no different from adding any external `.js` library file. Include the following tag in the `head` of your page:

```
<script type="text/javascript" src="MPAudioAPI.js"></script>
```

Except for two global variable initializations, no immediate code runs from the library. All of its activity is invoked from event handlers or other script statements in the main page.

Initializing the library

The first job for the library is to validate that the player has loaded successfully. Before the library can do this, all loading of the `object` elements must be concluded so that the objects exist for the initialization routine to examine. Therefore, use the `onload` event handler in the `body` to invoke the `initAudioAPI()` function. Parameters to be passed to this function are the IDs of the `object` elements that represent individual players (in case there are more than one).

The following is an excerpt from Listing 47-9 (found later in the chapter), which shows how the `jukebox` player object is initialized (all sound files for examples in this chapter have the `.aif` filename extension):

```
onload="initAudioAPI('jukebox')"
```

As you will see later in the chapter, in Listing 47-10, the `initAudioAPI()` function lets you initialize multiple player objects. Each object has its own ID. For example, the following initializes the library for two different embedded plug-in objects:

```
onload="initAudioAPI('cNatural','cSharp')"
```

When the function receives multiple arguments, it loops through them, performing the initializations in sequence. The `initAudioAPI()` function follows:

```
function initAudioAPI()
{
   var args = initAudioAPI.arguments;
   var id;
   for (var i = 0; i < args.length; i++)
   {
      // don't init any more if browser lacks scriptable sound
      if (OKToTest)
      {
         id = args[i];
         players[id] = new API(id);
         validateSupport(id);
      }
   }
}
```

Notice that parameter variables are not explicitly declared for the function, but are, instead, retrieved via the `arguments` property of the function. The global `OKToTest` flag, initialized to `true` when the library loads, is set to `false` if the validation of a plug-in fails. The conditional construction here prevents multiple alerts from appearing when multiple plug-in parameters are passed to the initialization function.

Sound player API objects

One of the jobs of the initialization routine is to create a player object for each plug-in identifier. The object's constructor is as follows:

```
// AudioAPI object constructor
function API(id) {
   this.id = id;
   this.play = API_play;
   this.stop = API_stop;
   this.pause = API_pause;
   this.rewind = API_rewind;
   this.load = API_load;
   this.getVolume = API_getVolume;
   this.setVolume = API_setVolume;
}
```

The object becomes a convenient place to preserve properties for each sound controller. But the bulk of the object is reserved for assigning methods — the methods that your main page's scripts

invoke to play and stop the player, adjust its volume, and so on. The method names to the left of the assignment statements in the object constructor are the names your scripts use; the functions in the library (for example, `API_play()`) are the ones that send the right command to the right plug-in.

Each of these objects (even if there is only one for the page) is maintained in a hash table–like array (named `players[]`) in the library. The plug-in object's identifier is the string index for the array entry. This provides the gateway to your page's scripts. For example, if you initialize the library with a single identifier, `jukebox`, you access the methods of the library's jukebox-related player object through the array and the identifier:

```
players["jukebox"].rewind();
```

Invoking methods

Many of the player's method names are simple enough as-is (e.g., `play()`), but developing an API allows you to devise your own vocabulary for more complex operations. For example, Windows Media Player has no explicit method for rewinding the current tune, but you can assemble the equivalent operations into your own `rewind()` method, as shown in Listing 47-8. When your script invokes `players["jukebox"].rewind()`, the combined operations of the `API_rewind()` method do their jobs.

LISTING 47-8

The API's Primary Functions

```
function API_play(n)
{
   if (document.all(this.id).HasError)
   {
      alert("MediaPlayer Alert: "  + document.all(this.id).ErrorDescription);
   }
   else
   {
      document.all(this.id).settings.playCount = n;
      document.all(this.id).controls.play();
   }
}

function API_stop()
{
   document.all(this.id).controls.stop();
}

function API_pause()
{
   document.all(this.id).controls.pause();
}
```

continued

LISTING 47-8 *(continued)*

```
function API_rewind()
{
   document.all(this.id).controls.stop();
   document.all(this.id).controls.currentPosition = 0;
}

function API_load(URL)
{
   document.all(this.id).URL = URL;
}
```

Building a jukebox

The first example that utilizes the `MPAudioAPI.js` library is a jukebox that provides an interface (admittedly not pretty — that's for you to whip up) for selecting and controlling multiple sound files with a single plug-in tag set. The assumption for this application is that only one sound at a time need be handy for immediate playing.

Listing 47-9 shows the code for the jukebox. All sound files specified in the example are in the same folder as the listing on the companion CD-ROM (the AIFF-format files sound better in some plug-ins than others, so don't worry about the audio quality of these demo sounds).

LISTING 47-9

A Scripted Jukebox

```
<html>
   <head>
      <title>Oldies but Goodies</title>
      <script type="text/javascript" src="MPAudioAPI.js"></script>
      <script type="text/javascript">
         // make sure currently selected tune is preloaded
         function loadFirst(id)
         {
            var choice = document.forms[0].musicChoice;
            var sndFile = choice.options[choice.selectedIndex].value;
            players[id].load(sndFile);
         }
         // swap tunes
         function changeTune(id, choice)
         {
            players[id].load(choice.options[choice.selectedIndex].value);
         }
         // control and display volume setting
         function raiseVol(id)
         {
```

```
            var currLevel = players[id].getVolume();
            currLevel += Math.ceil(Math.abs(currLevel)/10);
            players[id].setVolume(currLevel);
            displayVol(id);
         }
         function lowerVol(id)
         {
            var currLevel = players[id].getVolume();
            currLevel -= Math.floor(Math.abs(currLevel)/10);
            players[id].setVolume(currLevel);
            displayVol(id);
         }
         function displayVol(id)
         {
            document.forms[0].volume.value = players[id].getVolume();
         }
      </script>
   </head>
   <body onload="initAudioAPI('jukebox'); loadFirst('jukebox');
displayVol('jukebox')">
      <form>
         <table border="2" align="center">
            <caption align="top">
               <font size="+3">Classical Piano Jukebox</font>
            </caption>
            <tr>
               <td colspan="2" align="center">
                  <select name="musicChoice"
                          onchange="changeTune('jukebox', this)">
                     <option value="Beethoven.aif" selected="selected">
                        Beethoven's Fifth Symphony (Opening)
                     </option>
                     <option value="Chopin.aif">
                        Chopin Ballade #1 (Opening)
                     </option>
                     <option value="Scriabin.aif">
                        Scriabin Etude in D-sharp minor (Finale)
                     </option>
                  </select>
               </td>
            </tr>
            <tr>
               <th rowspan="4">Action:</th>
               <td>
                  <input type="button" value="Play"

onclick="players['jukebox'].play(parseInt(this.form.frequency[this.form.
frequency.selectedIndex].value))" />
                  <select name="frequency">
                     <option value="1" selected="selected">
                        Once
                     </option>
```

continued

LISTING 47-9 *(continued)*

         <input type="text" size="10" name="volume"
                onfocus="this.blur()" />
      </td>
   </tr>
   <tr>
      <td>
         <input type="button" value="Higher"
                onclick="raiseVol('jukebox')" />
      </td>
   </tr>
   <tr>
      <td>
         <input type="button" value="Lower"
                onclick="lowerVol('jukebox')" />
      </td>
   </tr>
```

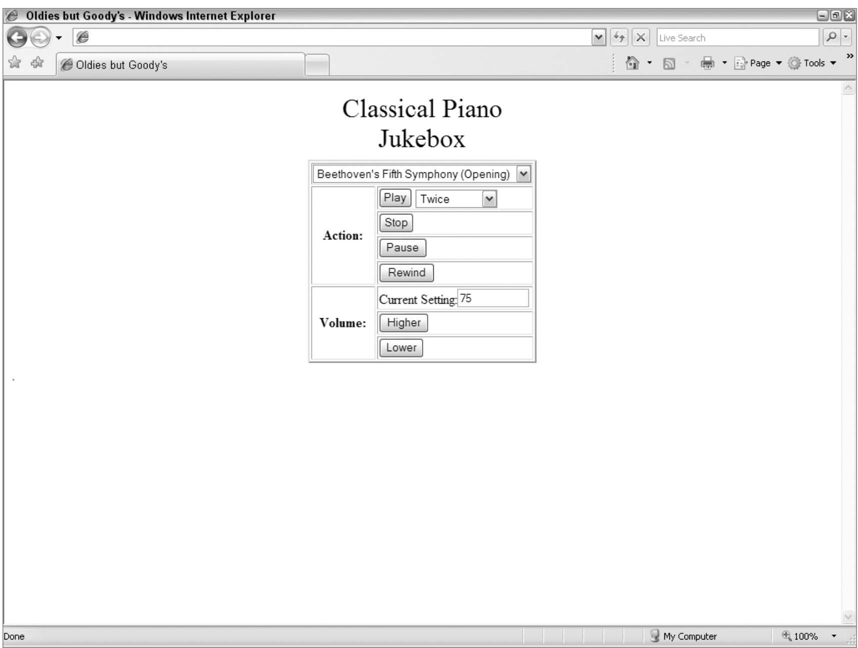
```
            </table>
         </form>

         <object id="jukebox" width="2" height="2"
                 classid="clsid:6BF52A52-394A-11d3-B153-00C04F79FAA6">
            <param name="autoStart" value="false" />
         </object>
      </body>
   </html>
```

You can see the user interface in Figure 47-4. One `select` element contains a list of three possible choices. Most of the interface, however, consists of buttons that ultimately invoke methods of the current plug-in.

FIGURE 47-4

The jukebox page.



All functions defined for this page are designed to be as generalizable as possible. Thus, the identifier of the plug-in is passed as a parameter to each. If another plug-in were added to this page, the same functions could be used without modification, provided calls to the functions passed the identifier of the other plug-in.

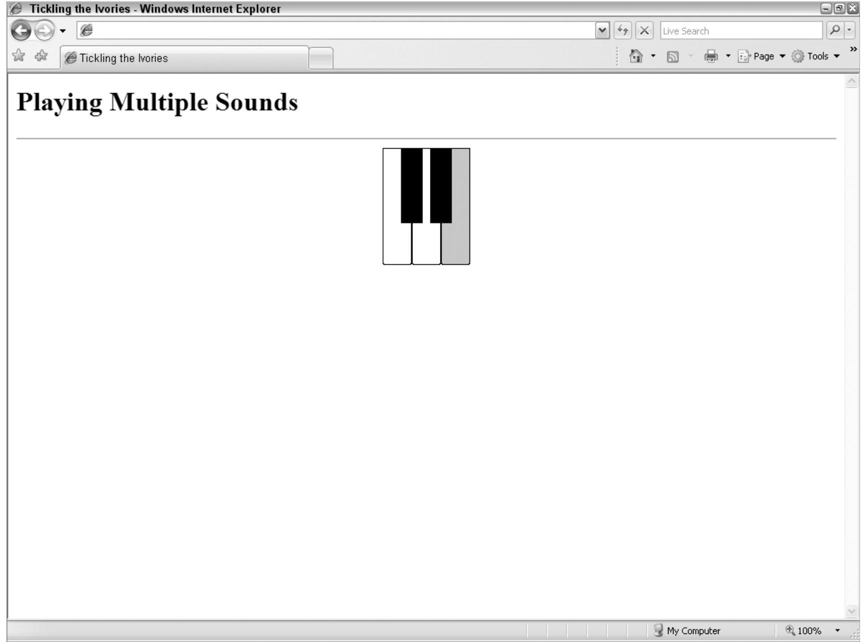
All of the button controls are pretty straightforward except the Play button's `onclick` event handler. It invokes the `players[id].play()` method, but that method requires a parameter of how many times the sound should be played. In this user interface, a `select` element controls that information. Getting the value of the selected item creates a lengthy reference, but that's what is taking up so much space in the parameter slot of the `play()` method call.

Embedding multiple sounds

The final example of embedded media serves as a base on which you can build a page that needs to play multiple sounds without the user explicitly loading them. For example, you may have buttons generate different sounds after users click them. (We're not recommending this interface, but that won't necessarily stop you.) Figure 47-5 shows you a simple five-key piano keyboard. The page loads five different sounds into the page, one for each note (actual piano sounds in this case). Each sound was recorded for about 4 seconds, so that you can get the action of attack and delay, just like a real piano. If you mouse-down on a key, the sound plays for up to 4 seconds (getting softer all the time), or until you mouse-up on the key (the attack time on the sample sounds on the CD-ROM is not instantaneous, so you may have to hold a key down for a fraction of a second to start the sound). The colors of the keys also change slightly to provide further user feedback to the action.

FIGURE 47-5

Controller for five sounds.



Thanks to the MPAudioAPI.js library, very little code in this page is associated with the sounds. Far more is involved with the image swaps and the loading of the five plug-ins. Listing 47-10 shows the code for the page.

LISTING 47-10

Scripting Multiple Sounds

```
<html>
   <head>

```

Perhaps the trickiest part of this entire demonstration lies in the way that the keyboard art and user interface are created. Because the white keys are not rectangular, the black key art is dropped atop the white keys by way of positioned elements.

When you use the page, you may notice a slight delay in getting the sound to be heard after pressing down on a key. On older, slower machines, this delay is even more noticeable. Take this behavior into account when designing interactive sound.

Scripting Java Classes Directly

The NPAPI, as implemented in Netscape and Mozilla browsers, allows scripts to access Java classes as if they were part of the JavaScript environment. Because you need to know your way around Java before programming Java classes directly from JavaScript, we won't get into too much detail in this book. Fortunately, the designers of JavaScript have done a good job of creating JavaScript equivalents for the most common Java language functionality, so there is not a strong need to access Java classes on a daily basis.

To script Java classes, it helps to have a good reference guide to the classes built into Java. Though intended for experienced Java programmers, *Java in a Nutshell* (O'Reilly & Associates, Inc.) offers a condensed view of the classes, their constructors, and their methods.

Java's built-in classes are divided into major groups (called *packages*) to help programmers find the right class and method for any need. Each package focuses on one particular aspect of programming, such as classes for user interface design in application and applet windows, network access, and basic language constructs — strings, arrays, and numbers. References to each class (object) defined in Java are "dot" references, just as in JavaScript. Each item following a dot helps zero-in on the desired item. As an example, consider one class that is part of the base language class. The base language class is referred to as

```
java.lang
```

One of the objects defined in `java.lang` is the `String` object, whose full reference is

```
java.lang.String
```

To access one of its methods, you use an invocation syntax with which you are already familiar:

```
java.lang.String.methodName([parameters])
```

To demonstrate accessing Java from JavaScript, we call upon one of Java's `String` object methods, `java.lang.String.equalsIgnoreCase()`, to compare two strings. Equivalent ways are available for accomplishing the same task in JavaScript (for example, comparing both strings in their `toUpperCase()` or `toLowerCase()` versions), so don't look to this Java demonstration for some great new powers along these lines.

Before you can work with data in Java, you have to construct a new object. Of the many ways to construct a new `String` object in Java, use the one that accepts the actual string as the parameter to the constructor:

```
var mainString = new java.lang.String("TV Guide");
```

At this point, your JavaScript variable, `mainString`, contains a reference to the Java object. From here, you can call this object's Java methods directly:

```
var result = mainString.equalsIgnoreCase("tv Guide");
```

Even from JavaScript, you can use Java classes to create objects that are Java arrays, and access them via the same kind of array references (with square brackets) as JavaScript arrays. In a few cases, you can use Java classes to obtain additional information about the user environment, such as the user's IP address (but not email address). The process involves a couple of Java class calls, as follows:

```
var localHost = java.net.InetAddress.getLocalHost();
var IP = localhost.getHostAddress();
```

The more you work with these two languages, the more you see how much Java and JavaScript have in common.

CHAPTER

Debugging Scripts

IN THIS CHAPTER

Identifying the type of error plaguing a script

Interpreting error messages

Preventing problems before they occur

One of the first questions that an experienced programmer asks about a programming environment is what support there is for debugging code. Even the best coders in the world make mistakes when they draft programs. Sometimes, the mistakes are a mere slip of a finger on the keyboard; other times, they result from not being careful with expression evaluation or object references. The cause of the mistake is not the issue: finding the mistake and getting help to fix it is.

Some debugging tools are available for the latest browsers. For the most part, they have come from the browser makers themselves, or they are tied very closely to a particular authoring environment. Some of these tools are very quirky; others require significant investments in authoring environments. Discussion about debugging tools in this chapter, however, focuses on simple tools you can download online. By understanding the true meaning of error messages and working out problems with the tools provided here, you should be able to overcome your bugs.

Syntax versus Runtime Errors

As a page loads into a JavaScript-enabled browser, the browser attempts to create an object model out of the HTML and JavaScript code in the document. Some types of errors crop up at this point. These are mostly syntax errors, such as failing to include a closing brace after a function's statements. Such errors are about structure, rather than about values or object references.

Runtime errors involve failed connections between function calls and their functions, mismatched data types, and undeclared variables located on

the wrong side of assignment operators. Such runtime errors can occur as the page loads if the script lines run immediately. Runtime errors located in functions won't crop up until the functions are called — either as the page loads or in response to user action.

Because of the interpreted nature of JavaScript, the distinction between syntax and runtime errors blurs. But as you work through whatever problem halts a page from loading or a script from running, you have to be aware of differences between true errors in language and your errors in logic or evaluation.

Error Message Notification

As browsers have evolved through several generations, the ways in which script errors are reported to the user (and to you as the author) have also changed. The biggest changes came in WinIE4 and NN4.5. Prior to those versions, script errors always displayed some kind of alert dialog box with information about the error. Because these alerts could confuse non-technical users, the newer browsers are much more subtle about the presence of errors. In fact, the notification mechanism is so subtle, it is easy to miss the fact that a script error has occurred. Even if you do notice, you must then exercise your mouse a bit more to view the details.

When a script error occurs in WinIE4+, the status bar displays a yellow alert icon, plus a brief text message indicating that an error has occurred. A syntax error that occurs while the page loads usually signifies that the page has loaded, but with errors. A runtime error's message simply indicates that an error occurred. To view details about the error, you must double-click the yellow icon in the status bar. The default appearance of the error message alert dialog box window includes a button named Show Details. Clicking this button expands the window to reveal whatever details the browser is reporting about the error.

If you leave the script error window expanded, the next time it opens, it will again be expanded. It is a good idea for scripters to also check the box that forces the browser to show the error dialog box whenever an error occurs. This is simply a shortcut to manually double-clicking the status bar error icon.

Mozilla console windows

In Mozilla-based browsers, error notifications are entirely hidden from the end user. However, if you type

```
javascript:
```

into the toolbar's Location text box, or into the dialog box that enables you to open a new page, an entirely new, non-modal window is displayed. This window is called the JavaScript Console, and it keeps track of JavaScript errors. You can also open the JavaScript Console by selecting JavaScript Console from the Tools menu in Firefox, for example. The console has been renamed Error Console, starting with Firefox 2.0.

In contrast to the one message per window approach of IE, the JavaScript Console window continues to record all script errors in sequence (in a scrolling frame), even when the Console window is closed. You can keep this window open all the time, and simply bring it to the front whenever you need to view errors.

Unlike earlier Netscape browsers, Mozilla does not provide notification of errors in the status bar, so it is up to you to be vigilant for something running amok. This is all the more reason to keep the JavaScript Console window open while you are writing and debugging your scripts. Even if things appear to be OK, periodically check the Console window to be sure.

Safari errors

As delivered to users, early versions of Safari completely concealed script errors. To be able to see script errors at all, you must enter a command into the Mac OS X Terminal program window to display an otherwise hidden Debug menu. With Safari closed, launch Terminal and enter the following command exactly as shown:

```
defaults write com.apple.Safari IncludeDebugMenu 1
```

Now launch Safari, where the Debug menu should appear in the menu bar, with the Log JavaScript Exceptions item already checked (if not, select it so that a check mark appears next to the item). Choose the Show JavaScript Console item to display the JavaScript Console window.

In later versions of Safari, whether on Mac OS or Windows, simply open Safari Preferences. On the Advanced tab, select “Show Develop menu in menu bar.” The Develop menu will appear on the menu bar with several options available, including Show Error Console and Start Debugging JavaScript.

Opera errors

Selecting Advanced on the Tools menu enables you to choose Developer Tools or the Error Console. (Developer Tools includes the Error Console.) A separate window is not opened in Opera. Rather, the current window is split. This is not that obvious; the splitter bar appears almost at the bottom of the window. Use the mouse to move the splitter bar so that you can better see the console. To the right of the embedded console is an icon to unlock it into a separate window.

Chrome errors

Google Chrome does not have a traditional menu bar. To the right of its tabs are two icons. One is the “Control the current page” icon. If you click on that, you’ll see a Developer selection, which allows you to open the JavaScript console.

Multiple error messages

The modality of IE error message alert dialog boxes tends to force just one message to appear. In other words, when the first error occurs, the browser stops recording further errors. In other

browsers, however, it is not uncommon for multiple errors to be listed (or, in older versions, multiple error windows to show up). But you need to understand how to treat multiple errors to get to the root of the problem.

The usual reaction is to look at the last message to appear in the sequence. That, however, is usually the error message least likely to lead you to the true problem. Error messages are dumped to the Error Console windows in the order in which they occur. This means that the first error in the list is the most important error message of them all. More than likely, the first error points to a problem that throws off the rest of the script, thus triggering all of the other error messages. For example, if a statement that initializes a variable has a syntax error in it, all other statements that rely on that variable will fail, because the variable appears to be undefined.

When you encounter multiple errors, don't start any serious debugging until you locate the first error message. You must tackle this one before any others. The solution to the first one may cause the other errors to go away. This is all the more reason, when authoring in any browser, to keep the Console window open, and to clear it before loading any page or executing any scripts.

Error Message Details

Each browser reports errors slightly differently, and often with different levels of specificity. By and large, however, you can count on error details to include three basic clues to help you track down the error: the file in which the error occurred, the location of the error within the source code, and a textual description of the error. The Mozilla-based browsers tend to furnish the most accurate and helpful error messages.

Error filename

Although MacIE error messages do not explicitly reveal the name of the file whose source code contains the error, in practice, Opera, recent versions of WinIE, and the Mozilla browsers do the best job of telling the truth. Of course, when the script and the HTML are all on one page, it doesn't require a brain surgeon to know that the error occurs from that page's source code. But if you link in external `.js` libraries, Opera, recent versions of WinIE, and the Mozilla browsers provide the URL to the `.js` file. Early versions of WinIE, on the other hand, indicates the HTML page that loads the external library, making it difficult to know precisely where the error is.

Error location

All browsers provide a source code line number and character position where the error supposedly occurs. For self-contained pages with no dynamically created content, the reporting tends to be accurate (also see the IE "Object expected" error message details described later in this chapter), but the accuracy is much closer in Opera and the Mozilla browsers than in IE. And if your page links in an external library, the line number provided by MacIE and older versions of WinIE is practically useless. The sense you get is that the lines of the `.js` file become embedded within the main page's script, but how that is supposed to help an author find the precise

problem line is a mystery — even the most feature-laden text editor knows only how to display line numbers for a single document.

Opera and Mozilla browsers, however, not only point to the correct `.js` file, but to the line number within that file. You are much more likely to get to the root of a problem, especially in an external `.js` file, through Opera and Mozilla error messages.

Line number reporting has improved with each browser generation, but anomalies still exist. Perhaps the most egregious is the tendency for IE to report a problem at a line number whose source code is HTML with an event handler. The problem, it turns out, will be somewhere in the function being invoked by the event handler. Another possibility in all browsers is that the line number being reported is below the line that contains the problem. Consider the following simple source code listing (with line numbers from the source code editor) that intentionally contains a syntax error (a missing brace after the first function):

```
1:    <html>
2:       <head>
3:          <script type="text/javascript">
4:          function tarzan() {
5:             var x = 1;
6:
7:          function jane() {
8:             var y = 3;
9:          }
10:         </script>
11:      </head>
12:      <body>
13:      Hello.
14:      </body>
15:   </html>
```

When you load this page into browsers, all of them report a problem with a missing right brace (Mozilla is a bit more explicit with its message, indicating that a right brace is missing after a function body). But where do the browsers point to the error? By looking at the code as a human, you can see that the missing brace belongs in Line 6. But now examine the code from the point of view of a script interpreter engine: It sees the opening brace on Line 4, and then a new function declaration starting on Line 7. To the interpreter, this means that the `jane()` function is probably nested inside the `tarzan()` function, and it is the `tarzan()` function that is lacking the right brace following the `jane()` function. Therefore, the error line number comes in at Line 10 (although MacIE5 reports Line 9). Your scripts won't likely be this simple, so the distance between the reported error line number and the location of the actual problem can be substantial, and difficult to spot without using some of the tips and tools described later in this chapter. This example also demonstrates how the writing style you use in your code can help identify or hide problems from you as a human. The writing style in this example contains the opening curly brace for a function's block of code on the same line as the `function` keyword. It can be argued that if the opening curly brace had been on the line following, it would have been easier for you, a human, to spot the problem visually.

IE sometimes has a nasty habit of identifying the location of the problem at Line 1, Character 1. All this means is that you need to put your detective skills to work that much harder. Common causes for this behavior are references to HTML objects that don't exist (or a mismatch between the identifier of the element and your script reference to it) and errors that affect global functions or window methods. To find the genuine problem line, you can use tracing techniques described later in this chapter.

Error message text

Because so many permutations exist of the potential errors you can make in scripts and the ways the JavaScript interpreters in different browsers regard these errors, presenting hard-and-fast solutions to every JavaScript error message is impossible. What we can do, however, is list the most common and head scratch–inducing error messages, and relate the kinds of non-obvious problems that can trigger such messages.

"Object expected"

This error message is often one of the least helpful that you see in IE. The line number associated with the message typically points to a line in the source code that invokes a function. If you define event handlers as attributes of element tags, the line number being reported may correspond to the line containing that HTML tag.

The most obvious problem is that the function being invoked is not regarded as a valid function in the page (the "object" referred to here is the function object). This problem can be the result of an HTML or script error earlier in the document. The problem can also be the result of some error in the function itself that failed to let the interpreter treat the function as a genuine function object. Most typically, these kinds of problems are detected as syntax errors while the page loads (for example, an imbalanced set of parentheses or braces), but not always.

As a first-strike tactic, you need to determine if the function is being invoked at all. By placing an alert in the first line of the function and triggering the function, you can see if script execution is reaching that point. If that works okay, move the alert downward through the function to find out where the error is actually being triggered. The line before the alert that fails is the likely culprit. As rudimentary a technique as it may be, carefully placing an alert here or there can go a long way toward tracking down bugs.

"Expected <something>"

This message usually points straight at the problem line. Most of the "things" that the statement expects are self-explanatory. If a right parenthesis is missing from a pair, that is the "thing" shown to be expected. Detecting in the message the difference between a brace and parenthesis isn't always easy, so look at the message carefully. Not quite as intuitive is when the message says "Expected identifier." This error refers to an expression that typically is trying to use a reserved word as a variable name. See Appendix C for a list of reserved words, none of which you may use as names of things or variables.

“<Something> is undefined”

This message is fairly easy to understand, yet at times difficult to diagnose. For variable names, the message usually means that you have an uninitialized variable name sitting in the position of a right-hand operand or a unary operand. This variable name has not been declared or assigned with any value prior to this erroneous statement. Perhaps you’re attempting to use a variable name that has been initialized only as a local variable in another function. You may also have intended the right-hand value to be a string, but you forgot to enclose it in quotes, forcing JavaScript to look upon it as a reference to something. Another possibility is that you misspelled the name of a previously declared variable. JavaScript rightly regards this item as a new, undeclared variable. Misspellings, you will recall, include errors in upper- and lowercase in the very case-sensitive JavaScript world.

If the item is a function name, you may have to perform a bit of detective work. Though the function may be defined properly, a problem in the script above the function (for example, imbalanced braces) makes JavaScript fail to see the function. In other cases, you may be trying to invoke a function in another window or frame, but forgot to include the reference to that distant spot in the call to the function.

A less likely case, but a confusing one to diagnose, is when you are assembling string versions of function calls or array references out of literal strings and variable values. The following simplified example is assembling a string that is a function call to be triggered by `setTimeout()`:

```
function doA()
{
   var x = "joe";
   setTimeout("doB(" + x + ")", 5000);
}
```

Even though the value of `x` is a string when it is concatenated to the call to the `doB()` function, the value gets evaluated as if it were a variable name. An error crops up saying that “joe is undefined.” Because you want to pass the value of `x` as a parameter, you must nest its value inside a pair of quotes, as follows:

```
function doA()
{
   var x = "joe";
   setTimeout("doB('" + x + "')", 5000);
}
```

The difference in the code is extremely subtle, but absolutely necessary.

“<Something> is not a function”

As with the preceding message, this error message can be one of the most frustrating, because when you look at the script, it appears as though you have clearly defined a function by that name, and you’re simply having an event handler or other running statement call that function. The first problems to look for are mismatched letter cases in the calling statement and function, and the reuse of a variable or HTML object name by the function name.

This latter item is a no-no — it confuses JavaScript into thinking that the function doesn't exist, even though the object name doesn't have parentheses appended to it, and the function does. We've also seen this error appear when other problems existed in the script above the function named in the error message, and the named function was the last one in a script.

"Object doesn't support this property or method"

This IE message reports that a valid object does not provide support for a method you just attempted to invoke. In practice, this message rarely appears as the result of referencing an object's nonexistent property, because the language allows for extending an object's list of properties by assignment. One scenario where you may encounter this message is when testing a page in MacIE that was developed in WinIE, since the MacIE complement of implemented object methods is somewhat smaller.

"Unterminated string literal"
"Unterminated string constant"

Mozilla is far more helpful than other browsers with this type of message, because along with the error message, it displays the code fragment that tripped the error. You will see the beginning (or all) of the string that is the culprit. If you simply forgot to close a string quote pair, the error most frequently appears when you try to concatenate strings or nest quoted strings. Despite the claim that you can nest alternating double and single quotes, we often have difficulties using this nesting method beyond the second nested level (single quotes inside a double-quoted string). At different times, we've gotten away with using a pair of `\"` inline quote symbols for a third layer. If that syntax fails, we break up the string so that nesting goes no deeper than two layers. If necessary, we even back out the most nested string and assign it to a variable in the preceding line — concatenating it into the more complex string in the next line.

"Missing } after function body"
"Expected }"

This error usually is easy to recognize in a simple function definition because the closing brace is missing at the end of the function. But when the function includes additional nested items, such as `if...else` or `for` loop constructions, you begin dealing with multiple pairs of braces within the function. The JavaScript interpreter doesn't always determine exactly where the missing brace belongs, and thus it simply defaults to the end of the function. This location is a natural choice, we guess, because from a global perspective of the function, one or more of the right braces that ripple down to the end of the function usually are missing.

In any case, this error message means that a brace is missing somewhere in a function above the referenced line number. Do an inventory count for left and right braces, and see whether a discrepancy occurs in the counts. One of those nested constructions is probably missing a closing brace. Some programmer-oriented text editors also include tools for finding balanced pairs of braces and parentheses.

“<Something> is not a number”

The variable name singled out in this error message is most likely a string or null value. The line of JavaScript that trips it up has an operator that demands a number. When in doubt about the data type of a variable destined for a math operation, use the `parseInt()` or `parseFloat()` functions to convert strings to numbers.

We have also encountered this error when it provides no clue about what isn’t a number — the error message simply says, “is not a number.” In our case, the root of the problem ended up having nothing to do with numbers. A structural imbalance in the script triggered this bogus error message.

“<Something> has no property named . . .”
“<Something> has no properties”

When a statement trips this error message, an object reference has usually gone awry in an assignment or comparison expression. You probably attempted to reference a property of an object, but something is wrong with the object reference, or you’re trying to retrieve a property that doesn’t exist for that object. If the reference is an extended one, you may have to dig to find the precise problem with the reference. Consider the following two statements that attempt to access the `value` property of a button named `calcMe`:

```
document.forms.calcme.value
document.forms[0].calcme.value
```

The Mozilla errors for these two statements would read “document.forms.calcme has no properties” and “document.forms[0].calcme has no properties.” Causes for the two errors are quite different. The obvious problem with them both may seem to be that the button’s name is incorrectly referenced as `calcme` instead of `calcMe`. That, indeed, is the error for the second statement. But a more fundamental problem also plagues the first statement: the `document.forms` reference (a valid object, returning an array of forms) needs an array index in this instance, because it needs to look into a particular form for one of its objects. Unfortunately, both error messages look alike at first glance, and you cannot tell from them which statement has two errors and which has one.

But what you can do when this kind of error appears is use the reference that is returned with the error message to check your work. Start verifying the accuracy of your references from left to right. Later in this chapter, you see how to use the embeddable Evaluator tool to verify the existence of object references.

“<Something> is null or not an object”

This message is the IE version of the previous Mozilla error message. A big difference is that the reference returned as part of the error message includes the complete reference. Therefore, a reference to a nonexistent `calcme` button in a form yields the error message “‘document.forms[0].calcme.value’ is null or not an object”. Your first instinct is to be suspicious of the `value` property part of the reference. The detective work to find the problem is the same as in the Mozilla version: verify the reference piece by piece, working from left to right. Again, the embeddable Evaluator described later in this chapter can assist in this task.

"<Something> has no property indexed by [i]"

Look carefully at the object reference in this error message. The last item has an array index in the script, but the item is not an array value type. Users commonly make this mistake within the complex references necessary for radio buttons and `select` options. Make sure that you know which items in those lengthy references are arrays and which are simply object names that don't require array values.

"<Something> can't be set by assignment"

This error message tells you either that the property shown is read-only or that the reference points to an object, which must be created via a constructor function rather than by simple assignment.

"Test for equality (==) mistyped as assignment (=)? Assuming equality test"

The first time I received this error, I was amazed by JavaScript's intelligence. I had, indeed, meant to use the equality comparison function (==) but had entered only a single equal sign. JavaScript is good at picking out these situations where Boolean values are required. In Mozilla, this message is demoted to just a warning rather than an error.

"Function does not always return a value"

Often while designing deeply nested `if...else` constructions, your mind follows a single logic path to make sure that a particular series of conditions is met, and that the function returns the desired values under those conditions. What is easy to overlook is that there may be cases in which the decision process may "fall through" all the way to the bottom without returning any value, at which point the function must indicate a value that it returns, even if it is a zero or empty (but most likely a Boolean) value. JavaScript checks the organization of functions to make sure that each condition has a value returned to the calling statement. The error message doesn't tell you where you're missing the return statement, so you have to do a bit of logic digging yourself.

"Access disallowed from scripts at <URL> to documents at <URL>" "Access is denied"

These messages (Mozilla and IE versions, respectively) indicate that a script in one frame or window is trying to access information in another frame or window that has been deemed a potential security threat. Such threats include any `location` object property or other information about the content of the other frame when the other frame's document comes from a protocol, server, or host that is different from the one serving up the document doing the fetching.

Even the best of intentions can be thwarted by these security restrictions. For example, you may be developing an application that blends data in cooperation with another site. Security restrictions, of course, don't know that you have a cooperative agreement with the other web site, and you have no workaround for accessing a completely different domain unless you use signed scripts for Mozilla (see Chapter 49, "Security and Netscape Signed Scripts"), or an IE user has browser security levels set dangerously loose.

Another possible trigger for these errors is that you are using two different servers in the same domain or different protocols (for example, using `https:` for the secure part of your commerce site, while all catalog info uses the `http:` protocol). If the two sites have the same domain (for example, `giantco.com`) but different server names or protocols, you can set the `document.domain` properties of documents so that they recognize each other as equals. See Chapter 49 for details on these issues and the restrictions placed on scripts that mean well, but that can be used for evil purposes.

IE, especially Windows versions, frequently clamps down too severely on inter-window and inter-frame communication. Don't be surprised to encounter security problems trying to communicate between a main window and another window whose content is dynamically generated by scripts in the main window. This error can be incredibly frustrating. Sometimes, serving the main page from a server (instead of reading it from a local hard disk) can solve the problem, but not always. You are safest if the content of both windows or frames are documents served from the same server and domain.

"Unspecified error"

This completely unhelpful IE error message is not a good sign because it means that whatever error is occurring is not part of the well-traveled decision tree that the browser uses to report errors. All is not lost, however. That the browser has not crashed means that you can still attempt to get at the root of the problem through various tracing tactics described later in this chapter.

"Uncaught exception"

You may encounter these messages in Mozilla, although usually not as a result of your scripts, unless you are using some of the browser's facilities to dive into inner workings of the browser. These messages are triggered by the browser's own programming code, and indicate a processing error that was not properly wrapped inside error trapping mechanisms. The details associated with such an error point to the Mozilla browser's own source code modules and internal routines. If you can repeat the error and can do so in a small test case page, you are encouraged to submit a report to `http://bugzilla.mozilla.org`, the bug-tracking site for the Mozilla browser.

"Too many JavaScript errors"

You may see this message in Mozilla if it detects a runaway train generating errors uncontrollably. This message was far more important in the bygone days of separate error windows, because a buggy repeat loop could cause Navigator to generate more error windows than it could handle.

Warnings in Mozilla's Console

The Mozilla browser's JavaScript/Error Console window reports both outright errors and another class of notices called *warnings*. Whereas an error may cause script execution to stop, a warning

is generally less catastrophic. A warning typically alerts the content author of looming problems, such as deprecated DOM terms that are still supported merely for backward compatibility — but that should be avoided going forward.

Another common warning advises that the server delivered some external content without correct headers. This happens frequently when a server supplies `.css` filters for link elements without the correct content-type header (`text/css` or similar). These are server configuration issues that should be fixed if they're under your control. You may turn off warnings in the JavaScript Console window by clicking the Errors button.

Sniffing Out Problems

It doesn't take many error-tracking sessions to get you in the save-switch-reload mode quickly. Assuming that you know this routine (described in Chapter 3, "Selecting and Using Your Tools"), the following are some techniques we use to find errors in our scripts when the error messages aren't being helpful in directing us right to the problem.

Check the HTML tags

Before we look into the JavaScript code, we review the document carefully to make sure that we've written all our HTML tags properly. That includes making sure that all tags have closing angle brackets and that all tag pairs have balanced opening and closing tags. Digging deeper, especially in tags near the beginning of scripts, we make sure that all tag attributes that must be enclosed in quotes have the quote pairs in place. Running your document through an HTML validator can help you spot markup mistakes in complex documents. The W3C's Markup Validation Service is a good place to start (`http://validator.w3.org/`).

A browser may be forgiving about sloppy HTML as far as layout goes, but the JavaScript interpreter isn't as accommodating. Finally, we ensure that the `<script>` tag pairs are in place (they may be in multiple locations throughout the document) and that the `type="text/javascript"` attribute value has both of its quotes.

View the source

Your success in locating bugs by viewing the source in the browser varies widely with the kind of content on the page and the browser you use. Very frequently, authors place perhaps too much importance in what they see in the source window. For a straight, no-frame HTML page, viewing the source provides a modicum of comfort by letting you know that the entire page has arrived from the server.

Examining the source code for framesetting documents or individual frames, you must first give focus to the desired element. For an individual frame, click in the frame, and then right-click (or Ctrl-click on the Mac) on the frame's background to get the contextual menu. One of the items should indicate a source view of the frame. To view the framesetter's source, press the Tab key

until the Address/Location field of the browser is selected. Then choose to view the source from the Edit menu.

Where the source view would be most helpful, but often fails, is to display dynamically generated HTML. Firefox's Web Developer, View Source menu enables you to View Generated Source. Otherwise, your best chance will be for pages whose entire content is generated by script. This is about the only place you can appreciate the difference between `document.write()` and `document.writeln()`, because the latter puts carriage returns after the end of each string passed as a parameter to the method. The result is a more readable source view. Most modern browsers display the HTML as written by your script.

But when only part of the page is generated by script, few browsers combine the hard-wired and dynamic code in the source view. Instead, you see only the hard-wired HTML and scripts. To work around this for IE4+ and Mozilla (other than Firefox), you can use the embeddable Evaluator (later in this chapter) and read the `innerHTML` property of any elements you want.

Timing problems

One problem category that is very difficult to diagnose is the so-called timing problem. There are no hard-and-fast rules that govern when you are going to experience such a problem. Very experienced scripters develop an instinct for when timing is causing a problem that has no other explanation.

A timing problem usually means that one or more script statements are executing before the complete action of an earlier statement has finished its task. JavaScript runs within a single thread inside the browser, meaning that only one statement can run at a time. But there are times when a statement invokes some browser service that operates in its own thread, and therefore doesn't necessarily finish before the next JavaScript statement runs. If the next JavaScript statement relies on the previous statement's entire task having been completed, the script statement appears to fail, even though it actually runs as it should.

These problems crop up especially when scripts work with another browser window, and especially in IE for Windows (ironic in a way). In discussions in this book about form field validation, for example, we recommend that after an instructive alert dialog box notifies the user of the problem with the form, the affected text field should be given focus and its content selected. In WinIE, however, after the user closes the alert dialog box, the script statements that focus and select operate before the operating system has finished putting the alert away and refreshing the screen. The result is that the focused and selected text box loses its focus by the time the alert has finally disappeared.

The solution is to artificially slow down the statements that perform the focus and select operations. By placing these statements in a separate function, and invoking this function through the `window.setTimeout()` method, the browser catches its breath before executing the separate function — even when the delay parameter is set to zero. A similar delay is utilized when opening and writing to a new window, as shown in the example for `window.open()` in Chapter 27, "Window and Frame Objects."

If a timing problem is caused by a time-consuming operation of some sort, you might consider performing the operation asynchronously within the confines of an Ajax construct so that you get a notification when it is complete. Structured in this manner, you can design your code so that it deliberately waits around until the time-consuming operation is finished, thereby guaranteeing that the figurative horse is indeed before the cart.

Cross-Reference

For more on Ajax and asynchronous JavaScript, check out Chapter 39, ‘‘Ajax, J4X, and XML Objects,’’ and Chapter 60, ‘‘Application: Transforming XML Data’’ (on the CD). ■

Reopen the file

If we make changes to the document that we truly believe should fix a problem, but the same problem persists after a reload, we reopen the file through the File menu. Sometimes, when you run an error-filled script more than once, the browser's internals get a bit confused. Reloading does not clear the bad stuff, although sometimes an unconditional reload (clicking Reload while holding Shift) does the job. Reopening the file, however, clears the old file entirely from the browser's memory and loads the most recently fixed version of the source file. We find this situation to be especially true with documents involving multiple frames and tables, and those that load external `.js` script library files. In severe cases, you may even have to restart the browser to clear its cobwebs, but this is less necessary in recent browsers. You should also consider turning off the cache in your development browsers.

Another scenario where the browser cache can cause you fits is when you are loading and accessing XML data from an external file. The browser may very well reload the HTML document and relevant JavaScript code just fine, only to open the XML file from the cache. We've banged our heads on our keyboards many a time trying to figure out why our JavaScript code won't process the XML data properly, only to find out that changes in the XML document were never entering the equation due to the browser cache. Either turn off the cache or make sure to clear it between changes to any XML data files that impact your JavaScript code.

Find out what works

When an error message supplies little or no clue about the true location of a runtime problem, or when you're faced with crashes at an unknown point (even during document loading), you need to figure out which part of the script execution works properly.

If you have added a lot of scripting to the page without doing much testing, we suggest removing (or commenting out) all scripts except the one(s) that may get called by the document's `onload` event handler. This is primarily to make sure that the HTML is not way out of whack. Browsers tend to be quite lenient with bad HTML, so this tactic won't necessarily tell the whole story (specifying a `DOCTYPE` and running your HTML through a validator will squelch bad HTML problems). Next, add back the scripts in batches. Eventually, you want to find where the problem really is, regardless of the line number indicated by the error message alert.

To narrow down the problem spot, insert one or more alert dialog boxes into the script with a unique, brief message that you will recognize as reaching various stages (such as `alert("HERE-1")`). Start placing alert dialog boxes at the beginning of any groups of statements that execute, and try the script again. Keep moving these dialog boxes deeper into the script (perhaps into other functions called by outer statements), until the error or crash occurs. You now know where to look for problems. See also an advanced tracing mechanism described later in this chapter.

Comment out statements

If the errors appear to be syntactical (as opposed to errors of evaluation), the error message may point to a code fragment several lines away from the problem. More often than not, the problem exists in a line somewhere above the one quoted in the error message. To find the offending line, begin commenting out lines one at a time (between reloading tests), starting with the line indicated in the error message. Keep doing this until the error message clears the area you're working on and points to some other problem below the original line (with the lines commented out, some value is likely to fail below). The most recent line you commented out is the one that has the beginning of your problem. Start looking there.

Check runtime expression evaluation

We've said many times throughout this book that one of the two most common problems scripters face is an expression that evaluates to something you don't expect (the other common problem is an incorrect object reference). In lieu of a debugger that would let you step through scripts one statement at a time while watching the values of variables and expressions, you have a few alternatives to displaying expression values while a script runs.

The simplest approaches to implement are an alert box and the status bar. Both the alert dialog box and status bar show you almost any kind of value, even if it is not a string or number. An alert dialog box can even display multiple-line values.

Because most expression evaluation problems come within function definitions, start such explorations from the top of the function. Every time you assign an object property to a variable or invoke a string, math, or date method, insert a line below that line with an `alert()` method or `window.status` assignment statement (`window.status = someValue`) that shows the contents of the new variable value. Do this one statement at a time, save, switch, and reload. Study the value that appears in the output device of choice to see if it's what you expect. If not, something is amiss in the previous line involving the expression(s) you used to achieve that value.

This process is excruciatingly tedious for debugging a long function, but it's absolutely essential for tracking down where a bum object reference or expression evaluation is tripping up your script. When a value comes back as being undefined or null, more than likely the problem is an object reference that is incomplete (for example, trying to access a frame without the `parent.frames[i]` reference), using the wrong name for an existing object (check case), or accessing a property or method that doesn't exist for that object.

When you need to check the value of an expression through a long sequence of script statements or over the lifetime of a repeat loop's execution, you are better off with a listing of values along the way. In the section "A Simple Trace Utility" later in this chapter, we show you how to capture trails of values through a script.

Debugging Tools

For a truly interactive debugger to work effectively with client-side JavaScript, the debugger must be highly integrated into the browser. This appears to have been a primary stumbling block in the availability of JavaScript debuggers. At best, we have some browser-specific debuggers, but this leaves other browsers completely out in the cold. Modern browsers that currently have debuggers available for them are Internet Explorer for Windows, Mozilla (including one specifically for Firefox), and Safari.

WinIE's Script Debugger

You can download the Microsoft Script Debugger and documentation from `http://www.microsoft.com/downloads/details.aspx?familyid=2f465be0-94fd-4569-b3c4-dffdf19ccd99&displaylang=en`.

After you install the Script Debugger, you must tell your copy of IE to enable it. Go to the Tools ➪ Internet Options menu, click the Advanced tab, and look for the "Disable script debugging (Internet Explorer)" item in the Browsing category. Make sure that this check box is cleared. For good measure, quit and relaunch the browser. There is another option called "Disable script debugging (Other)" that applies to script errors as they are handled in other applications that utilize the IE browser engine.

When a runtime error occurs, you will be brought to the Debugger window, which will highlight the affected line. Script execution is paused, enabling you to inspect the value of variables and such. Open the Command window, and type any variable name (local or global) that should be active at the paused line. Press Enter, and the next line of the Command window shows the value of that variable.

You can also explicitly set breakpoints in the code, and single-step through the code. At each step, you can enter another variable name or property reference to see its current value.

Be prepared, however, for a less than satisfactory experience with this debugger. If your scripts are loaded from external `.js` files, the debugger does not track that code or line numbers reliably. In fact, it's not uncommon for the debugger to open with the completely wrong line of code highlighted, making single stepping impossible. Simply put, don't bring high expectations to the Script Debugger.

Perhaps Microsoft would rather you use the more sophisticated debugging facilities of their Visual Studio development software. It is a rather expensive solution if all you need is script debugging.

Mozilla's Venkman Debugger

Venkman is the code name of Mozilla's official debugger that is designed for use in Mozilla-based browsers. Venkman is automatically installed in some Mozilla browsers, namely Netscape browsers, but you'll likely need to download and install it in other Mozilla browsers, such as Firefox and Camino. You can easily tell if Venkman is installed in your browser by clicking Tools ➪ Web Development. If you see JavaScript Debugger on the menu, then you're good to go; otherwise, download Venkman from `http://www.mozilla.org/projects/venkman/`.

When the debugger is open, any script error brings the debugger window to the front, with execution paused at the problem line. If the code is from an external `.js` file, that file's source code is displayed, with the problem line highlighted. This debugger automatically tracks objects and their property values in one of the window's panes. You may also set breakpoints in code so that you can single-step through code and observe values at each step.

Firefox's FireBug Debugger

Perhaps the overall best of JavaScript debuggers is the debugger developed exclusively for Firefox. We're referring to FireBug, which is a lightweight debugger with tight integration into the Firefox browser. Similar to the error notification icon in the lower-left corner of the IE browser window, FireBug alerts you to a script problem via a small status bar icon. You can then open up the FireBug console within Firefox and begin analyzing the problematic code.

One interesting feature unique to FireBug is an Ajax log that enables you to carefully track Ajax requests as they are made and responded to. There is also a JavaScript command line where you can execute JavaScript statements and examine variables.

FireBug was developed by Joe Hewitt and is freely available for download from `http://joehewitt.com/software/firebug/`.

WebKit's Drosera Debugger

Relatively new on the debugging scene is a debugger exclusively for WebKit-based browsers (such as Safari and Chrome) called Drosera. Unlike Venkman, which is a reference to a character from the movie Ghostbusters, Drosera takes a more literal approach to its name in that Drosera is the largest genera of bug-eating plants. Drosera is a modern debugger with most of the bells and whistles found in other full-featured JavaScript debuggers such as Firebug.

Drosera is automatically included in the WebKit application framework that forms the basis for the Safari and Chrome browsers. So, by updating your WebKit installation you will automatically get the latest Drosera debugger. WebKit is updated regularly, and is freely available for download at `http://nightly.webkit.org/`.

Opera's Dragonfly Debugger

You can view documentation for Opera's script debugger at `http://dev.opera.com/articles/view/how-to-debug-javascript-problems-with-op/`. In a similar manner

to the other debuggers, you can step through scripts and view threads. You can also examine the DOM.

Using the embeddable Evaluator

As soon as a page loads, or after some scripts run, the window contains objects whose properties very likely reveal a lot about the environment at rest (that is, not while scripts are running). Those values are normally disguised from you, and the only way to guarantee successful access to view those values is through scripting within the same window or frame. That's where the embeddable Evaluator comes in handy.

As you probably recall from Chapter 4, "JavaScript Essentials," and the many example sections of Parts III and IV of this book, the code within the standalone Evaluator provides two text boxes for entry of expressions (in the top box) and object references (the bottom box). Results of expression evaluation and object property dumps are displayed in the Results `textarea` between the two input boxes. A compact version of The Evaluator is contained by a separate library version called `evaluator.js` (located in the Chapter 48 folder of listings on the CD-ROM). As you embark on any substantial page development project, you should link in the library with the following tag at the top of your `head` section:

```
<script type="text/javascript" src="evaluator.js"></script>
```

Be sure to either have a copy of the `evaluator.js` file in the same directory as the document under construction or to specify a complete `file:` URL to the library file on your hard drive for the `src` attribute.

Immediately above the closing `body` tag of your document, include the following:

```
<script type="text/javascript">
   printEvaluator();
</script>
```

If your page contains lots of positioned content, you'll need to put The Evaluator into its own positioned layer, out of the way of your primary content. For example:

```
<div style="position:absolute; top:800px; left:100px">
   <script type="text/javascript">
      printEvaluator();
   </script>
</div>
```

The `printEvaluator()` function draws a horizontal rule (`hr`) followed by the complete control panel of The Evaluator, including the codebase principal support for Mozilla. From this control panel, you can reference any document object supported by the browser's object model or global variable. You can even invoke functions located in other scripts of the page by entering them into the top text box. Whatever references are available to other scripts on the page are also available to The Evaluator, including references to other frames of a frameset and even other windows (provided a reference to the newly opened window has been preserved as a global variable, as recommended in Chapter 27).

If you are debugging a page on multiple browsers, you can switch between the browsers and enter property references into The Evaluator on each browser, making sure all browsers return the same values. Or, you can verify that a DOM object and property are available on all browsers under test. If you are working on W3C DOM–compatible browsers, invoke the `walkChildNodes()` function of The Evaluator to make sure that modifications your scripts make to the node tree are achieving the desired goals. Experiment with direct manipulation of the page's objects and node tree by invoking DOM methods as you watch the results on the page.

You should be aware of only two small cautions when you embed The Evaluator into the page. First, The Evaluator declares its own one-letter lowercase global variable names (`a` through `z`) for use in experiments. Your own code should therefore avoid one-letter global variables (but local variables, such as the `i` counter of a `for` loop, are fine, provided they are initialized inside a function with a `var` keyword). Second, while embedding The Evaluator at the bottom of the page should have the least impact on the rest of your HTML and scripts, any scripts that rely on the length of the `document.forms` array will end up including the form that is part of The Evaluator. You can always quickly turn off The Evaluator by commenting out the `printEvaluator()` statement in the bottom script to test your page on its own.

The embeddable Evaluator is without question the most valuable and frequently used debugging tool in our personal arsenal. It provides x-ray vision into the object model of the page at any resting point.

Emergency evaluation

Using The Evaluator assumes that you thought ahead of time that you want to view property values of a page. But what if you haven't yet embedded The Evaluator, and you encounter a state that you'd like to check out without disturbing the currently loaded page?

To the rescue comes the `javascript:` URL and the Location/Address box in your browser's toolbar. By invoking the `alert()` method through this URL, you can view the value of any property. For example, to find out the content of the cookie for the current document, enter the following into the Location/Address box in the browser:

```
javascript:alert(document.cookie)
```

Object methods or script functions can also be invoked this way, but you must be careful to prevent return values from causing the current page to be eliminated. If the method or function is known to return a value, you can display that value in an alert dialog box. The syntax for a function call is:

```
javascript:alert(myFunction("myParam1"))
```

And if you want to invoke a function that does not necessarily return a value, you should also protect the current page by using the void operator, as follows:

```
javascript:void myFunction("myParam1")
```

One more way to grab a "snapshot" of the current document tree, complete with all tags, is to use the following pseudo-URL in the Location/Address box:

```
javascript: "<textarea cols=120 rows=40>" +
     document.body.parentNode.innerHTML + "</textarea>"
```

When you execute this script, the current page goes away, replaced by a page containing a textarea filled with the current HTML state of the entire document (except for the `<html>` tag). If your scripts perform document tree modification, and you want to observe the current tree state, this command acts as a cross-browser x-ray into the document. You should consider making a bookmark out of the above URL, and keeping it handy.

A Simple Trace Utility

Single-stepping through running code with a JavaScript debugger is a valuable aid when you know where the problem is. But when the bug location eludes you, especially in a complex script, you may find it more efficient to follow a rapid trace of execution and viewing intermediate values along the way. The kinds of questions that this debugging technique addresses include:

- How many times is that loop executing?
- What are the values being retrieved each time through the loop?
- Why won't the while loop exit?
- Are comparison operators behaving as I'd planned in `if...else` constructions?
- What kind of value is a function returning?

A bonus feature of the embeddable Evaluator is a simple trace utility that lets you control where in your running code values can be recorded for viewing after the scripts run. The resulting report you get after running your script can answer questions like these and many more.

The trace() function

Listing 48-1 shows the `trace()` function that is built into the `evaluator.js` library file. By embedding the Evaluator into your page under construction, you can invoke the `trace()` function wherever you want to capture an interim value.

LISTING 48-1

trace() function

```
function trace(flag, label, value)
{
   if (flag)
   {
      var msg = "";
         if (trace.caller)
         {
            var funcName = trace.caller.toString();
            funcName = funcName.substring(9, funcName.indexOf(")") + 1);
            msg += "In " + funcName + ": ";
         }
      msg += label + "=" + value + "\n";
      document.forms["ev_evaluator"].ev_output.value += msg;
   }
}
```

The `trace()` function takes three parameters. The first, `flag`, is a Boolean value that determines whether the trace should proceed. (We show you a shortcut for setting this flag later.) The second parameter is a string used as a plain-language way for you to identify the value being traced. The value to be displayed is passed as the third parameter. Virtually any type of value or expression can be passed as the third parameter — which is precisely what you want in a debugging aid.

Only if the flag parameter is `true` does the bulk of the `trace()` function execute. The first task is to extract the name of the function from which the `trace()` function was called. By retrieving the rarely used `caller` property of a function, the script grabs a string copy of the entire function that has just called `trace()`. A quick extraction of a substring from the first line yields the name of the function. That information becomes part of the message text that records each trace. The message identifies the calling function followed by a colon; after that comes the label text passed as the second parameter, plus an equal sign and the value parameter. The format of the output message adheres to the following syntax:

```
In <funcName>: <label>=<value>
```

The results of the trace — one line of output per invocation — are appended to the Results textarea in The Evaluator. It's a good idea to clear the textarea before running a script that has calls to `trace()`, so that you can get a clean listing.

Preparing documents for trace.js

As you build your document and its scripts, you need to decide how granular you want tracing to be: global or function-by-function. This decision affects at what level you place the Boolean "switch" that turns tracing on and off.

You can place one such switch as the first statement in the first script of the page. For example, specify a clearly named variable and assign either false or zero to it so that its initial setting is off:

```
var TRACE = 0;
```

To turn debugging on at a later time, simply edit the value assigned to `TRACE` from zero to one:

```
var TRACE = 1;
```

Be sure to reload the page each time you edit this global value.

Alternatively, you can define a local `TRACE` Boolean variable in each function for which you intend to employ tracing. One advantage of using function-specific tracing is that the list of items to appear in the Results textarea will be limited to those of immediate interest to you, rather than all tracing calls throughout the document. You can turn each function's tracing facility on and off by editing the values assigned to the local `TRACE` variables.

Invoking trace()

All that's left now is to insert the one-line calls to `trace()`, according to the following syntax:

```
trace(TRACE,"label",value);
```

By passing the current value of `TRACE` as a parameter, you let the library function handle the decision to accumulate and display the trace. The impact on your running code is kept to a one-line statement that is easy to remember. To demonstrate how to make the calls to `trace()`, Listing 48-2 shows a pair of related functions that convert a time in milliseconds to the string format "hh:mm". To help verify that values are being massaged correctly, the script inserts a few calls to `trace()`.

LISTING 48-2

Calling trace()

```
function timeToString(input)
{
   var TRACE = 1;
   trace(TRACE,"input",input);
   var rawTime = new Date(eval(input));
   trace(TRACE,"rawTime",rawTime);
   var hrs = twoDigitString(rawTime.getHours());
   var mins = twoDigitString(rawTime.getMinutes());
   trace(TRACE,"result", hrs + ":" + mins);
   return hrs + ":" + mins;
}

function twoDigitString(val)
```

continued

LISTING 48-2 *(continued)*

```
{
   var TRACE = 1;
   trace(TRACE,"val",val);
   return (val < 10) ? "0" + val : "" + val;
}
```

After running the script, the Results box in The Evaluator shows the following trace:

```
In  timeToString(input): input=976767964655
In  timeToString(input): rawTime=Wed Dec 13 20:26:04 GMT-0800 2006
In  twoDigitString(val): val=20
In  twoDigitString(val): val=26
In  timeToString(input): result=20:26
```

Having the name of the function in the trace is helpful in cases in which you might justifiably reuse variable names (for example, `i` loop counters). You can also see more clearly when one function in your script calls another.

One of the most valuable applications of the `trace()` function comes when your scripts accumulate HTML that gets written to other windows or frames, or replaces HTML segments of the current page. Because the source view may not display the precise HTML that you assembled, you can output it via the `trace()` function to the Results box. From there, you can copy the HTML and paste it into a fresh document to test in the browser by itself. You can also verify that the HTML content is being formatted the way that you want it.

Browser Crashes

Each new browser generation is less crash-prone than its predecessor, which is obviously good news for everyone. It seems that most crashes, if they occur, do so as the page loads. This can be the result of some ill-advised HTML, or something happening as the result of script statements that either run immediately as the page loads or in response to the `onload` event handler.

Finding the root of a crash problem is perhaps more time consuming because you must relaunch the browser each time (and in some cases, even reboot your computer). But the basic tactics are the same. Reduce the page's content to the barest minimum HTML by commenting out both scripts and all but `head` and `body` tags. Then begin enabling small chunks to test reloading of the page. Be suspicious of `meta` tags inserted by authoring tools. Their removal can sometimes clear up all crash problems. Eventually, you will add something into the mix that will cause the crash. It means that you are close to finding the culprit.

Preventing Problems

Even with the help of authoring and debugging tools, you probably want to avoid errors in the first place. We offer a number of suggestions that can help in this regard.

Getting structure right

Early problems in developing a page with scripts tend to be structural: knowing that your objects are displayed correctly on the page; making sure that your `<script>` tags are complete; and completing brace, parenthesis, and quoted pairs. We start writing our page by first getting down the HTML parts — including all form definitions. Because so much of a scripted page tends to rely on the placement and naming of interface elements, you will find it much easier to work with these items after you lay them out on the page. At that point, you can start filling in the JavaScript.

When you begin defining a function, repeat loop, or `if` construction, fill out the entire structure before entering any details. For example, when we define a function named `verifyData()`, we enter the entire structure for it:

```
function verifyData()
{

}
```

We leave a blank line between the beginning of the function and the closing brace in anticipation of entering at least one line of code.

After we decide on a parameter to be passed and assign a variable to it, we may want to insert an `if` construction. Again, we fill in the basic structure:

```
function verifyData(form)
{
   if (form.checkbox.checked)
   {

   }
}
```

This method automatically pushes the closing brace of the function lower, which is what we want — putting it securely at the end of the function where it belongs. It also ensures that we line up the closing brace of the `if` statement with that grouping. Additional statements in the `if` construction push down the two closing braces.

If you don't like typing, or don't trust yourself to maintain this kind of discipline when you're in a hurry to test an idea, you should prepare a separate document that has templates for the

common constructions: `<script>` tags, function, `if`, `if...else`, `for` loop, `while` loop, and conditional expressions. Then, if your editor and operating system support it, drag and drop the necessary segments into your working script.

Build incrementally

The worst development tactic you can follow is to write tons of code before trying any of it. Error messages may point to so many lines away from the source of the problem that it could take hours to find the true source of difficulty. The save-switch-reload sequence is not painful, so the better strategy is to try your code every time you have written a complete thought — or even enough to test an intermediate result in an alert dialog box — to make sure that you're on the right track.

Test expression evaluation

Especially while you are learning the ins and outs of JavaScript, you may feel unsure about the results that a particular string, math, or date method yields on a value. The longer your scripted document gets, the more difficult it will be to test the evaluation of a statement. You're better off trying the expression in a more controlled, isolated environment, such as The Evaluator. By doing this kind of testing in the browser, you save a great deal of time over experimenting by going back and forth between the source document and the browser.

Build function workbenches

A similar situation exists for building and testing functions, especially generalizable ones. Rather than test a function inside a complex scripted document, drop it into a skeletal document that contains the minimum number of user interface elements that you need to test the function. This task gets difficult when the function is closely tied to numerous objects in the real document, but it works wonders for making you think about generalizing functions for possible use in the future. Display the output of the function in a text or textarea object, or include it in an alert dialog box.

Testing Your Masterpiece

If your background strictly involves designing HTML pages, you probably think of testing as determining your user's ability to navigate successfully around your site. But a JavaScript-enhanced page — especially if the user enters input into fields or implements Dynamic HTML techniques — requires a substantially greater amount of testing before you unleash it to the online masses.

A large part of good programming is anticipating what a user can do at any point, and then being sure that your code covers that eventuality. With multiframe windows, for example, you need to see how unexpected reloading of a document affects the relationships between all the frames — especially if they depend on each other. Users will be able to click Reload at any time

or suspend document loading in the middle of a download from the server. How do these activities affect your scripting? Do they cause script errors based on your current script organization?

The minute you enable a user to type an entry into a form, you also invite the user to enter the wrong kind of information into that form. If your script expects only a numeric value from a field, and the user (accidentally or intentionally) types a letter, is your script ready to handle that "bad" data? Or no data? Or a negative floating-point number?

Just because you, as author of the page, know the "proper" sequence to follow and the "right" kind of data to enter into forms, your users will not necessarily follow your instructions. In days gone by, such mistakes were relegated to "user error." Today, with an increasingly consumer-oriented web audience, any such faults rest solely on the programmer — you.

If we sound as though we're trying to scare you, we have succeeded. We were serious in the early chapters of this book when we said that writing JavaScript is *programming*. Users of your pages are expecting the same polish and smooth operation (no script errors and certainly no crashes) from your site as from the most professional software publisher on the planet. Don't let them or yourself down. Test your pages extensively on as many browsers and as many operating systems as you can, and with as wide an audience as possible, before putting the pages on the server for all to see.

CHAPTER 49

Security and Netscape Signed Scripts

IN THIS CHAPTER

Exploring browser security policies

Applying JavaScript to Navigator security mechanisms

Using Netscape signed scripts

The paranoia levels about potential threats to security and privacy on the Internet are at an all-time high. As more people rely on email and web site content for their daily lives and transactions, the fears will only increase for the foreseeable future (an indeterminate number of web weeks). As a jokester might say, however, "I may be paranoid, but how do I know someone really isn't out to get me?" The answer to that question is that you don't know, and such a person may be out there.

But web software developers are doing their darnedest to put up roadblocks to those persons out to get you — hence, the many levels of security that pervade browsers. Unfortunately, these roadblocks also get in the way of scripters who have completely honest intentions. Designing a web site around these barriers is one of the greatest challenges that many scripters face.

Battening Down the Hatches

When Navigator 2 first shipped to the world, way back in the previous century (February 1996), it was the first browser released to include support for Java applets and scripting — two entirely different, but often confused, technologies. It didn't take long for clever programmers in the Internet community to find the ways in which one or the other technology provided inadvertent access to client computer information (such as reading file directories) and web surfer activities (such as histories of where you've been on the Net and even the passwords you may have entered to access secure sites).

JavaScript, in particular, was the avenue that many of these programmers used to steal such information from web site visitors' browsers. The sad part is that the same features that provide the access to the information were

intentionally made a part of the initial language to aid scripters who would put those features to beneficial use in controlled environments, such as intranets. But out in the Wild Wide Web, a scripter could capture a visitor's email address by having the site's home page surreptitiously send a message on behalf of the visitor to the site's author without the visitor even knowing it. It was a spammer's delight.

Word of security breaches of this magnitude not only circulated throughout the Internet, but also reached both the trade and mainstream press. As if the security issues weren't bad enough on their own, the public relations nightmare compounded the sense of urgency to fix the problem. To that end, Netscape released two revised editions of Navigator 2. The final release of that generation of browser, Navigator 2.02, took care of the scriptable security issues by turning off some of the scripted capabilities that had been put into the original 2.0 version: no more capturing visitors' browser histories; no more local file directory listings; no more silent email. Users could even turn off JavaScript support entirely if they so desired.

The bottom line on security is that scripts are prevented from performing automated processes that invade the private property of a web author's page or a client's browser. Thus, any action that may be suspect, such as sending an email message, requires an explicit action on the part of the user — clicking a Submit button, in this case — to carry it out. Security restrictions must also prevent a web site from tracking your activity beyond the boundaries of that web site.

When Worlds Collide

If a script tries to do something that is not allowed or is a potential personal security breach, the browser reports the situation to the user. For example, browsers display a warning to the user when a script in a subwindow tries to close the main window.

Another security error message often confuses scripters who don't understand the possible privacy invasions that can accrue from one window or frame having access to the URL information in another window or frame. In WinIE, for example, an ominous error message — "Access denied" — warns users of an attempt to access URL information from another frame if that URL is from a different web site.

Despite the fact that a scripted web site may have loaded the foreign URL into the other frame, the security restrictions guard against unscrupulous usage of the ability to snoop in other windows and frames.

More recently, browsers have started cracking down on web pages that open new browser windows. Most browsers now offer this feature as an option that allows the user to permit designated web sites to open pop-up windows, while preventing pop-ups in all others.

The Java Sandbox

Much of the security model for JavaScript is similar to that originally defined for Java applets. Applets had a potentially dangerous facility of executing Java code on the client machine. That is a far cry from the original deployment of the World Wide Web as a read-only publishing

medium on the Internet. Here were mini-programs downloaded into a client computer that, if unchecked, could have the same access to the system as a local software program.

Access of this type would clearly be unacceptable. Imagine the dismay caused by someone clicking a link that said Free Money, only to have the linked page download an applet that read or damaged local disk files, unbeknownst to the user. In anticipation of pranksters, the designers of Java and the Java virtual machine built in a number of safeguards to prevent applets from gaining access to local machines. This mechanism is collectively referred to as the *sandbox*, a restricted area in which applets can operate. Applets cannot extend their reach outside of the sandbox to access local file systems and many sensitive system preferences. Any applet runs only while its containing page is still loaded in the browser. When the page goes away, so does the applet, without being saved to the local disk cache.

JavaScript adopted similar restrictions. The language provided no read or write access to local files beyond the highly regulated cookie file. Moreover, because JavaScript works more closely with the browser and its documents than applets typically do, the language had to build in extra restrictions to prevent browser-specific privacy invasions. For example, it was not possible for a script in one window to monitor the user's activity in another window, including the URL of the other window, if the page didn't come from the same server as the first window. Sometimes the restrictions on the JavaScript side are even more severe than in Java. For example, although a Java applet is permitted to access the network anytime after the applet is loaded, an applet is prevented from reaching out to the Net if the trigger for that transaction comes from JavaScript (see Chapter 47, "Scripting Java Applets and Plug-Ins"). Only partial workarounds are available.

Neither the Java nor the JavaScript security blankets were fully bug-free at the outset. Some holes were uncovered by the languages' creators and others in the community. To their credit, Sun, Netscape, and Microsoft have been quick to plug any discovered holes. Although the plugs don't necessarily fix existing copies of unsecure browsers out there, it does mean that a bad guy can't count on every browser to offer the same security hole for exploitation. That generally makes the effort not worth the bother.

Security Policies

Netscape originally defined security mechanisms under the term *policies*. This usage of the word mirrors that of institutions and governments: A policy defines the way potentially insecure or invasive requests are handled by the browser or scripting language. Modern Mozilla-based browsers include two different security policies: *same origin* and *signed script* policies. The same origin policy dates back to Navigator 2, although some additional rules have been added to that policy as the browser has matured. The signed script policy started with NN4 and utilizes the state of the art in cryptographic signatures of executable code inside a browser, whether that code is a plug-in, a Java applet, or a JavaScript script. Signed script facilities allow scripts to have a wider range of control over the browser's interior working parts, provided the user grants permission for such activity (more about this later in the chapter).

By and large, the same origin policy is in force inside Internet Explorer, Safari, and other scriptable browsers. Precise details may not match up with Mozilla browsers one-for-one, but the most common features are identical. The signed script policy is a different story, with respect

to Internet Explorer. Although Microsoft offers digital signatures for some items that may be embedded within an HTML page (such as ActiveX controls and other components), scripts that are in an HTML page's source code or linked in as a `.js` library cannot be signed for Internet Explorer. Although everything you read in this chapter about signed scripts applies only to Mozilla, you should find the next couple of sections informative, even if you develop solely for Internet Explorer or only cross-platform JavaScript code.

The Same Origin Policy

The "origin" in *same origin policy* refers to the protocol and domain of a source document. If all the source files currently loaded in the browser come from the same server and domain, scripts in any one part of the environment can poke around the other documents. Restrictions come into play when the script doing the poking and the document being poked come from different origins. The potential security and privacy breaches this kind of access can cause put it out of bounds within the same origin policy.

An origin is not the complete URL of a document. Consider the two popular URLs for Mozilla's web sites:

```
http://www.mozilla.org
http://developer.mozilla.org
```

The protocol for both sites is `http:`. Both sites also share the same domain name: `mozilla.org`. But the sites run on two different servers: `www` and `developer` (at least this is how the sites appear to browsers accessing them; the physical server arrangement may be quite different).

If a frameset contains documents from the same server at `mozilla.org`, and all frames are using the same protocol, they have the same origin. Completely open and free access to information, such as `location` object properties, is available to scripts in any frame's document. But if one of those frames contains a document from the other server, their origins don't match. A script in a document from one server would display an "access disallowed" or "permission denied" error message if it tried to get the `location` property of that other document.

A similar problem occurs if you were creating a web-based shopping service that displays the product catalog in one window and the order form from a secure server in another window. The order form, whose protocol might be `https:`, would not be granted access to the `location` object properties in a catalog page whose protocol is `http:`, even though both share the same server and domain name.

Setting the document.domain

When both pages in an origin-protected transaction are from the same domain (but different servers or protocols), you can instruct JavaScript to set the `document.domain` properties of both pages to the domain that they share. When this property is set to that domain, the pages are treated as if from the same origin. Making this adjustment is safe, because JavaScript doesn't

allow setting the `document.domain` property to any domain other than the origin of the document making the setting. See the `document.domain` property entry in Chapter 29, "The Document and Body Objects," for further details.

Origin checks

Scattered throughout the language reference chapters are notes about items that undergo what you now know to be origin checks. For the sake of convenience, we list them all here to help you get a better feeling for the kind of information that is protected. The general rule is that any object property or method that exposes a local file in a user's system, or can trace web surfing activity in another window or frame, undergoes an origin check. Failure to satisfy the same origin rule yields an "access disallowed" or "permission denied" error message on the client's machine.

Window object checks

The document object models of windows and frames that don't share the same origin are not available to each other. Each separate origin window or frame is its own little world that has very little ability to communicate with another window or frame. Internet Explorer sometimes takes this to the extreme, causing problems between a main window and a subwindow whose content is entirely dynamically generated from the main window's scripts.

Location object checks

All `location` object properties are restricted to same origin access. Of all same origin policy restrictions, this one seems to interfere the most with well-meaning page authors' plans, preventing them from providing a frame for users to navigate around the Web. Such access, however, would allow spying on your users.

Document object checks

A `document` object's properties are by necessity loaded with information about the content of that document. Just about every property other than the ones that specify color properties are off-limits if the origin of the target document is different from the one making the request:

```
anchors[]    lastModified
applets[]    length
cookie       links[]
domain       referrer
embeds       title
forms[]      URL
```

In addition, no normally modifiable `document` property can be modified if the origin check fails. This, of course, does not prevent you from using `document.write()` to write an entirely new page of content to the frame to replace a document from a different origin. But in modern browsers, scripts from one origin won't be able to modify (or even copy) partial content from a frame whose content comes from another origin.

Form object checks

Form data is generally protected by the restriction to a document's `forms[]` array. But should a script in another window or frame also know the name of the form, that, too, won't enable access unless both documents come from the same origin.

Applet object checks

The same goes for named Java applets. A script cannot retrieve information about the class filename unless both documents are from the same origin (although the applet can be from anywhere).

Access from a Java applet to JavaScript is not an avenue to other windows and frames from other origins. Any calls from the applet to the objects and protected properties described here undergo origin checks when those objects are in other frames and windows. The applet assumes the origin of the document that contains the applet, not the applet codebase.

Image object checks

Although image objects are accessible from other origins, their `src` and `lowsrc` properties are not. These URLs could reveal some or all of the URL info about the document containing them.

Linked script library checks

To prevent a network-based script from hijacking a local script library file, Mozilla prevents a page from loading a `file:` protocol library in the `src` attribute of a `<script>` tag unless the main document also comes from a `file:` protocol source. If you are beginning to think that security engineers are a suspicious and paranoid lot, you are starting to get the idea. It's not easy to curb potential abuses of Bad Guys in a networked environment initially established for openness and free exchange of information among trusted individuals.

The Netscape Signed Script Policy

Just as there are excellent reasons to keep web pages from poking around your computer and browser, there are equally good reasons to allow such access to a web site that you trust not to be a Bad Guy. To permit trusted access to the client machine and browser, Sun Microsystems and Netscape (in cooperation with other sources) developed a way for web application authors to identify themselves officially as authors of the pages, and to request permission of the user to access well-defined parts of the computer system and browser.

The technology is called object *signing*. In broad terms, object signing means that an author can electronically lock down a chunk of computer code (whether it be a Java applet, a plug-in, or a script) with the electronic equivalent of a wax seal stamped by the author's signet ring. At the receiving end, a user is informed that a sealed chunk of code is requesting some normally-protected access to the computer or browser. The user can examine the electronic seal to see who authored the code and the nature of access being requested. If the user trusts the author not to be a Bad Guy, the user grants permission for that code to execute; otherwise

the code does not run at all. Additional checks take place before the code actually runs. That electronic seal contains an encrypted, reduced representation of the code as it was locked by the author. If the encrypted representation cannot be re-created at the client end (it takes only a fraction of a second to check), it means the code has been modified in transit, and it will not run.

In truth, nothing prevents an author from being a Bad Guy, including someone you may normally trust. The point of the object signing system, however, is that a trail leads back to the Bad Guy. An author cannot use this technology to sneak into your computer or browser without your explicit knowledge and permission. Think of it like this: just because you willingly let someone into your home doesn't guarantee they won't steal your television, but the fact that you were able to decide whether or not to let them in at the front door goes a long way toward preventing a theft. And should it still occur, you know who the culprit is.

Since the key principle behind object signing is simply to verify the source of a script, for better or for worse, it should come as no surprise that object signing makes more sense within the realm of intranets as opposed to the Internet as a whole. That's not to say you can't sign scripts for the whole world to see, but don't just assume that because you know you're reputable, everyone else will assume the same. Within an intranet, the assumption that your own company can be trusted is a much safer pill to swallow.

Signed objects and scripts

A special version of the signed object technology is the one that lets scripts be locked down by their author and electronically signed. Virtually any kind of script in a document can be signed: a linked `.js` library, scripts in the document, event handlers, and JavaScript entities. As described later in this chapter, you must prepare your scripts for being signed, and then run the entire page through a special tool that attaches your electronic signature to the scripts within that page.

What you get with signed scripts

If you sign your scripts, and the user grants your page permission to do its job, signed scripts open up your application to a long list of capabilities, some of which border on acting like genuine local applications. A huge number of properties and actions are exposed to authors of signed scripts.

The most obvious power you get with signed scripts is freedom from the restrictions of the same origin policy. All object properties and methods that perform origin checks for access in other frames and windows become available to your scripts without any special interaction with the user, beyond the dialog box that requests the one-time permission for the page.

Some operations that normally display warnings about impending actions — closing the main browser window under script control, for example — lose those warning dialog boxes if the user grants the appropriate permission to a signed script. Object properties considered private information, such as individual URLs stored in the history object and browser preferences, are opened up, including the possibility of altering browser preferences. Existing windows can have their chrome elements hidden. New windows can be set to be always raised or lowered, sized to

very small sizes, or positioned offscreen. The `dragdrop` event of a window reveals its URL. All these are powerful points of access, provided the user grants permission.

Again, however, we emphasize that these capabilities are accessible through the Netscape signed script policy only, which is available in all Mozilla-based browsers. Internet Explorer, at least through Version 8, does not support Netscape's (Mozilla's) signed script policy.

The Digital Certificate

Before you can sign a script or other object, you must apply for a digital certificate. A digital certificate (also called a digital `id`) is a small piece of software that is downloaded and bound to the developer's browser on a particular computer. Each downloaded digital certificate is accessible from the Certificate Manager in Mozilla browsers, which is found in Firefox, for example, under the Security tab of the Advanced Options window. Click the View Certificates button to open the Certificate Manager. The Certificate Manager displays a list of the certificates currently available on your system. If you have not yet applied for a certificate, the list is empty. When you sign a page with the certificate, information about the certificate is included in the file generated by the signing tool.

Possession of a certificate makes you what is known as a *principal*. If a user loads a page that has signed "stuff" in it, a security alert advises the user that a web site is requesting enhanced privileges.

Certificates are issued by organizations established as certificate authorities. A certificate authority (known as a *CA* for short), or a certificate server authorized by a CA, registers applicants and issues certificates to individuals and software developers. When you register for a certificate, the CA queries you for identification information, which it verifies as best it can. The certificate that is issued to you identifies you as the holder of the certificate. Under the Authorities tab of the Security Manager window are the certificate authorities that were loaded into the browser when you installed it. These are organizations that issue certificates. The CA of the organization that issues your certificate must be listed for you to sign scripts.

How to get a certificate

You must visit a certificate vendor to obtain your certificate. The cost ranges from about $100 to many hundreds of dollars, depending on the vendor and the type of certificate you want to obtain. Vendors that are aware of the needs of Netscape object signing include Thawte Digital Certificate Services (`www.thawte.com`), VeriSign (`www.verisign.com`), and Instant SSL (`www.instantssl.com`). These certificate authorities offer certificates expressly for developers performing Netscape object signing. Make sure the certificate is specifically designed for signing objects.

Because one of the foundations of a certificate is the identity of the certificate owner, registration requires submitting documentation that proves the identity of your organization. Each CA has different requirements, so check the latest information at the CA's enrollment web site. After the

CA processes your application, the company sends you an email message with a code number to pick up your certificate at the CA's web site. The act of picking up the certificate is actually downloading the certificate into your browser. Therefore, be sure you are using a Mozilla-based browser on the computer with which you will use to sign your pages.

Activating the codebase principal

If you want to try out the capabilities available to signed scripts from a server without purchasing a certificate (or without going through the signing process described later in this chapter during script development and debugging), you can set up Mozilla to accept what is called a *codebase* principal in place of a genuine certificate. A codebase principal means that the browser accepts the source file as a legitimate principal, although it contains no identification as to the owner or certificate.

Note

You can experiment with properties and methods that normally require signed scripts without modifying the codebase principal preferences or signing scripts with a certificate. Each time you activate the Privilege Manager (as The Evaluator does when you select the "Use NN Codebase Security" check box), a security alert lets you elect to continue with the untrusted access to your browser or system. Do not select the box in the alert dialog box that remembers this choice, because it could leave your browser and system vulnerable to other unsigned scripts without your knowledge. ■

Depending on which Mozilla-based browser you are running, if you set up your browser for codebase principals, you may not be able to verify a certificate that is presented to you when accessing someone else's web site — even if it is a valid cryptographic certificate. Therefore, even though secure requests won't slip past you silently, your browser won't necessarily have the protective shield it normally does to identify certificate holders beyond the URL of the code. Enable codebase principals only on a browser installation that doesn't venture beyond your development environment. As an example, to activate codebase principals for Firefox browsers, follow these steps:

1. Navigate to the URL `about:config` in Firefox.
2. Scroll down the list of preferences until you find the one named `signed.applets.codebase_principal_support`.
3. Double-click the `signed.applets.codebase_principal_support` preference to change its value from `false` to `true`.

To deactivate codebase principals, change the `true` setting of the `signed.applets.codebase_principal_support` preference back to `false`. This preferences setting does not affect your ability to sign scripts with your certificate as described in the rest of this chapter.

Signing Scripts

The process of signing scripts entails some new concepts for even experienced JavaScript authors. You must use a separate signing tool program. You must also prepare the page that bears scripts so that the tool and the object signing facilities of the browser can do their jobs.

Signing tool

Download the latest version of Mozilla's SignTool from links you find at `http://www.mozilla.org/projects/security/pki/nss/tools/`. This tool includes a utility program called a `JAR` Packager. A `JAR` file is a special kind of zipped file collection that has been designed to work with the Navigator security infrastructure. The letters of the name stand for Java ARchive, which is a file format standard developed primarily by Sun Microsystems, in cooperation with Netscape and others.

Note

Unfortunately, the SignTool application is currently distributed as a suite of security applications that are available in source code form only. This means that you'll have to create the binary executables for the tools yourself by building them after downloading the source code. The source is freely available for download at `http://www.mozilla.org/projects/security/pki/nss/tools/`**.** ■

A `JAR` file's extension is `.jar`, and when it contains signed script information, it holds at least one file, known as the *manifest*, or list of items zipped together in the file. Among the items in the manifest is certificate information and data (a hash value code) about the content of the signed items at the instant they were signed. In the case of a single page containing signed scripts, the `JAR` file contains only the certificate and hash values of the signed scripts within the document. If the document links in an external `.js` script library file, that library file is also packaged in the `JAR` file. Thus, a page with signed scripts occupies space on the server for the HTML file and its companion `JAR` file.

The SignTool program combines the `JAR` Packager with the script signing functions. Follow links on the SignTool download page to the latest instructions on packaging and signing your finished files from the command line (there is no GUI for this tool). But before you reach that point, you need to compose your pages in such a way that the security mechanism can protect your scripts.

Preparing scripts for signing

In NN4, signifying which items in a page are script items that require signing was an important consideration. Modern Mozilla-based browsers require you to sign an entire page, not just the scripts within the page. Of course, any externally referenced scripts must still be signed if they need to be granted privileges within the context of the page. The good news is that the SignTool application makes it relatively painless to sign all the files associated with a page.

Accessing signed scripts

Once you've signed a page and its relevant scripts, you'll end up with a JAR file, or files, containing all the resources. To access a published page that lives within a signed JAR file, you must use the following syntax:

```
jar:http://www.mydomain.com/secure/topsecret.jar!/index.html
```

In this example, the domain is `www.mydomain.com`, the page is `index.html`, and it is located in the JAR file named `topsecret.jar` within the folder `secure`. Notice that the URL is preceded by `jar:`, which lets the browser know that it is dealing with a JAR archive.

Seeing as how this is somewhat of an unusual URL to require users to enter, especially as the front end on a secure web site, you may opt to display a redirection page of some sort that automatically redirects to the secure page. Here's a <meta> tag that accomplishes this task for the preceding example URL:

```
<meta http-equiv="refresh" content="0;
     url=jar:http://www.mydomain.com/secure/topsecret.jar!/index.html" />
```

By specifying 0 as the amount of time before the redirection, the net effect is an instant redirection to the secure page that contains signed JavaScript code.

Editing and moving signed scripts

The nature of the script signing process means that even the slightest modification you make to a signed script source code requires re-signing the page. For this reason, enabling codebase principals while you create and debug your early code is a convenient alternative.

The rigid link between the hash value of a script element at both the signing and visitor loading times means that you must exercise care when shifting an HTML file that contains signed script elements between servers of differing operating systems. Windows, UNIX, and Macintosh have different ways of treating carriage returns. If you change the representation of an HTML source file when you move the source from, say, a Windows machine to a UNIX server, the signature may no longer work. However, if you perform a purely binary transfer of the HTML files, every byte is the same, and the signature should work. This operating system–specific text representation affects only how files are stored on servers, not how various client platforms interpret the source code.

Accessing Protected Properties and Methods

For the browser to allow access to protected properties or methods, it must have its privileges enabled. Only the user can grant permission to enable privileges, but it is up to your code to make the request.

Gaining privileges

Mozilla-based browsers come with some Java classes that allow signed scripts and other signed objects to display the privilege request alert windows, and then turn on the privileges if the user clicks the OK or Grant button. A lot of these classes show up in the netscape.security package, but scripters only work directly with one class and three of its methods:

```
netscape.security.PrivilegeManager.enablePrivilege(["targetName"])
netscape.security.PrivilegeManager.revertPrivilege(["targetName"])
netscape.security.PrivilegeManager.disablePrivilege(["targetName"])
```

The `enablePrivilege()` method is the one that displays the security alert for the user. In its original inception in NN4, the specific target, named as a parameter, influenced the details of the security alert message; for Mozilla browsers, the security alert is generic (and far less intimidating).

If the user grants the privilege, script processing continues with the next statement. But if the user denies access, then processing stops, and the `PrivilegeManager` class throws a Java exception that gets displayed as a JavaScript error message. Later in this chapter, we show you how to gracefully handle the user's denial of access.

Enabling a privilege in JavaScript is generally not as risky as enabling a Java applet. The latter can be more easily hijacked by an alien class to piggyback on the trusted applet's privileges. Even though the likelihood of such activity taking place in JavaScript is very low, turning privileges off after the statement that requires privileges is always a good idea. Use the `revertPrivilege()` method to temporarily turn off the privilege; another statement that enables the same privilege target will go right ahead without asking the user again. Disable privileges only when the script requiring privileged access won't be run again until the page reloads.

Specifying a target

Rather than opening blanket access to all protected capabilities in one blow, the Netscape security model defines narrow capabilities that are opened up when privileges are granted. Each set of capabilities is called a target. Netscape defines dozens of different targets, but not all of them are needed to access the kinds of methods and properties available to JavaScript. You will likely confine your targets to the nine discussed here.

Because NN4's security alerts provided detail (at times excruciating) about the nature of the privilege being requested by the web site, targets had various risk levels and categories. These concerns are less of an issue in Moz1+, but they are provided here for your more complete understanding of the mechanisms beneath the Privilege Manager.

Each target has associated with it a risk level (low, medium, or high) and two plain-language descriptions about the kinds of actions the target exposes to code. All the targets related to scripted access are medium or high risk, because they tend to open up local hard disk files and browser settings.

Netscape produced two categories of targets: primitive and macro. A *primitive target* is the most limited target type. It usually confines itself to either the reading or writing of a particular kind of data, such as a local file or browser preference. A *macro target* usually combines two or more primitive targets into a single target to simplify the user experience when your scripts require multiple kinds of access. For example, if your script must both read and write a local file, it could request privileges for each direction, but the user would be presented with a quick succession of two similar-looking security dialog boxes. Instead, you can use a macro target that combines both reading and writing into the privilege. The user sees one security dialog box, which explains that the request is for both read and write access to the local hard disk.

Likely targets for scripted access include a combination of primitive and macro targets. Table 49-1 shows the most common script-related targets and the information that appears in the security dialog box.

TABLE 49-1

Scripting-Related Privilege Targets

Target Name	Risk	Short Description	Long Description
`UniversalBrowserAcess`	High	Reading or modifying browser data	Reading or modifying browser data that may be considered `BrowserAccess` private, such as a list of websites visited or the contents of web forms you may have filled in. Modifications may also include creating windows that look like they belong to another program or positioning windows anywhere on the screen.
`UniversalBrowserRead`	Medium	Reading browser data	Access to browser data that may be considered `BrowserRead` private, such as a list of web sites visited or the contents of web page forms you may have filled in.
`UniversalBrowserWrite`	High	Modifying the browser	Modifying the browser in a potentially dangerous `BrowserWrite` way, such as creating windows that may look like they belong to another program or positioning windows anywhere on the screen.
`UniversalFileAccess`	High	Reading, modifying, or deleting any of your files	This form of access is typically required by a `FileAccess` program such as a word processor or a debugger that needs to create, read, modify, or delete files on hard disks or other storage media connected to your computer.
`UniversalFileRead`	High	Reading files stored in your computer	Reading any files stored on hard disks or other `FileRead` storage media connected to your computer.
`UniversalFileWrite`	High	Modifying files stored in your computer	Modifying any files stored on hard disks or other `FileWrite` storage media connected to your computer.
`UniversalPreferencesRead`	Medium	Reading preferences settings	Access to read the current settings of your `PreferencesRead` preferences.
`UniversalPreferencesWrite`	High	Modifying preferences settings	Modifying the current settings of your `PreferencesWrite` preferences.
`UniversalSendMail`	Medium	Sending SendMail email messages on your behalf	

For each call to `netscape.security.PrivilegeManager.enablePrivilege()`, you specify a single target name as a string, as in

```
netscape.security.PrivilegeManager.enablePrivilege("UniversalBrowserRead");
```

This specification allows you to enable, revert, and disable individual privileges as required in your script.

Adding Privileges to Scripts

The implementation of signed scripts in Mozilla browsers protects scripters from many of the potential hazards that Java applet and plug-in developers must watch for. The chance that a privilege enabled in a script can be hijacked by code from a Bad Guy is very small. Still, exercising safe practices in case you someday work with other kinds of signed objects is a good idea.

Keep the window small

Privilege safety is predicated on limiting exposure according to two techniques. The first technique is enabling only the level of privilege required for the protected access your scripts need. For example, if your script only needs to read a normally protected `document` object property, enable the `UniversalBrowserRead` target rather than the wider `UniversalBrowserAccess` target.

The second technique is to keep privileges enabled only as long as the scripts need them enabled. If a statement calls a function that invokes a protected property, enable the privilege for that property in the called function, not at the level of the calling statement. If a privilege is enabled inside a function, the browser automatically reverts the privilege at the end of the function. Even so, if the privilege isn't needed all the way to the end of the function, you should explicitly revert it after you are through with the privilege.

Think of the users

One other deployment concern focuses more on the user's experience with your signed page. You should recognize that the call to the Java `PrivilegeManager` class is an NPAPI (Netscape Plug-in Application Programming Interface) call from JavaScript. Because the Java virtual machine does not start up automatically when the browser does, a brief delay occurs the first time an NPAPI call is made in a session (the status bar displays "Starting Java ... "). Such a delay may interrupt the user flow through your page if, for example, a click of a button needs access to a privileged property. Therefore, consider gaining permission for protected access as the page loads. Execute an `enablePrivilege()` and `revertPrivilege()` method in the very beginning. If Java isn't yet loaded into the browser, the delay is added to the other loading delays for images and the rest of the page. Thereafter, when privileges are enabled again for a specific action, neither the security dialog box, nor the startup delay, get in the way for the user.

Also remember that users don't care for security dialog boxes interrupting their navigation. If your page utilizes a couple of related primitive targets, enable the macro target that encompasses those primitive targets at the outset. The user gets one security dialog box covering all potential actions in the page. Then, let your script enable and revert each primitive target as needed.

Examples

To demonstrate signed scripts in action, we show a couple of examples of scripted code that normally wouldn't be allowed based upon default browser security limitations. More specifically, you see a script that accesses the current home page setting for the browser, which is considered private and off-limits under normal circumstances. You also take a look at a page that allows the script to open an always-raised new window. No error checking occurs for the user's denial of privilege in this example. Therefore, if you experiment with this page (either with codebase principals turned on or signing them yourself), you will see the JavaScript error that displays the Java exception. Error detection is covered later in the chapter.

Accessing private browser information

Listing 49-1 contains a very simple HTML document that attempts to read the home page of the browser and display it in an alert box. Keep in mind that this is considered privileged information and is off-limits unless the script is signed and the user explicitly grants permission.

LISTING 49-1

Peeking at the Default Home Page

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Home Page Extractor</title>
      <script type="text/javascript">
         function showHome()
         {
            try
            {
netscape.security.PrivilegeManager.enablePrivilege("UniversalPreferencesRead");
               var home = navigator.preference("browser.startup.homepage");
               alert("The home page for this browser is currently set to "
               + home + ".");
            }
            catch (e)
            {
               alert("This browser's home page is none of your business.");
            }
         }
      </script>
   </head>
   <body onload="showHome();">
      <h1>Home Page Extractor</h1>
   </body>
</html>
```

In this example, a universal read privilege is first requested, which is ultimately where the check takes place to see if the secure action (reading the home page) will be allowed. If so, the home page is read via the `browser.startup.homepage` preference and then displayed in an alert box. If the action is declined, a message is displayed indicating the failure.

Accessing a protected window property

Listing 49-2 is a small document that contains one button. The button calls a function that opens a new window with the Moz-specific `modal` parameter turned on. Setting protected `window.open()` parameters in Moz1+ requires the `UniversalBrowserWrite` privilege target. Inside the function, the privilege is enabled only for the creation of the new window. For this simple example, we do not enable the privilege when the document loads.

LISTING 49-2

Creating an alwaysRaised Window

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Simple Signed Script</title>
      <script type="text/javascript">
         function newModalWindow()
         {
netscape.security.PrivilegeManager.enablePrivilege("UniversalBrowserWrite");
            var newWindow = window.open
           ("jsb49-03.html","","height=100,width=300,modal");
netscape.security.PrivilegeManager.disablePrivilege("UniversalBrowserWrite");
         }
      </script>
   </head>
   <body>
      <b>This button generates a modal-style new window.</b>
      <form>
         <input type="button" value="New Modal Window"
                onclick="newModalWindow()" />
      </form>
   </body>
</html>
```

Note

The property assignment event handling technique used in this example and throughout the chapter is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event-handling technique is explained in detail in Chapter 32, "Event Objects."** ■

Listing 49-2 has two security-related script items: the `<script>` tag and the event handler for the button. These two components are automatically signed when you pass the entire page

through the SignTool application. Note that this example file is not signed, and therefore does not include a companion JAR archive on the CD-ROM.

Handling Privilege Manager Errors

Handling privilege manager errors is important because an error is generated any time a user denies access to advanced privileges. Although the error is not destructive in any way, and it appears only in the JavaScript/Error Console window, accounting for such factors is good coding practice.

You can use the native `try...catch` exception handling to respond to privilege errors, which means that the calls to the `enablePrivilege()` method of the `PrivilegeManager` class must be wrapped inside a `try` block. The function from Listing 49-2 is modified as follows:

```
function newModalWindow()
{
   try
   {
      netscape.security.PrivilegeManager.enablePrivilege(
         "UniversalBrowserWrite");
      var newWindow = window.open("jsb49-03.html","",
         "height=100,width=300,modal");
      netscape.security.PrivilegeManager.disablePrivilege(
         "UniversalBrowserWrite");
   }
   catch(err)
   {
      alert("You have elected not to grant privileges to this script.");
   }
}
```

Signed Script Miscellany

In this section, we list some of the more esoteric issues surrounding signed scripts. Three in particular are: how to allow unsigned scripts in other frames, windows, or layers to access signed scripts; how to make sure your signed scripts are not stolen and reused; and special notes about international text characters.

Exporting and importing signed scripts

JavaScript provides an escape route that lets you intentionally expose functions from signed scripts for access by unsigned pages. If such a function contains a trusted privilege without careful controls on how that privilege is used, a page that is not as well intentioned as yours could hijack the trust.

The command for exposing this function is export. The following example exports a function named `fileAccess()`:

```
export fileAccess;
```

A script in another window, frame, or layer can use the import command to bring that function into its own set of scripts:

```
import fileAccess;
```

Even though the function is now also a part of the second document, it executes within the context of the original document, whose signed script governs the privilege. For example, if you exported a function that did nothing but enable a file access privilege, a Bad Guy who studies your source code could write a page that imports that function into a page that now has unbridled file access.

If you want to share functions from signed scripts in unsigned pages loaded into your own frames or layers, avoid exporting functions that enable privileges. Other kinds of functions, if hijacked, can't do the same kind of damage as a privileged function can.

Locking down your signed pages

Speaking of hijacking scripts, it would normally be possible for someone to download your HTML and JAR archive files and copy them to another site. When a visitor comes to that other site and loads your copied page and JAR file, your signature is still attached to the scripts. Although this may sound good from a copyright point of view, you may not want your signature to appear as coming from someone else's web server. You can, however, employ a quick trick to ensure that your signed scripts work only on your server. By embedding the domain of the document in the code, you can branch execution so that scripts work only if the file comes from your server.

The following script segment demonstrates one way to employ this technique:

```
<script type="text/javascript">
   if (document.URL.match(/^http:\/\/www.myDomain.com\//))
   {
      // privileges statements execute only from my server
   }
</script>
```

Even though this branching code is visible in the HTML file, the hash value of your code is saved and signed in the archive. If someone modifies the HTML, the hash value that is recalculated when a visitor loads the page won't match the JAR file manifest, and the script signature fails.

International characters

Although international characters are fine for HTML content, they should not be used in signed scripts. The problem is that international characters are often converted to other character sets for display. This conversion invalidates the signature, because the signed and recalculated hash values don't match. Therefore, do not put international characters in any signable script item. If you must include such a character, you should escape it.

CHAPTER 50

Cross-Browser Dynamic HTML Issues

IN THIS CHAPTER

Introducing Dynamic HTML

The common denominator of DHTML functionality across browsers

Upgrading to modern compatibility techniques

Version 4 browsers — NN4 and IE4 — were the first to include World Wide Web technologies that gave page authors far more control over the display and interactive behavior of web page content. Lumped together under the heading of Dynamic HTML (DHTML), these technologies dramatically extended the simple formatting of standard HTML that page authors had used for years. These days, scripters and designers coming to web development for the first time take DHTML capabilities for granted; they are probably unaware that plain ol' HTML is little more than a specification to assign context to static text and images on a page.

A lot of what the user gets with DHTML had previously been accomplished only through Java applets and plug-ins, such as early versions of Shockwave (pre-Flash). Not that DHTML eliminates these technologies from the web author's arsenal (DHTML doesn't do sound or video, for example), but because DHTML can accomplish much more of what authors look for in assembling page content and layout, without the long downloads of applets or plug-in content, it becomes an attractive way for nonprogrammers to spice up web applications. At the same time, however, some recent technologies, such as Ajax, have brought legions of experienced programmers onto the scene to create some amazing application-like web pages for mapping, email, and much more.

What Is DHTML?

You can find practically as many definitions of Dynamic HTML as there are people to ask. Our definition covers a broad range, because DHTML is not really any one "thing." Instead, it is an amalgam of several technologies, each of which has a standards effort in varying stages of readiness. The key technologies are as follows: Cascading Style Sheets (CSS);

Document Object Model (DOM); and client-side scripting. It will help your authoring skills if you have a little historical perspective on how the Web arrived at DHTML.

For many years, the HTML standard was intended for the rendering of static content — not much more than an electronic version of a printed page. The most interactive part of a page was a form, which included buttons to click and text boxes to fill in. But for anything to change on the page, the content had to be served up again from the host computer.

Client-side scripting, as first implemented through JavaScript way back in NN2, opened the way for HTML pages to not only contain some smarts, but to also control individual pieces of content on the page without fetching a modified page from the server. At first, only form control elements were scriptable. Soon thereafter, images could be swapped, although the rectangular space for the image was fixed when the page loaded. More dynamism accrued to pages in NN4 by way of the layer, which acted like a borderless, transparent, or opaque window that could contain its own HTML document content and be positioned anywhere on the page — it could even overlap content on the main page or other layers. A layer's entire content could be modified without touching the rest of the page or other layers.

But the real breakthrough in dynamism came in IE4, whose rendering engine permitted any element to be modified, inserted, or removed on the fly, while the rest of the page reflowed its content quickly and automatically in response to the change. At the same time, an accepted standard for style sheets (CSS) opened the way for scripts to modify the look of content already on the page. Text could change colors when a cursor rolled atop it by either adjusting the style sheet property associated with the text or changing the style sheet rule that applies to the text.

Development activity at both Netscape and Microsoft eventually led to a standard for the Document Object Model as a way for scripts to control HTML content directly. Unfortunately, the browser makers frequently implemented first, and only then tried to establish their implementations as standards. Sometimes, the implementations were not as complete as the standards became, leaving the browsers in states that only partially implement the standards, while paying homage to legacy implementations. Netscape used the occasion of developing an entirely new code base for what became the Mozilla browser family to try to sever some ties with the past. In many respects the Mozilla browser represents the state of the standard art as implemented so far, although an argument could certainly be made that Opera is even more standards-compliant than Mozilla browsers.

Unfortunately, IE is still attempting to cater to both the legacy implementation and the standards, creating a massive DOM implementation with significant overlap in functionality with different syntaxes. Thus, the result of proprietary explorations and industry standards is a choice of modern browsers that permit a wide range of dynamic activity on content that reaches the user. Browsers that had started life as sleepy renderers of a tiny HTML vocabulary have grown into powerful front ends for server applications, and even self-contained applications of a sort that execute entirely on the client computer.

Although it's safe to say that version 4 browsers are now officially passé, mobile browsers are becoming increasingly popular, and they share some of the same limitations as legacy browsers. More specifically, many mobile browsers are streamlined to the extent that they have limited or no DOM support, and therefore little or no scripting support. If you're creating a scripted web

application, even if it is targeting modern browsers, it may still make sense to include code that gracefully degrades for mobile browsers.

Standards for CSS, DOM, and JavaScript/ECMA scripting have been well covered earlier in this book. The purpose of this chapter is to help you produce content that runs on DHTML-capable browsers, as well as mobile browsers with no DHTML support at all. Historically, most of the DHTML compatibility problems stem from page authors trying to develop for essentially three different document object models: NN4, IE4+, and W3C DOM (as implemented in IE5+/NN6+/Moz, Gecko, and WebKit- and Presto-based browsers). Nowadays, with the exception of having to accommodate IE's proprietary event model, it's reasonably safe to focus on the latter approach, while taking into consideration the limitations that are often associated with mobile browsers.

Striving for Compatibility

With as many as three object models to support (you can, of course, elect to support only a subset of browsers, if you like) you should look for ways to minimize your pain. If the NN4 object model is in your mix, you will very likely experience moments of sheer torture, as you try to get even the CSS-supported HTML to behave as it does in browsers of the other object models. Thankfully, the NN4 browser's installed base is quickly becoming a remnant of the past.

There are two keys to survival among the object models: knowing each DOM's limitations and finding common denominators.

Between the IE4+ and W3C DOMs, the biggest differences, outside of the conflicting event model syntax, fall along operating system and browser brand lines. For example, Microsoft takes advantage of the integration of the IE browser and the Windows operating system to such an extent that it can provide IE services, such as ActiveX controls and filters, that work only on Windows versions of IE. MacIE users are out of luck, as are users of any other browser brand.

Looking for areas of commonality — or at least gaining a clear understanding of where the models diverge — can be a tedious, yet personally rewarding, pursuit. Because Microsoft implemented some basic W3C DOM element referencing syntax as early as IE5, one compatibility hassle has all but disappeared. That still leaves, however, the W3C DOM's finger-twisting industry standard `document.getElementById()` method to obtain a reference to any ID'd element (implemented in IE5+/NN6+/ Moz, Gecko, and WebKit- and Presto-based browsers).

As soon as your script has a valid reference to an element, the next step is to read or write some property, or invoke some method that governs the element's position (and possibly other style) attributes. Here, again, the object models diverge, but not quite as severely. The W3C DOM works its positioning magic through the `style` property of a positioned element. In some cases the "last-dot" property names are identical across all three models (for example, `document.myLayer.zIndex`, `document.all.myLayer.style.zIndex`, and `document.getElementById("myLayer").style.zIndex`). Building a reference to reach that last dot, however, is where some of your hard work must go. You can also use the W3C `window.getComputedStyle()` method to obtain read-only access to all of the CSS styles associated with a particular element.

Each DOM also has its own event model. Whereas IE5+ overlaps its DOM features with both the IE4+ and, to some extent, the W3C DOM, the event models don't follow the same lines of

implementation. As of WinIE8 and MacIE5, IE does not implement any of the W3C DOM event model, although Mozilla-based browsers and Safari do.

The bottom line, then, is that letting your scripts decide how to perform actions based on the browser version is not a good idea. Instead, the scripts should be smart enough to act based on the capabilities of the browser that is currently running the script. The good news is that with a few exceptions (IE events, for example) it is now possible to forego the version 4 DOMs and focus solely on supporting the W3C DOM in modern browsers.

Working Around Incompatibilities

To create DHTML for multiple DOMs, you must find ways to accommodate incompatible object references and occasionally incompatible property names. Scripting gives you several alternatives to working your way around these potential problems. Some of the approaches you can take are now passé. They are described here partly for the sake of historical reference, but also because you will see many instances of these approaches in legacy DHTML applications from the days when authors only had to worry about two DOMs (NN4 and IE4). The real meat of this discussion comes later, when you learn more about object detection and custom APIs.

Old-fashioned compatibility tricks

Until late 2000, it was necessary to write cross-browser DHTML applications that had to run on two classes of browser: NN4 and IE4. Two approaches to writing code for these two DOMs grew in popularity: inline branching and platform equivalency. They are described here, not for you to apply, but for you to understand what the pioneers did, in case you encounter their code in your web surfing.

Inline branching

The idea behind inline branching is that your scripts use `if...else` decisions to execute one branch of code for one browser and another branch for the other browser. Before you can begin to write code that creates branches for each browser, you should define two global variables at the top of the page that act as Boolean flags for your `if...else` constructions later. Therefore, at the first opportunity for a `<script>` tag in a page, include the following code fragment to set flags named `isNav4` and `isIE4`:

```
var isNav4, isIE4;
if (parseInt(navigator.appVersion) == 4)
{
   if (navigator.appName == "Netscape")
   {
      isNav4 = true;
   }
   else if (navigator.appVersion.indexOf("MSIE") != -1)
   {
      isIE4 = true;
   }
}
```

Version checking here is quite specific. First of all, it intentionally confines access to browsers whose versions come back as version 4. This code, written when the browsers were still at version 4, was remarkably prescient. Our concern at the time was that DHTML was so volatile that it was unknown if future browser versions would be backward compatible with the code to be run inside branches governed by the two global variables. As it turned out, NN6 (whose `navigator.appVersion` reports 5) is not backward compatible with the layer structure of NN4, so that locking the NN4 branches to NN4 became a good thing. On the IE side, the `navigator.appVersion` property continues to report 4, even through IE8, which is backward compatible with IE4. Thus, any branch dedicated to IE4 executes under this scheme and remains syntactically accurate.

Another aspect of the flag-setting script we should mention is that the example provides no escape route for browsers that aren't level 4, and aren't either Navigator or Internet Explorer (should there be a level 4 browser from another brand). In a production environment, we would either prefilter access to the page or redirect ill-equipped users to a page that explains why they can't view the page. In the structure of the preceding script, redirection would have to be made in two places, as follows:

```
var isNav4, isIE4;
if (parseInt(navigator.appVersion) == 4)
{
   if (navigator.appName == "Netscape")
   {
      isNav4 = true;
   }
   else if (navigator.appVersion.indexOf("MSIE") != -1)
   {
      isIE4 = true;
   }
   else
   {
      location = "sorry.html";
   }
}
else
{
   location = "sorry.html";
}
```

Note

In case you're curious, Firefox and other Mozilla-based browsers still report `Netscape` **as their** `appName`**. See for yourself by entering** `navigator.appName` **in the first entry box in The Evaluator Sr. (discussed in Chapter 4, "JavaScript Essentials").** ■

With the global variables defined in the document (and unsupported browsers redirected elsewhere), you can use them as conditional values in branching statements that address an object according to the reference appropriate for each platform. For example, to change the `visibility` property of an object named `instructions`, you use the flags as follows:

```
if (isNav4)
{
   document.instructions.visibility = "hidden";
}
else
{
   document.all.instructions.style.visibility = "hidden";
}
```

As the browser DOMs evolve, expand, and fragment, inline branching becomes increasingly less practical. With so many permutations of the DOM, according to browser brand, browser version, and operating system, you can drive yourself crazy trying to accommodate them all and maintain the code going forward. This approach also eliminates from consideration any non-NN or non-IE browser (such as Opera or WebKit-based browsers, although all of them have reported themselves as something other than they are at one time or another) that may have the capabilities needed to play your DHTML scripts. This approach also limits the possibility that future browsers with higher `navigator.appVersion` values can take advantage of your scripts. In short, this browser-sniffing approach is predominantly a remnant of the scripting days of old, although it does still resonate now on occasion when you need to take advantage of a Microsoft-specific browser feature, or must accommodate a bug in a specific previous version of a browser.

Platform equivalency

Another legacy compatibility technique attempts to limit the concern for the different ways the IE4 and NN4 platforms refer to a positionable element (because cross-browser DHTML were pretty much limited to the properties affecting positionable elements). If you examine the formats for each platform's object references, you see that they all contain a reference to the `document` and to the object name or ID. The IE4+ DOM syntax also includes property words, such as `all` and `style`. If you assign these extra property names to variables for IE4, and leave those variables as empty strings for NN4, you can assemble an object reference for those two platforms in one statement.

Note

If all this talk of version 4 browsers has you thinking we're living in the wrong century, just keep in mind that you have to understand history in order to learn from it. Even modern browsers are far from perfect with regard to compatibility, so unfortunately it still isn't possible to think entirely in terms of JavaScript code that can be written once and run everywhere, without a few compatibility hacks here and there. Understanding how version 4 compatibility problems were solved will help when you inevitably run across a modern day browser problem. ■

To begin using this technique, set two global variables that store reference components for the scope (`all` in IE4) and the `style` object (`style` in IE4):

```
var range = "";
var styleObj = "";
if (parseInt(navigator.appVersion) == 4)
{
```

```
      if (navigator.appVersion.indexOf("MSIE") != -1)
      {
         range = "all.";
         styleObj = ".style";
      }
   }
```

From this point, you can assemble an object reference with the help of the JavaScript `eval()` function, as follows:

```
var instrux = eval("document." + range + "instructions" + styleObj);
instrux.visibility = "hidden";
```

Or, you can use the `eval()` function to handle the entire property assignment in one statement, as follows:

```
eval("document." + range + "instructions" + styleObj +
     ".visibility = 'hidden'");
```

If your page does not have a lot of objects that your scripts will be adjusting, you can use this platform equivalency approach to create global variables holding references to your positionable objects at load time (triggered by the `onload` event handler so that all objects exist and can be referenced by the `eval()` function). Then, use those variables for object references throughout the scripts.

Unfortunately, the platform equivalency methodology breaks down when an NN4 layer object is nested inside another layer. The platform equivalency formulas assume that each object is directly addressable from the outermost `document` object. If your objects have a variety of nested locations, you can use either the inline branching method described earlier, or batch-assign objects to global variables at load time, using platform branching techniques.

Modern approaches to compatibility

Although in-line branching and platform equivalency were suitable for their generations, modern browsers call for better approaches to simplify authoring for multiple DOMs. Browser-sniffing is no longer a workable strategy, except in rare instances. Techniques more suitable for today — object detection and custom APIs — are not really new. But these techniques are the preferred way to build cross-browser scripts with an eye to compatibility, both backward and forward. The good news is that these techniques are becoming less and less necessary as time goes by and browsers continue to adhere more closely to published standards.

Object detection

The subject of object detection has been mentioned in several places in earlier chapters of this book. The technique has been used for a long time to let a browser not equipped to handle image objects gracefully skip over image swapping script segments:

```
if (document.images)
{
   // statements to work with image objects
}
```

If there is no `document.images` property for a browser, the condition evaluates to `undefined`, which the condition treats as being `false`.

But object detection has also been misused in the past, especially in the DHTML realm, to substitute for browser version detection. For example, if a browser supported the `document.all` collection, a global variable was set to indicate that the browser was IE4 or later; the existence of `document.layers` supposedly meant that the browser was NN4. It was a mistake, however, to link a browser version with the existence of an object or property (Opera supports the `document.all` collection, as well as the W3C). Instead, object detection should be used only if your script statements will be addressing that object, just as the `document.images` condition does in the previous example.

To demonstrate this tactic, consider the need to assemble a reference to an object so that it is ready to have one of its DHTML properties adjusted. Each of the three DOMs (NN4, IE4+, W3C) has its own syntax for assembling such a reference, and each syntax relies on the existence of a particular object or property. The function shown in Listing 50-1 (not by itself, but as a part of Listing 50-3) enables you to pass the name or ID of a positioned element (either in string form or object form) to receive back a valid reference to the object with which style-related properties are associated — all without resorting to the `eval()` function in any form.

LISTING 50-1

Using Object Detection to Assemble an Element Object Reference

```
function getObject(obj)
{
   if (document.getElementById)
   {
      if (typeof obj == "string")
      {
         return document.getElementById(obj).style;
      }
      else
      {
         return obj.style;
      }
   }
   if (document.all)
   {
      if (typeof obj == "string")
      {
         return document.all(obj).style;
      }
      else
      {
         return obj.style;
      }
   }
```

continued

LISTING 50-1 *(continued)*

```
   if (document.layers)
   {
      if (typeof obj == "string")
      {
         // just one layer deep
         return document.layers[obj];
      }
      else
      {
         // can be a nested layer
         return obj;
      }
   }
   return null;
}
```

The primary object detection for each of the three sections of this function looks for the presence of categories of objects (`document.layers` and `document.all`) or a particular method (`document.getElementById()`), and then — this is the important part — the script uses those detected objects in the statements. The script doesn't know IE4 from NN7; it *does* know how to derive valid references for three different object models, and employs the syntax of the first one for which the associated object property or method is supported.

In practice, the order of the three sections should have no bearing on your scripts, but you should be aware of one subtlety: IE5+ can work with either of the first two sections, because those browsers detect `document.all` and `document.getElementById` as valid references. In the order shown in the listing, you force IE5+ to use W3C DOM syntax. The results, however, are the same: A valid reference to the `style` object associated with an element.

The code in Listing 50-1 is backward compatible with browsers all the way back to NN4 and IE4, which is fine but probably not necessary at this point in time. If you want to focus solely on modern (W3C) browsers, then the previous code can be easily modified (see Listing 50-2) to accommodate them.

LISTING 50-2

Assembling a W3C DOM Element Object Reference

```
function getObject(obj)
{
   if (document.getElementById)
   {
      if (typeof obj == "string")
      {
         return document.getElementById(obj).style;
```

```
      }
      else
      {
         return obj.style;
      }
   }
   return null;
}
```

In Listing 50-2, only the final `if` clause is kept around since it focuses solely on W3C browsers. You could argue that the function isn't even necessary since it calls the `getElementById()` function regardless of the browser. However, this version of `getObject()` still includes the flexibility of allowing you to pass an object or an ID.

Custom APIs

Notions of object detection and simplifications of your scripts come together in the final approach to building cross-browser DHTML: Writing a custom application programming interface (API). A JavaScript custom API is a library of functions you design to act as an intermediary between your scripts and other scriptable entities. Ideally, an API simplifies access to, or control of, other entities. In the context of designing a cross-browser DHTML page, an API can offer a single function that smoothes over the differences in object references or property names among several platforms. Your custom function provides a single access point that is consistent across all platforms. In essence, you are creating your own meta-vocabulary for methods and property settings.

The element object reference maker in Listings 50-1 and 50-2 is a good start for such an API, because all other functions for moving, hiding, showing, and changing the stacking order of a positionable element need a valid style-oriented reference to the element.

Consider an interface that deals with incompatible ways of adjusting the location of a positionable element. In this case, the act of moving an element has different syntax in different DOMs. One group (NN4 for layers) uses the `moveTo()` method; the rest support `left` and `top` properties of their `style` object:

```
// position an object at a specific pixel coordinate
function shiftTo(obj, x, y)
{
   var theObj = getObject(obj);
   if (theObj.moveTo)
   {
      theObj.moveTo(x,y);
   }
   else if (typeof theObj.left != "undefined")
   {
      theObj.left = x + "px";
      theObj.top = y + "px";
   }
}
```

Note

In reality, it is no longer necessary to write JavaScript code that is backward compatible with version 4 browsers. However, with the track records that browser vendors have established, you are still likely to encounter situations where you may need to employ such branching techniques to fully support popular browsers. Therefore, this example is a good reference for how to develop code that can live happily across browsers with compatibility issues. ■

Notice one workaround, which, on the surface, isn't pretty: The second branch must perform an odd way of object detection. We're stuck with having to make a tradeoff when it comes to checking for the existence of a style property. If the page uses style sheets defined in `<style>` tags (or imported into the page from external style sheet files), the element affected by the rule does not yield the rule's property values through the element's `style` property. The property exists, but its value in this case (or until it is set by script) is an empty string. IE5+ provides a `currentStyle` property to give us the effective values, but that property is not (yet) a part of the DOM standard. It's true that you can derive the effective style property of an element through the W3C DOM (see Chapter 38, "Style Sheet and Style Objects"), but even if you assign the style sheet through the element's `style` attribute (in which case the style property values come through), detecting the presence of the property with the conditional expression

```
if (theObj.left)
```

is not practical here anyway. If the effective value of the `left` and `top` properties were empty strings (or zero for numeric style property values), the conditional expression would evaluate to the equivalent of `false`, making it appear as though the property doesn't exist. To validate the existence of the property, the conditional expression verifies that the value of a named property has a type other than *undefined*. It may seem like a long way to go to prove the existence of a property, but it works, even if the value is an empty string or zero.

It is important that both branches perform object detection. Although it is unlikely (but, as we learned from the transition between NN4 and NN6, not impossible), if a future browser should completely alter its vocabulary, omitting the objects being detected here, the function ends gracefully, without generating script errors.

An API is usually best deployed as an external `.js` file. One such API file is described later in this chapter. Bear in mind, however, that a lengthy API is downloaded to the browser, no matter how much or how little of it your main scripts use. Blindly linking in a big library just to use a few of its functions is a mistake. You serve your users better if you create a subset of the API, and link the subset to the page (or drop the few functions directly into the page's scripts if the combination is not reused on a lot of pages).

Handling non-DHTML browsers

An important question to ask yourself as you embark on a DHTML-enhanced page is how you intend to treat visitors whose browsers aren't up to the task. In many respects, the problem is similar to the problem of treating nonscriptable browsers when your page relies on scripting (see Chapter 4). Both mobile browsers and desktop browsers that have scripting disabled are potentially capable of presenting a problem in this regard. Keep in mind, however, that multiple CSS style sheets can be specified by the page, which is a non-scripting way to handle the look and feel of your web site on a mobile browser, accessible device, or other device.

The moment your page uses DHTML to position an element, you must remember that non-DHTML browsers display the content according to traditional HTML rendering rules. No elements are allowed to overlap. Any block-level tag is rendered at the left margin of the page, unless some other non-DHTML alignment (center or right) is at work. This goes for elements that you design to be DHTML-positioned to sit offscreen (perhaps with a clickable tab) until called by the user. An element defined as being hidden or not displayed in DHTML will be visible. In most cases, your carefully designed DHTML page will look terrible.

However, a page that does not use too radical a layout strategy may still be usable in non-DHTML browsers. You should try to check your DHTML-enabled page in a mobile browser with limited or no scripting support to see how it looks. Perhaps there isn't too much you need to do to degrade the DHTML so that the page is acceptable in limited browsers.

The ultimate responsibility for deciding your compatibility strategy with mobile browsers rests with you and your perceptions about your page visitors. If they are in need of vital information from your site and that information is readable in non-DHTML browsers, that may be enough. Otherwise, you must provide a separate content path for both types of browsers. This may make more sense anyway since mobile web pages often benefit from their own unique graphical content and layout schemes.

A DHTML API Example

Now it's time to get to a real DHTML API that you can use and build upon for your own applications. Listing 50-3 contains the API code, which is most likely to be deployed as an external `.js` library file. In fact, this API is used as-is in a map puzzle game application in Chapter 59, "Application: Cross-Browser DHTML Puzzle Map" (on the CD-ROM). You can see there how it is used to control element positioning, dragging, and layering for W3C DOM browsers, while also making sure that features are supported before summoning them. The code in Listing 50-3 is longer than most listings in this book, so, for your convenience, we interlace commentary within the long listing.

The library starts with the `getObject()` function shown earlier in this chapter. Virtually every other function in this library makes a trip to `getObject()` to convert the name of the object passed as a parameter to an object reference whose positionable (or other style-related property) can be adjusted.

LISTING 50-3

The Custom API

DHTML api.js

```
// convert object name string or object reference
// into a valid object reference ready for style change
function getObject(obj)
{
   if (document.getElementById)
   {
      if (typeof obj == "string")
```

continued

LISTING 50-3 *(continued)*

```
      {
         return document.getElementById(obj).style;
      }
      else
      {
         return obj.style;
      }
   }
      if (document.all)
      {
         if (typeof obj == "string")
         {
            return document.all(obj).style;
         }
         else
         {
            return obj.style;
         }
      }
      if (document.layers)
      {
         if (typeof obj == "string")
         {
            return document.layers[obj];
         }
         else
         {
            return obj;
         }
      }
   return null
}
```

A pair of functions handles all motion of positionable elements. The first function, `shiftTo()` takes three parameters: the ID of the object being moved, and the horizontal and vertical pixel coordinates of the top-left corner of the element. The assumption is that the main page script that invokes this library function performs the calculation of the coordinates. You see that code in Chapter 59. Inside this function, the `left` and `top` style properties for W3C DOM browsers are set. Even though the adjustments are made in separate statements, the action on the screen does not follow the action statement by statement. Between screen buffering and quick execution, the repositioning appears as a single shift.

```
// position an object at a specific pixel coordinate
function shiftTo(obj, x, y)
{
   var theObj = getObject(obj);
      if (theObj.moveTo)
```

```
        {
           theObj.moveTo(x,y);
        }
        else if (typeof theObj.left != "undefined")
        {
           theObj.left = x;
           theObj.top = y;
        }
}
```

The shiftBy() function mimics the NN4 layer.moveBy() method. The second and third parameters represent the number of pixels that the object should be moved on the page. A positive number means a shift to the right or down; a negative number means to the left or up; a value of zero means no change to the axis. The passed values are added to the left and top properties to carry out the shift. Notice that because these properties return strings that include the units for the measurements, the incremental values are added to integer extractions from the current settings. And because the units being used here are the default (pixels), no units have to be assigned with the new values (although they could without penalty). However, the CSS standard requires specification of the units.

```
// move an object by x and/or y pixels
function shiftBy(obj, deltaX, deltaY)
{
   var theObj = getObject(obj);
      if (theObj.moveBy)
      {
         theObj.moveBy(deltaX, deltaY);
      }
      else if (typeof theObj.left != "undefined")
      {
         theObj.left = parseInt(theObj.left) + deltaX;
         theObj.top = parseInt(theObj.top) + deltaY;
      }
}
```

The setZIndex() function does little more than convert the object reference and assign the incoming value to the zIndex property.

```
// set the z-order of an object
function setZIndex(obj, zOrder)
{
   var theObj = getObject(obj);
   theObj.zIndex = zOrder;
}
```

The setBGColor() function utilizes the backgroundColor style property in order to alter the background color.

```
// set the background color of an object
function setBGColor(obj, color)
{
   var theObj = getObject(obj);
      if (theObj.bgColor)
      {
```

```
            theObj.bgColor = color;
         }
         else if (typeof theObj.backgroundColor != "undefined")
         {
            theObj.backgroundColor = color;
         }
      }
```

Allowable values for the `visibility` property are very unprogrammatic in our opinion. We expect a Boolean value rather than strings. To accede to reality while making the process of showing and hiding elements more logical to us, we created API functions called `show()` and `hide()`.

```
      // set the visibility of an object to visible
      function show(obj)
      {
         var theObj = getObject(obj);
         theObj.visibility = "visible";
      }

      // set the visibility of an object to hidden
      function hide(obj)
      {
         var theObj = getObject(obj);
         theObj.visibility = "hidden";
      }
```

Although the `left` and `top` properties of visual objects in modern browsers include unit values, it is still safe to use `parseInt()` on the values returned from the properties. The need for these API functions came from the way the map puzzle application in Chapter 59 works. For a couple of operations, it calculates the destination for an object with respect to the position of one of the other positioned elements. These functions return the values needed for the main program's calculation. This is also an example of how you may need to embellish the API for your own application.

```
      // retrieve the x coordinate of a positionable object
      function getObjectLeft(obj)
      {
         var theObj = getObject(obj);
         return parseInt(theObj.left);
      }

      // retrieve the y coordinate of a positionable object
      function getObjectTop(obj)
      {
         var theObj = getObject(obj);
         return parseInt(theObj.top);
      }
```

The previous API is generalizable enough to be used as a library with any modern cross-platform DHTML application using positioning. Should the API be used in a browser that doesn't support DHTML, the code will fail cleanly and without error.

CHAPTER

51

Internet Explorer Behaviors

IN THIS CHAPTER

- Introducing IE behaviors
- Understanding the structure of behavior XML files
- Exploring behavior samples

Back in the days of Internet Explorer 5 for Windows, Microsoft first introduced a technology known as *DHTML behaviors*, which added enhanced features to the behaviors familiar to standard HTML elements. Microsoft and others have proposed the behaviors concept to the W3C, and it could someday become one of the W3C standard recommendations. Such a standard might not be implemented exactly the way Microsoft has implemented behaviors, but most of the concepts are the same, and the syntax being discussed so far is similar. While there is no guarantee that the W3C will adopt behaviors as a standard, you will see that the concept seems to be a natural extension to the work that has already been adopted for both CSS and XML.

Although the W3C did initiate an effort called Behavioral Extensions to CSS, there hasn't been much progress on the behavior standardization front recently. For the latest document describing the work of the participants of the standards discussions, visit `http://www.w3.org/TR/becss`.

Style Sheets for Scripts

You can best visualize what a behavior is in terms of the way you use style sheets. Consider a style sheet rule whose selector is a tag or a class name. The idea behind the style sheet is that one rule, which can define dozens of rendering characteristics for a chunk of HTML content, can be applied to perhaps dozens, if not hundreds, of elements within the document. A corporation may design a series of rules for the way its web documents will look throughout the web site. If the designer decides to alter the font family or color for, say, `h1` elements, that change is made in one place (the external style sheet file), and the impact is felt immediately across the entire site. Any page that includes an `h1` element renders the header with the newly modified style.

Imagine now that instead of visual styles associated with an element, you want to define a behavioral style for a particular group of elements. A *behavioral style* is the way an element responds to predominantly user interaction with the element. For example, suppose the design specifications for a web site indicate that all links should have their text colored a certain way when at rest, but on mouse rollovers, the text color changes to a more contrasting color, the font weight increases to bold, and the text becomes underlined. Those modifications require scripts to change the style properties of the element in response to the mouse action of the user. The scripts that fire in response to specific user actions (events) are written in an external file known as a behavior, and a behavior is associated with an element, class, or tag through the same CSS syntax that you use for other style properties.

A behavior, of course, assumes that its scripts can work with whatever HTML element is associated with the behavior. Just as it would be illogical to associate the `tableLayout` style property with an element that wasn't a `table`, so, too, would it be illogical to associate a behavior, whose scripts employed `table` object properties and methods, to a `p` element. Even so, a well-designed behavior can obtain details about the element being manipulated through the element object's properties. The better you are at writing generalizable JavaScript functions, the more successful you will be in implementing behaviors.

Embedding Behavior Components

IE treats each behavior as a component, or add-on building block for the browser. WinIE5+ comes equipped with a handful of behaviors built into the browser (the so-called default behaviors, which happen to rely on specific XML elements embedded in a document). Behaviors that you create most likely exist as separate files on the server, just like external `.css` and `.js` files do. The file extension for a behavior file is `.htc` (standing for HTML Component).

Linking in a behavior component

To associate a behavior with any single element, class of elements, or tag as the page loads, use CSS rule syntax and the IE-specific `behavior` attribute. The basic syntax is as follows:

```
selector {behavior:url(componentReference);}
```

As with any style sheet rule, you can combine multiple rule properties, delimiting them with semicolons. The format of the `componentReference` depends on whether you are using one of the IE default behaviors or a behavior you've written to an external file. For default behaviors, the reference is in the format:

```
#default#componentName
```

For example, if you want to associate the `download` behavior with any element of class `downloads` use:

```
.downloads {behavior:url(#default#download);}
```

Relative or absolute URIs to external `.htc` files can also be specified. For example, if your site contains a directory named `behaviors` and a file named `hilite.htc`, the style sheet rule from the root directory is:

```
.hiliters {behavior:url(behaviors/hilite.htc);}
```

As with all Cascading Style Sheet rules, behaviors can be specified in a `style` element of the page, in the `style` attribute of an individual element, or in a rule defined inside an imported `.css` file.

Enabling and disabling behaviors

In Chapter 26, "Generic HTML Element Objects," you can find details of IE methods for all HTML elements that let scripts manage the association of a behavior with an element after the page has loaded. Invoking the `addBehavior()` method on an element assigns an external `.htc` file to that element. When you no longer need that behavior associated with the element, invoke the `removeBehavior()` method.

Component Structure

An `.htc` behavior file is a text file consisting of script statements inside a `<script>` tag set, and some special XML tags that IE knows how to parse. You create `.htc` files in the same kind of plain text editor that you use for external `.js` or `.css` files.

Script statements

Unlike external `.js` files, an `.htc` behavior file includes `<script>` tags, which surround any JavaScript (or VBScript, if you like) statements that control the behavior. Because a behavior most typically is written to control one or more aspects of the HTML element to which it is connected, statements tend to operate only on the associated object element. A special reference — `element` — is used to refer to the element object itself (much like the way the `this` keyword in a custom object's method self-refers to the object associated with the method).

If your behavior will be modifying either the content or style of the element, use the `element` reference as a foundation for the reference to one of that element object's properties or methods. For example, if a statement in a behavior needs to set the `style.visibility` property so that the element hides itself, the statement in the behavior script is:

```
element.style.visibility = "hidden";
```

Any valid reference from the point of view of the element object is fair game, including references to the element's `parentElement`, even though the parent element is not explicitly associated with the behavior.

Variable scope

Except for the special `element` reference, script content of a behavior is completely self-contained. You can define global variables in the behavior that are accessible to any script statement in the behavior. But a global variable in a behavior does not become a global variable for the main document's scripts to use. You can expose variables so that scripts outside of the behavior can get to them (as described later in the chapter), but this exposure is not automatic.

Most of the script content of a behavior consists of functions that usually interact in some fashion with the associated element (via the element's properties and/or methods). Local variables in functions have the same scope and operate just like they do in regular script functions. Global variables you define in a behavior, if any, are usually there for the purpose of preserving values between separate invocations of the functions.

Assigning event handlers

Functions in a behavior are triggered from outside the behavior through two means: event handlers and direct invocation of functions declared as public (described in the next section). Event handler binding is performed in a way that is not used elsewhere in the IE DOM. Each event type (for example, `onmouseover`, `onkeypress`) requires its own special XML tag at the top of the behavior file. The format for the event handler tag is as follows:

```
<public:attach event="eventName" onevent="behaviorFunctionName()" />
```

As the behavior loads, the `public:attach` tag instructs the browser to expose to the "public" (that is, the world outside of the behavior) an event type (whose name always begins with the "on" prefix in the IE4+ event model); whenever an event of that type reaches the behavior's element, the function (defined within the behavior file) is invoked. In XML terminology, the `public:` part of the tag is known as a *namespace*, and IE includes a built-in parser for the `public` namespace. Notice, too, the XML syntax at the end of the tag that allows a single set of angle brackets to act as a start and end tag set (there is no content for this tag, just the attributes and their values).

To demonstrate, imagine that a behavior has a function named `underlineIt()`, which sets the `element.style.textDecoration` property to underline. To get the element to display the underline decoration as the user rolls the mouse atop the element, bind this function to the element's `onmouseover` event handler as follows:

```
<public:attach event="onmouseover" onevent="underlineIt()" />
```

If you examine the wording of the opening part of the tag, you may recognize a connection to the IE event model's `attachEvent()` method, which operates on all HTML elements (see Chapter 26). You can have as many event-binding tags as your element needs. To invoke multiple functions in response to a single event type, simply add the subsequent function invocation statements to the `onevent` attribute, separating the calls by semicolons (the same as with regular JavaScript statement delimiters).

Exposing properties and methods

XML tags with the `public:` namespace are also used (with different attributes) to expose a behavior's global variables as properties of the element and a behavior's functions as methods of the element. The syntax for both types of "public" announcements is as follows:

```
<public:property name="globalVarName" />
<public:method name="functionName" />
```

Values for both items are string versions of references to the variable and function (no parentheses). Again, you can define as many properties and methods for a behavior as you need.

As soon as a property and/or method is made public in a behavior, scripts from outside the behavior can access those items as if they were properties or methods of the element associated with the behavior:

```
document.all.elementID.behaviorProperty
document.all.elementID.behaviorMethod()
```

If you associate a behavior with a style sheet class selector, and several document elements share that class name, each one of those elements gains the public properties and methods of that behavior, accessible through references to the individual elements. That's because a behavior's scripts are written to read or modify properties of whatever element receives a bound event, or is referenced along the way to the public property or method.

Behavior Examples

The following two examples are intentionally simple to help you grasp the concepts of behaviors if they are new to you. The first example interacts with multiple elements strictly through event binding; the second example exposes a property and method that the main page's scripts access to interesting effect.

Example 1: Element dragging behavior

This book contains several examples of how to script a page to let a user drag an element around the browser window (Chapters 43, "Positioned Objects," and 59, "Application: Cross-Browser DHTML Map Puzzle," in particular). In all those examples, the dragging code and event handling was embedded in some fashion into the page's scripts. The first example of a behavior, however, drives home the notion of separating an element's behavior from its content (just as a CSS2 style sheet separates an element's appearance from its content).

Imagine that it's your job to design a page that employs three draggable elements. Two of the elements are images, while the third is a panel layer that also includes a form. If you haven't scripted DHTML before, this may sound like a daunting task at first, one rife with the possibility of including multiple versions of the same scripts to accommodate different kinds of draggable elements.

Now imagine that to the rescue comes a scripter who has built a behavior that takes care of all of the dragging scripting for you. All you do is assign that behavior by way of one attribute of each draggable element's style sheet rule. Absolutely no other scripting is required on the main page to achieve the element dragging.

Listing 51-1 shows the behavior file (`drag.htc`) that controls basic dragging of a positionable element on the page. You may recognize some of the code as an IE version of the cross-browser dragging code used elsewhere in this book (for a blow-by-blow account of these functions, see the description of the map puzzle game in Chapter 59). The names of the three operative functions and the basic way they do their jobs are identical to the other dragging scripts. Event binding, however, follows the behavior format through the XML tags. All interaction with the outside world occurs through the "public" event handlers.

LISTING 51-1

An Element Dragging Behavior

```
<public:attach event="onmousedown" onevent="engage()" />
<public:attach event="onmousemove" onevent="dragIt()" />
<public:attach event="onmouseup"   onevent="release()" />
<public:attach event="onmouseover" onevent="setCursor()" />
<public:attach event="onmouseout"  onevent="release();restoreCursor()" />

<script type="text/javascript">
   // global declarations
   var offsetX = 0;
   var offsetY = 0;
   var selectedObj;
   var oldZ, oldCursor;

   // initialize drag action on mousedown
   function engage()
   {
      selectedObj = (element == event.srcElement) ? element : null;
         if (selectedObj)
         {
            offsetX = event.offsetX - element.document.body.scrollLeft;
            offsetY = event.offsetY - element.document.body.scrollTop;
            oldZ = element.runtimeStyle.zIndex;
            element.style.zIndex = 10000;
            event.returnValue = false;
         }
   }

   // move element on mousemove
   function dragIt()
   {
```

```
      if (selectedObj)
      {
         selectedObj.style.pixelLeft = event.clientX - offsetX;
         selectedObj.style.pixelTop = event.clientY - offsetY;
         event.cancelBubble = true;
         event.returnValue = false;
      }
   }

   // restore state on mouseup
   function release()
   {
      if (selectedObj)
      {
         selectedObj.style.zIndex = oldZ;
      }
      selectedObj = null;
   }

   // make cursor look draggable on mouseover
   function setCursor()
   {
      oldCursor = element.runtimeStyle.cursor;
      element.style.cursor = "hand";
   }

   // restore cursor on mouseout
   function restoreCursor()
   {
      element.style.cursor = oldCursor;
   }
</script>
```

Notice a subtlety in Listing 51-1 that is implied by the element-specific scope of a behavior. Two statements in the `engage()` function need to reference scroll-related properties of the `document.body` object. Because the only connection between the behavior and the document is via the `element` reference, that reference is used along with the `document` property (a property of every HTML element object, as shown in Chapter 26). From there, the `body` object and the required properties can be accessed.

Listing 51-2 is a simple page that contains three elements that are associated with the `drag.htc` behavior through a style sheet rule definition (for the `draggable` class). The document is incredibly uncomplicated. Even the `drag.htc` file isn't very big. But together they produce a far more interesting page for the user than a couple of static images and a form.

LISTING 51-2

Three Draggable Elements Using the Behavior

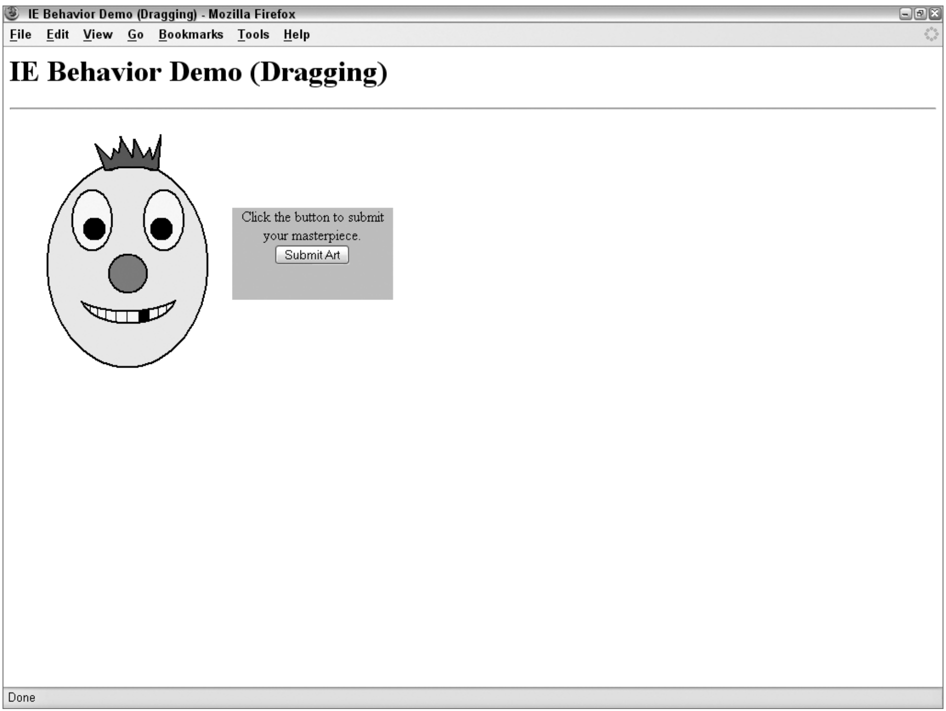
```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>IE Behavior Demo (Dragging)</title>
      <style type="text/css">
         .draggable {position:absolute; behavior:url(drag.htc)}
         #head {left:48px; top:125px}
         #eyes {left:75px; top:155px}
         #nose {left:115px; top:225px}
         #mouth {left:85px; top:275px}
         #hair {left:100px; top:95px}
         #txt1 {left:250px; top:175px; background-color:aqua; width:175px;
                                      height:100px; text-align:center}
      </style>
   </head>
   <body>
      <h1>IE Behavior Demo (Dragging)</h1>
      <hr />
      <img alt="head" class="draggable" id="head" src="head.png" />
      <img alt="eyes" class="draggable" id="eyes" src="eyes.png" />
      <img alt="nose" class="draggable" id="nose" src="nose.png" />
      <img alt="mouth" class="draggable" id="mouth" src="mouth.png" />
      <img alt="hair" class="draggable" id="hair" src="hair.png" />
      <div class="draggable" id="txt1">
         Click the button to submit your masterpiece.
         <form>
            <input type="button" value="Submit Art" />
         </form>
      </div>
   </body>
</html>
```

Obviously, the dragging example here is very rudimentary. It isn't clear from the sample code what the user gets from the page, other than the joy of moving things around and manipulating the smiley face (see Figure 51-1).

If you were designing an application that genuinely benefits from draggable objects (for example, the map puzzle in Chapter 59), you can easily enhance the behavior to perform actions, such as snapping a dragged element into place when it is within a few pixels of its proper destination. For such an implementation, the behavior can be given some extra global variables, akin to the values assigned to the state objects in Chapter 59, including the pixel coordinates of the ideal destination for a dragged element. An `onload` event handler for the page can fire a public `init()` function in each element's behavior to assign those coordinate values. Any event that can bubble (such as mouse events) does so from the behavior to the target. Therefore, you can extend the event action of the behavior by adding a handler for the same event to the element outside of the behavior.

FIGURE 51-1

This draggable JavaScript example is somewhat of an ode to the classic Mr. Potato Head toy.



Example 2: Text rollover behavior

In the second example, you see how a behavior exposes a global variable and function as a public property and method, respectively. The demonstration reinforces the notion that even if a single behavior file is associated with multiple elements (for example, the elements share the same class, and the behavior is assigned to the class), each behavior maintains its own variable values, independent of the other elements and their behaviors.

The nature of this behavior is to set the `color` style property of the associated element to either a default color (red) or to another color that has been passed into the behavior via one of its public methods. The color setting is preserved in one of the behavior's global variables, and that variable is exposed as a public property.

Listing 51-3 shows the `.htc` behavior file's content. Only two events are bound to this behavior: `onmouseover` and `onmouseout` — the typical rollover events. The `onmouseover` event invokes the `makeHot()` function, while the `onmouseout` event invokes the `makeNormal()` function. Before the `makeHot()` function makes any changes to the `color` and `fontWeight` style properties of the element, existing settings are preserved in (non-public) global variables in the behavior. This allows the `makeNormal()` function to restore the original settings, regardless of what document styles may be applied to the element in a variety of pages. That's something to

keep in mind when you design behaviors: they can be deployed in pages controlled by any number of style sheets. Don't assume any basic style setting; instead, use the `currentStyle` property to read and preserve the effective property values before touching them with your behavior's modification scripts.

Neither of the event handler functions are exposed as public methods. This was a conscious decision for a couple of reasons. The most important reason is that both functions rely on being triggered by a known event occurring on the element. If either function were invoked externally, the event object would contain none of the desired information. Another reason behind this comes from a common programming style for components, which protects inner workings, while exposing only those methods and properties that are "safe" for others to invoke. For this code, the public method does little more than set a property. It's an important property, to be sure, and one of the protected functions relies on it. But by allowing the public method little room to do any damage other than execution of the behavior, the design makes the behavior component that much more robust.

Assigning a color value to the public property and passing it as a parameter to the public method accomplishes the same result in this code. As you will see, the property gets used in the demonstration page to retrieve the current value of the global variable. In a production behavior component, the programmer would probably choose to expose this value strictly as a read/write property, or to expose two methods, one for getting and one for setting the value. The choice would be at the whim of the programmer's style and would likely not be both. Using a method, however, especially for setting a value, creates a framework in which the programmer can also perform validation on the incoming value before assigning it to the global variable (something the example here does not do).

LISTING 51-3

Rollover Behavior (makeHot.htc)

```
<public:attach event="onmouseover" onevent="makeHot()" />
<public:attach event="onmouseout" onevent="makeNormal()" />
<public:property name="hotColor" />
<public:method name="setHotColor" />
<script type="text/javascript">
   var oldColor, oldWeight;
   var hotColor = "purple";

   function setHotColor(color)
   {
      hotColor = color;
   }

   function makeHot()
   {
      if (event.srcElement == element)
      {
         oldColor = element.currentStyle.color;
```

```
         oldWeight = element.currentStyle.fontWeight;
         element.style.color = hotColor;
         element.style.fontWeight = "bold";
      }
   }

   function makeNormal()
   {
      if (event.srcElement == element)
      {
         element.style.color = oldColor;
         element.style.fontWeight = oldWeight;
      }
   }
</script>
```

To put the public information and the behavior, itself, to work, a demonstration page includes three spans within a paragraph that are associated with the behavior. Listing 51-4 shows the code for the demo page.

In addition to the text with rollover spans, the page contains two `select` controls, which let you assign a separate color to each of the three elements associated with the behavior. The first `select` element lets you choose one of the three elements. Making that choice invokes the `readColor()` function in the same page. This is the function that reads the `hotColor` public property of the chosen span. That color value is used to select the color name for display in the second `select` element. If you make a choice in the list of colors, the `applyVals()` function invokes the public `setHotColor()` method of the element currently selected from the list of elements. Rolling the mouse over that element now highlights it with the newly selected color, while the other elements maintain their current settings.

LISTING 51-4

Applying the Rollover Behavior

```
<!DOCTYPE html>
<html>
   <head>
      <title>IE Behavior Demo (Styles)</title>
      <style type="text/css">
         .hotStuff
         {
            font-weight:bold; behavior:url(makeHot.htc);
         }
      </style>
      <script type="text/javascript">
         function readColor(choice)
         {
            var currColor = document.all(choice.value).hotColor;
```

continued

LISTING 51-4 *(continued)*

```
            var colorList = choice.form.color;
            for (var i = 0; i < colorList.options.length; i++)
            {
               if (colorList.options[i].value == currColor)
               {
                  colorList.selectedIndex = i;
                  break;
               }
            }
         }
         function applyVals(form)
         {
            var elem = form.elem.value;
            document.all(elem).setHotColor(form.color.value);
         }
      </script>
   </head>
   <body>
      <h1>IE Behavior Demo (Styles)</h1>
      <hr />
      <form>
         Choose Element (the bolded text) to highlight when mousing over:
         <select name="elem" onchange="readColor(this)">
            <option value="elem1">First</option>
            <option value="elem2">Second</option>
            <option value="elem3">Third</option>
         </select>
         Choose Highlight Color:
         <select name="color" onchange="applyVals(this.form)">
            <option value="red" selected="selected">Red</option>
            <option value="blue">Blue</option>
            <option value="green">Green</option>
         </select>
      </form>
      <p>Lorem ipsum dolor sit amet,
         <span id="elem1" class="hotStuff">consectetaur</span>
         adipisicing elit, sed do eiusmod tempor incididunt ut
         <span id="elem2" class="hotStuff">labore et dolore magna aliqua</span>.
         Ut enim adminim veniam, quis nostrud exercitation ullamco laboris
         <span id="elem3" class="hotStuff">nisi ut aliquip ex ea commodo
             consequat</span>.
      </p>
   </body>
</html>
```

Behaviors are not the solution for every scripting requirement. As demonstrated here, they work very well for generic style manipulation, but you are certainly not limited to that sphere. By having a reference back to the element associated with the behavior, and then to the document that contains the element, a behavior's scripts can have free run over the page — provided the actions are either generic among any page, or generic among a design template that is used to build an entire web site or application.

Even if you don't elect to use behaviors now (perhaps because you must support browsers other than IE), they may be in your future. Behaviors are fun to think about, and using them instills good programming practice in the art of creating reusable, generalizable code.

For More Information

In addition to the address of W3C activity on behaviors listed at the beginning of the chapter, you can find much more about behaviors on Microsoft's developer site. Here are some useful pointers.

- Overview:
  `http://msdn.microsoft.com/en-us/library/ms531079%28VS.85%29.aspx`
- Using DHTML Behaviors:
  `http://msdn.microsoft.com/en-us/library/ms532147%28VS.85%29.aspx`
- Default Behaviors Reference:
  `http://msdn.microsoft.com/en-us/library/ms531081%28VS.85%29.aspx`
- Element Behaviors (an extension to the original behaviors):
  `http://msdn.microsoft.com/en-us/library/ms531426%28VS.85%29.aspx`

Each of these locations ends with yet more links to related pages at the Microsoft Developer Network (MSDN) web site.

Application: Tables and Calendars

IN THIS CHAPTER

Accommodating older browsers

Scripted tables

Date calculations

Working with HTML tables is a lot of fun, especially if you are not a born graphic designer. By adding a few tags to your page, you can make your columnar data look more organized, professional, and appealing. Having this power under scripting control is even more exciting, because it means that in response to a user action or other variable information (such as the current date or time), a script can do things to the table as the table is being built. Modern browsers allow scripts to modify the content and structure of a table even after the page has loaded, allowing the page to almost "dance."

You have three options when designing scripted tables for your pages, although only two are compatible with non-DHTML browsers (such as legacy browsers and some mobile browsers):

- Static tables
- Dynamic tables
- Dynamic HTML tables

The design path you choose is determined by whether you need to dynamically update some or all fields of a table (data inside `<td>...</td>` tags), and which browser levels you need to support. To highlight the differences among the three styles, this chapter traces the implementation of a monthly calendar display in all three formats.

About the Calendars

Because the emphasis here is on the way tables are scripted and displayed, we quickly pass over structural issues in the calendar versions described in the following sections. The first two examples are backward compatible to all

but the first-generation scriptable browsers. The final example, however, is a much more modern affair, utilizing table-related DOM objects and methods to simplify the code. It requires a modern browser (WinIE4+/Moz1+/W3C), and is definitely the desired approach unless you are specifically worried about legacy or mobile browser compatibility.

All three calendars follow similar (if not over-simplified) rules for displaying calendar data. English names of the months are coded into the script, so that they can be plugged into the calendar heading as needed. To make some of the other calendar calculations work (such as figuring out which day of the week is the first day of a given month in a given year), we define a method for the month objects. The method returns the JavaScript date object value for the day of the week of a month's first date. Virtually everything we do to implement the month objects is adapted from the custom objects discussion in Chapter 23, "Function Objects and Custom Objects."

Static Tables

The issue of updating the contents of a table's fields is tied to the nature of an HTML document being loaded and fixed in the browser's memory. Recall that for early browsers, you can modify precious few elements of a document and its objects after the document has loaded. This certainly applies for typical data points inside a table's `<td>` tag pair. After a document loads — even if JavaScript has written part of the page — none of its content (except for `text` and `textarea` field contents, and a few limited form element properties) can be modified without a complete reload.

Listing 52-1 contains the static version of a monthly calendar. The scripted table assembly begins in the `body` portion of the document. Figure 52-1 shows the results.

LISTING 52-1

A Static Table Generated by JavaScript

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>JavaScripted Static Table</title>
      <script type="text/javascript">
         // function becomes a method for each month object
         function getFirstDay(theYear, theMonth)
         {
            var firstDate = new Date(theYear,theMonth,1);
            return firstDate.getDay() + 1;
         }
         // number of days in the month
         function getMonthLen(theYear, theMonth)
         {
```

```
            var oneHour = 1000 * 60 * 60;
            var oneDay = oneHour * 24;
            var thisMonth = new Date(theYear, theMonth, 1);
            var nextMonth = new Date(theYear, theMonth + 1, 1);
            var len = Math.ceil((nextMonth.getTime() -
                      thisMonth.getTime() - oneHour)/oneDay);
            return len;
         }
         // create array of month names
         theMonths = new Array("January", "February", "March", "April",
                               "May", "June", "July", "August", "September",
                               "October", "November", "December");
      </script>
   </head>
   <body>
      <h1>A Static Scripted Month at a Glance</h1>
      <hr />
      <script type="text/javascript">
         // initialize some variables for later
         var today = new Date("4/11/1999");
         var theYear = today.getFullYear();
         var theMonth = today.getMonth(); // for index into our array

         // which is the first day of this month?
         var firstDay = getFirstDay(theYear, theMonth);
         // total number of <TD>...</TD> tags needed in for loop below
         var howMany = getMonthLen(theYear, theMonth) + firstDay;

         // start assembling HTML for table
         var content = "<center><table border='1'>";
         // month and year display at top of calendar
         content += "<tr><th colspan='7'>" + theMonths[theMonth];
         content += " " + theYear + "<\/th><\/tr>";
         // days of the week at head of each column
         content += "<tr><th>Sun<\/th><th>Mon<\/th><th>Tue<\/th><th>Wed<\/th>";
         content += "<th>Thu<\/th><th>Fri<\/th><th>Sat<\/th><\/tr>";
         content += "<tr>";

         // populate calendar
         for (var i = 1; i < howMany; i++)
         {
            if (i < firstDay)
            {
               // 'empty' boxes prior to first day
               content += "<td><\/td>";
            }
            else
            {
               // enter date number
               content += "<td align='center'>" + (i - firstDay + 1) + "<\/td>";
            }
```

continued

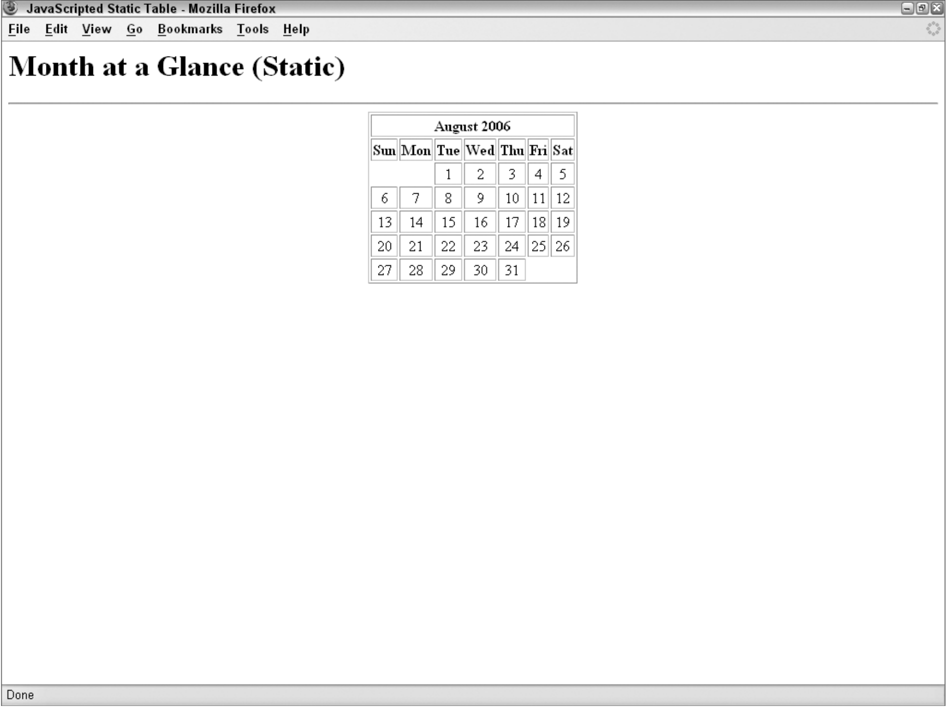
LISTING 52-1 *(continued)*

```
            // start new row after each week
            if (i % 7 == 0 &&  i != howMany)
            {
               content += "<\/tr><tr>";
            }
         }
         content += "<\/table><\/center>";

         // blast entire table's HTML to the document
         document.write(content);
      </script>
   </body>
</html>
```

FIGURE 52-1

The static table calendar generated by Listing 52-1.



In this page, a little bit of the HTML — the `<h1>` heading and `<hr>` divider — is unscripted. The rest of the page consists entirely of the table definition, all of which is constructed in JavaScript. Most of the work for assembling the calendar's data points occurs inside the `for` loop. Because not every month starts on a Sunday, the script determines the day of the week on which the current month starts. For all fields prior to that day, the `for` loop writes empty `<td></td>` tags as placeholders. After the numbered days of the month begin, the `for` loop writes the date number inside the `<td>...</td>` tags. Whatever the script puts inside the tag pair is written to the page as flat HTML. Under script control like that in the example, however, the script can designate what goes into each data point — rather than writing fixed HTML for each month's calendar.

The important point to note in this example is that although the content of the page may change automatically over time (without having to redo any HTML for the next month), after the page is written, its contents cannot be changed. If you want to add controls or links that are to display another month or year, you have to rewrite the entire page. This can be accomplished by passing the desired month and year as a search string for the current page's URL, and then assigning the combination to the `location.href` property. You also have to add script statements to the page that look for a URL search string, extract the passed values, and use those values to generate the calendar while the page loads. (See Chapter 28, "Location and History Objects," for examples of how to accomplish this feat.) But to bring a calendar such as this even more to life (while avoiding page reloading between views), you can implement it as a dynamic table.

Dynamic Tables

The only way to make data points of a table dynamically updatable in backward-compatible browsers is to turn those data points into `text` (or `textarea`) objects. The approach to this implementation is different from the static table because it involves the combination of *immediate* and *deferred* scripting. Immediate scripting facilitates the building of the table framework, complete with fields for every modifiable location in the table. Deferred scripting enables users to make choices from other interface elements, causing a new set of variable data to appear in the table's fields.

Listing 52-2 turns the preceding static calendar into a dynamic one by including controls that enable the user to select a month and year to display in the table. As testament to the support for absolute backward compatibility, a button triggers the redrawing of the calendar contents, rather than `onchange` event handlers in the `select` elements; a bug in an older version of Netscape Navigator caused that event not to work for the `select` object. But don't worry, the last example you see a bit later in the chapter does away with backward compatibility in favor of a sleeker design.

Form controls aside, the look of this version is quite different from the static calendar. Compare the appearance of the dynamic version shown in Figure 52-2 against the static version in Figure 52-1.

LISTING 52-2

A Dynamic Calendar Table

            <option value="2008" selected="selected">2008</option>
            <option value="2009">2009</option>
            <option value="2010">2010</option>
            <option value="2011">2011</option>
            <option value="2012">2012</option>
            <option value="2013">2013</option>
            <option value="2014">2014</option>
            <option value="2015">2015</option>
         </select>
         <br />
         <input type="button" name="updater" value="Update Calendar"
                onclick="populateFields(this.form)" />
         </form>
      </body>
   </html>
```

Note

The property assignment event handling technique in this example is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." ■**

When you first load Listing 52-2, it creates an empty table, along with numerous text objects. An `onload` event handler in the `body` definition also could easily set the necessary items to load the current month.

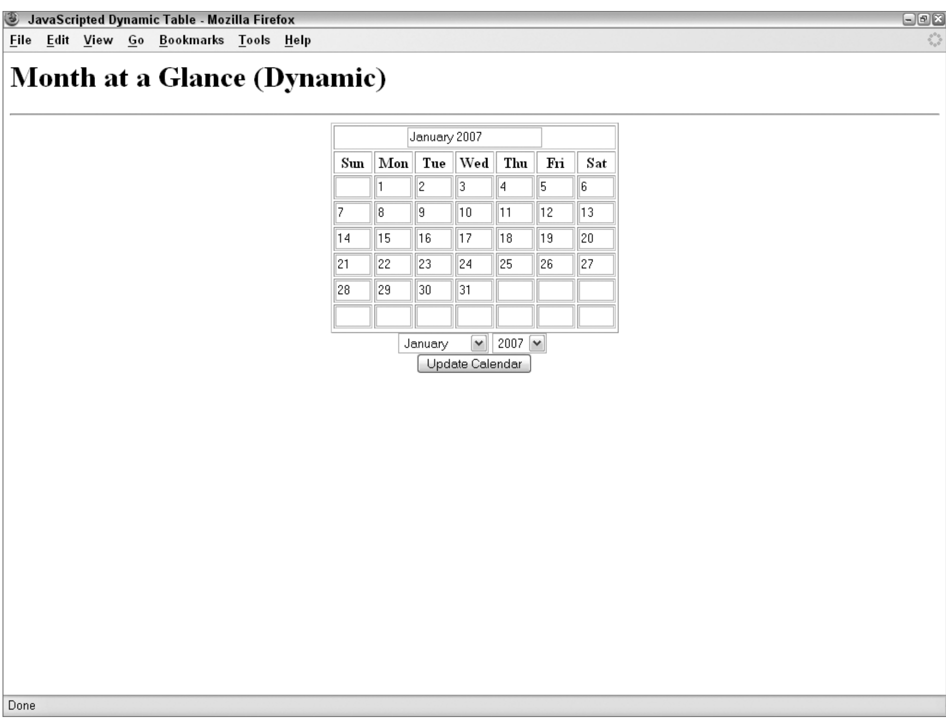
From a cosmetic point of view, the dynamic calendar may not be as pleasing as the static one in Figure 52-1. Several factors contribute to this appearance.

From a structural point of view, creating a table that can accommodate any possible layout of days and dates that a calendar may require is essential. That means a basic calendar consisting of six rows of fields. For many months, the last row remains completely empty. But because the table definition must be fixed when the page loads, this layout cannot change on the fly.

On the other hand, this version includes pop-up menus from which the user can select a month and year of choice. Clicking the Update Calendar button refills the calendar fields with data from the selected month.

FIGURE 52-2

Dynamic calendar generated by Listing 52-2.



A disadvantage to this dynamic table involves the fact that all text objects can be edited by the user. For many applications, this capability may not be a big deal. But if you're creating a table-based application that encourages users to enter values in some fields, be prepared (in other words, have event handlers in place) to either handle calculations based on changes to any field, or to alert users that the fields cannot be changed (and restore the correct value).

Hybrids

It will probably be the rare scripted table that is entirely dynamic. In fact, the one in Figure 52-2 is a hybrid of static and dynamic table definitions. The days of the week at the top of each column are hard-wired into the table as static elements. If your table design can accommodate both styles, implement your tables that way. The fewer the number of text objects defined for a page, the better the performance for rendering the page, and the less confusion for the page's users.

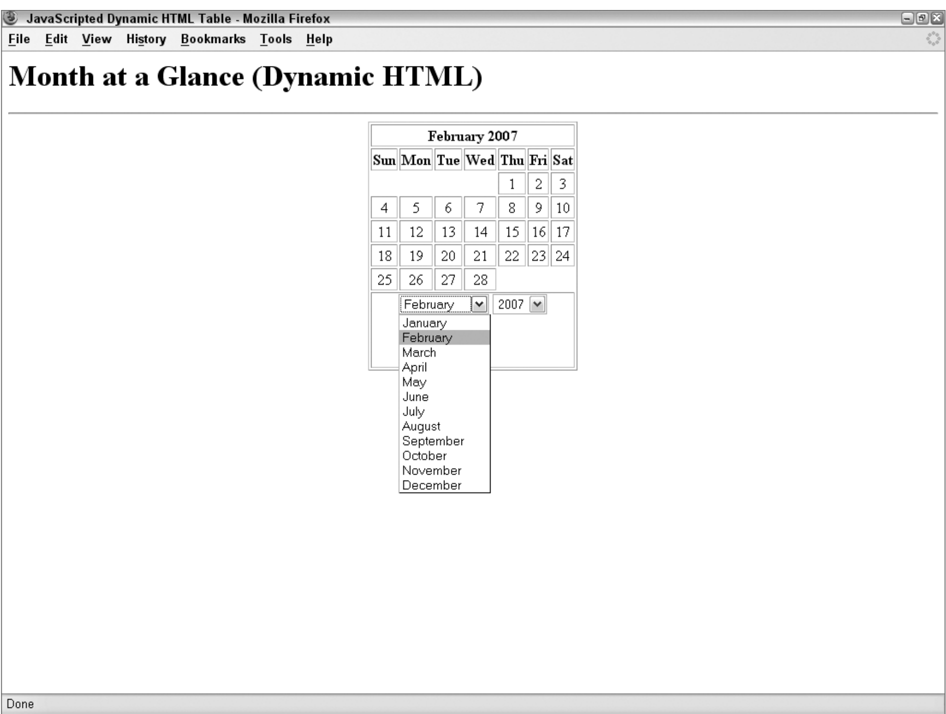
Dynamic HTML Tables

If you're committed to developing JavaScript code solely for modern browsers, which is entirely realistic at this point in time, you have all the resources of the `table` and related element objects, as described in Chapter 41, "Table and List Objects." The resulting application will appear to be much more polished, because not only does your content flow inside a table (which you can style to your heart's delight), but the content is dynamic within the table. The first two calendar examples were really just opening acts for the third and final version.

Listing 52-3 blends the calendar calculations from the earlier two calendar versions with the powers of the modern DOM (IE4+/Moz1+/W3C). A change to a requested calendar month or year instantly redraws the body of the table, without disturbing the rest of the page (see Figure 52-3).

FIGURE 52-3

DHTML table.



Basic date calculations are identical to the other two versions. Because this page has to be viewed with more modern browsers, we can use the shortcut array creation syntax for the month names array. Also, the way the table must be constructed each time is very different from two previous

versions. In this version, the script creates new table rows, creates new cells for those rows, and then populates those cells with the date numbers. Repeat loop logic is quite different, relying on a combination of `while` and `for` loops to get the job done.

Other features made possible by more modern browsers include automatic population of the list of available years. This page will never go out of style (unless browsers in 2050 no longer use JavaScript). There is also more automation in the triggers of the function that populates the table.

      }
   }
}
```

Further Thoughts

The best deployment of an interactive calendar requires the kind of Dynamic HTML currently available in modern DOMs. Moreover, the cells in those DOMs can receive mouse events, so that a user can click a cell and it will, perhaps, highlight in a different color or display some related, but otherwise hidden, information.

A logical application for such a dynamic calendar would be a pop-up window or frame that enables a user to select a date for entry into a form date field, such as in a travel web site where you select a date for travel through a calendar interface. It eliminates the need to type in a specific date format, thereby ensuring a valid date entry every time. For the sake of browsers with limited functionality (such as mobile and legacy), you can create a static version of the calendar that renders the numbers in the calendar cells as HTML links. Those links can use a `javascript:` URL to invoke a function call that sets a date field in the main form.

CHAPTER

53

Application: A Lookup Table

IN THIS CHAPTER

Server-less data collection lookup

Data-entry validation

One of the first ideas that intrigued me about JavaScript was the notion of delivering CGI-like functionality along with an HTML document. On the Web, numerous, small data collections currently require CGI scripting and a back-end database engine to drive them. Of course, not everyone who has information to share has access to the server environment (or the expertise) to implement such a solution. JavaScript provides that power.

A Server-Less Database

Before you get too carried away with the idea of letting JavaScript take the place of your SQL database, you need to recognize several limitations that prevent JavaScript from being a universal solution. First, any database that you embed into an HTML document is read-only. Although you can script an interface and lookup routines for the user, no provisions are available for writing revised information back to the server, if that is your intention.

A second consideration is the size of the data collection. Unlike databases residing on servers, the entire JavaScript database (or subset you define for inclusion into a single HTML document) must be downloaded to the user's browser before the user can work with the data. As a point of reference, think about image files. At 56.6 Kbps through a dial-up connection, how large an image file would you tolerate downloading? Granted, a vast majority of users now have broadband access of some kind, but that still doesn't mean that size has no relevance. Whatever that limit may be (based upon your bandwidth assumptions and how long you're willing to make users wait

for the database to download) is what your database size limit should be. For many special-purpose collections, you can get by with databases measured in the tens of kilobytes, assuming one byte per character. Unlike what happens when the user downloads an embedded image file, the user doesn't see special status bar messages about your database: to the browser, these messages are all part of the HTML coming in with the document.

The kind of data we're talking about here is obviously text data. That's not to say you can't let your JavaScript-enhanced document act as a front end to data files of other types on your server. The data in your embedded lookup table can be URLs to images that get swapped into the page as needed.

The Database

While thinking about writing a demonstration of a server-less database, we encountered a small article in the *Wall Street Journal* that related information we had always suspected. The Social Security numbers assigned to virtually every U.S. citizen are partially coded to indicate the state in which you registered for your Social Security number. This information often reveals the state in which you were born (another study indicates that two-thirds of U.S. citizens live their entire lives in the same state). The first three digits of the nine-digit number comprise this code.

When the numbering system was first established, each state was assigned a block of three-digit numbers. Therefore, if the first three digits fall within a certain range, the Social Security Administration has you listed as being registered in the corresponding state or territory. We thought this would be an interesting demonstration for a couple of reasons: first, the database is not that large, so it can be easily embedded into an HTML document without making the document too big to download, even on slow Internet connections; second, it offers some challenges to data-entry validation, as you will see in a moment.

Note

Before young people from populous states write to tell me that their numbers are not part of the database, let us emphasize that we are well aware that several states have been assigned number blocks not reflected in the database. This example is only a demonstration of scripting techniques, not an official Social Security Administration page. ■

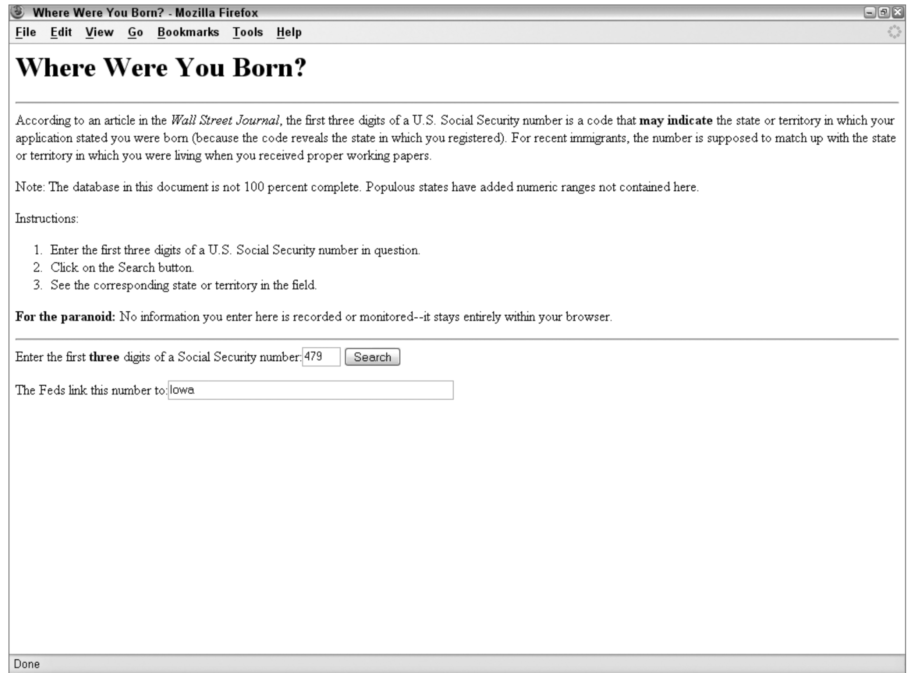
The Implementation Plan

For this demonstration, all we started with was a printed table of data. We figured that the user interface for this application would probably be very plain: a text field in which the user can enter a three-digit number, a clickable button to initiate the search, and a text

field to show the results of the lookup. Figure 53-1 shows the page. Pretty simple by any standards.

FIGURE 53-1

The Social Security number lookup page.



Given that user interface (we almost always start a design from the *interface* — how our page's users will experience the information presented on the page), we next planned the internals. We needed the equivalent of two tables: one for the numeric ranges, and one for the state names. Because most of the numeric ranges are contiguous, we could get by with a table of the high number of each range. This meant that the script would have to trap elsewhere for the occasional numbers that fall outside of the table's ranges — the job of data validation.

Because the two tables were so closely related to each other, we had the option of creating two separate arrays, so that any given index value would correspond to both the numeric and state name entries in both tables (*parallel arrays*, we call them). The other option was to create a two-dimensional array (see Chapter 18, "The Array Object"), in which each array entry has data points for both the number and state name. For purposes of demonstration to first-time database builders, we decided to stay with two parallel arrays. This method makes visualizing how the lookup process works with two separate arrays a little easier.

The Code

The HTML document starts normally through the definition of the document title:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Where Were You Born?</title>
      <style text="text/css">
         .caution
         {
            font-weight:bold;
         }
      </style>
      <script type="text/javascript" src="../jsb-global.js"></script>
      <script type="text/javascript" src="jsb53-01.js"></script>
   </head>
```

In this application, the script is in a separate file. You'll notice that two files are identified, each in their own `script` element. The first is a global script file that contains the generic cross-browser, event-binding function described in Chapter 32. The second contains the JavaScript specific to this application. The balance of the HTML code is the Body part of the document. The real action takes place within the Form definition:

```
   <body>
      <h1>Where Were You Born?</h1>
      <hr />
      <p>According to an article in the <cite>Wall Street Journal</cite>,
         the first three digits of a U.S. Social Security number is a code
         that <span class="caution">may indicate</span> the state or
         territory in which your application stated you were born
         (because the code reveals the state in which you registered).
         For recent immigrants, the number is supposed to match up with
         the state or territory in which you were living when you received
         proper working papers.
      </p>
      <p>Note: The database in this document is not 100 percent complete.
         Populous states have added numeric ranges not contained here.</p>
      <p>Instructions:</p>
      <ol>
         <li>Enter the first three digits of a U.S. Social Security number
             in question.</li>
         <li>Click on the Search button.</li>
         <li>See the corresponding state or territory in the field.</li>
      </ol>
      <p><span class="caution">For the paranoid:</span> No information
         you enter here is recorded or monitored--it stays entirely
         within your browser.
      </p>
      <hr />
      <form id="searchForm" name="searchForm" onsubmit="return false;">
```

```
            <span>Enter the first <span class="caution">three</span> digits of
               any Social Security number:
            </span>
            <input type="text" id="entry" name="entry" size="3"
                   tabindex="1" />
            <input type="button" id="searchButton" value="Search"
                   tabindex="2" />
            <p>The Feds link this number to:
               <input type="text" id="result" name="result"
                      size="50" />
            </p>
         </form>
      </body>
   </html>
```

The form's `onsubmit` event handler is set to prevent accidental submission (or pseudo-submission, because no `action` attribute is specified for the form) that MacIE does from any form's text box (other browsers submit on Return from only a single-field form). Each of the text objects is sized to fit the expected data.

Now on to the JavaScript file that is specific to this application. In it you will see that we place utility function definitions close to the top of the script sections and put any action-oriented scripts (functions acting in response to event handlers) closer to the bottom of the script sections. My preference is to have all dependencies resolved before the script needs them. This philosophy carries over from the logic that dictates putting as many scripts in the Head or an external script as possible, so that even if the user (or network) should interrupt downloading of a page before every line of HTML reaches the browser, any user interface element relying on scripts will have those scripts loaded and ready to go. The order of functions in this example is not critical, because as long as they all reside in the Head section or an external script, they are defined and loaded by the time the field and button appear at the bottom of the page. But after we develop a style, we find it easier to stick with it — one less matter to worry about while scripting a complex application.

After creating an array (named `ssn`) with 57 empty slots, the script populates all 57 data points of the array, starting with the first entry going into the slot numbered 0. These data numbers correspond to the top end of each range in the 57-entry table. For example, any number greater than 3 but less than or equal to 7 falls into the range of the second data entry of the array (`ssn[1]`).

```
// create array listing all the top end of each numeric range
var ssn = new Array(57);
ssn[0] = 3;
ssn[1] = 7;
ssn[2] = 9;
ssn[3] = 34;
ssn[4] = 39;
ssn[5] = 49;
ssn[6] = 134;
ssn[7] = 158;
ssn[8] = 211;
ssn[9] = 220;
```

```
ssn[10] = 222;
ssn[11] = 231;
ssn[12] = 236;
ssn[13] = 246;
ssn[14] = 251;
ssn[15] = 260;
ssn[16] = 267;
ssn[17] = 302;
ssn[18] = 317;
ssn[19] = 361;
ssn[20] = 386;
ssn[21] = 399;
ssn[22] = 407;
ssn[23] = 415;
ssn[24] = 424;
ssn[25] = 428;
ssn[26] = 432;
ssn[27] = 439;
ssn[28] = 448;
ssn[29] = 467;
ssn[30] = 477;
ssn[31] = 485;
ssn[32] = 500;
ssn[33] = 502;
ssn[34] = 504;
ssn[35] = 508;
ssn[36] = 515;
ssn[37] = 517;
ssn[38] = 519;
ssn[39] = 520;
ssn[40] = 524;
ssn[41] = 525;
ssn[42] = 527;
ssn[43] = 529;
ssn[44] = 530;
ssn[45] = 539;
ssn[46] = 544;
ssn[47] = 573;
ssn[48] = 574;
ssn[49] = 576;
ssn[50] = 579;
ssn[51] = 580;
ssn[52] = 584;
ssn[53] = 585;
ssn[54] = 586;
ssn[55] = 599;
ssn[56] = 728;
```

We do the same for the array containing the states and territory names. Both of these array populators seem long but pale in comparison to what you would have to do with a database of many kilobytes. Unfortunately, JavaScript doesn't give you the power to load existing data files into arrays (but see the recommendations at the end of the chapter), so any time you want to embed a database into an HTML document, you must go through this array-style assignment frenzy:

```
// create parallel array listing all the states/territories
// that correspond to the top range values in the first array
var geo = new Array(57);
geo[0] = "New Hampshire";
geo[1] = "Maine";
geo[2] = "Vermont";
geo[3] = "Massachusetts";
geo[4] = "Rhode Island";
geo[5] = "Connecticut";
geo[6] = "New York";
geo[7] = "New Jersey";
geo[8] = "Pennsylvania";
geo[9] = "Maryland";
geo[10] = "Delaware";
geo[11] = "Virginia";
geo[12] = "West Virginia";
geo[13] = "North Carolina";
geo[14] = "South Carolina";
geo[15] = "Georgia";
geo[16] = "Florida";
geo[17] = "Ohio";
geo[18] = "Indiana";
geo[19] = "Illinois";
geo[20] = "Michigan";
geo[21] = "Wisconsin";
geo[22] = "Kentucky";
geo[23] = "Tennessee";
geo[24] = "Alabama";
geo[25] = "Mississippi";
geo[26] = "Arkansas";
geo[27] = "Louisiana";
geo[28] = "Oklahoma";
geo[29] = "Texas";
geo[30] = "Minnesota";
geo[31] = "Iowa";
geo[32] = "Missouri";
geo[33] = "North Dakota";
geo[34] = "South Dakota";
geo[35] = "Nebraska";
geo[36] = "Kansas";
geo[37] = "Montana";
geo[38] = "Idaho";
geo[39] = "Wyoming";
geo[40] = "Colorado";
geo[41] = "New Mexico";
geo[42] = "Arizona";
geo[43] = "Utah";
geo[44] = "Nevada";
geo[45] = "Washington";
geo[46] = "Oregon";
geo[47] = "California";
geo[48] = "Alaska";
geo[49] = "Hawaii";
```

```
geo[50] = "District of Columbia";
geo[51] = "Virgin Islands";
geo[52] = "Puerto Rico";
geo[53] = "New Mexico";
geo[54] = "Guam, American Samoa, N. Mariana Isl., Philippines";
geo[55] = "Puerto Rico";
geo[56] = "Long-time or retired railroad workers";
```

Then the `onload` event is bound to the `window` via the cross browser function `addEvent`. This is followed by the declaration of global variables:

```
// initialize when the page has loaded
addEvent(window, 'load', initialize);

// global variables
   var oEntry;
   var oResult;
   var oSearchButton;
```

Next, you'll see the initialization function that was bound to the `onload` event. First, the different objects the script will use are assigned to the global variables, and then the rest of the events are bound to the appropriate objects. As you'll recall from Chapters 26 and 32, the balance of the events are bound after the page has loaded to ensure the objects exist before event binding.

```
function initialize()
{
   // get IE4+ or W3C DOM reference for an element
   if (document.getElementById)
   {
      oEntry = document.getElementById("entry");
      oResult = document.getElementById("result");
      oSearchButton = document.getElementById("searchButton");
   }
   else
   {
      oEntry = document.searchForm.entry;
      oResult = document.searchForm.result;
      oSearchButton = document.searchForm.searchButton;
   }
   addEvent(oEntry, 'change', search);
   addEvent(oSearchButton, 'click', search);

}
```

Now comes the beginning of the data validation functions. Under control of a master validation function shown in a minute, the `stripZeros()` function removes any leading zeros that the user may have entered. Notice that the instructions tell the user to enter the first three digits of a Social Security number. For 001 through 099, that means the numbers begin with one or two zeros. JavaScript, however, treats any numeric value starting with 0 as an octal value. Because we have to do some numeric comparisons for the search through the `ssn[]` array, the script must make sure that the entries (which are strings to begin with, coming as they do from text objects)

can be converted to decimal numbers. The `parseInt()` function, with the all-important second parameter indicating Base 10 numbering, does the job. But because the remaining validations assume a string value, the integer is reconverted to a string value before it is returned:

```
// **BEGIN DATA VALIDATION FUNCTIONS**
// JavaScript sees numbers with leading zeros as octal values,
// so strip zeros
function stripZeros(inputStr)
{
   return parseInt(inputStr, 10).toString();
}
```

The next three functions are described in full in Chapter 46, which discusses data validation. In the last function, a copy of the input value is converted to an integer to enable the function to make necessary comparisons against the boundaries of acceptable ranges:

```
// general purpose function to see if an input value has been entered
function isEmpty(inputStr)
{
   if (inputStr == "" || inputStr == null)
  {
      return true;
   }
   return false;
}

// general purpose function to see if a suspected numeric input
// is a positive integer
function isNumber(inputStr)
{
   for (var i = 0; i < inputStr.length; i++)
   {
      var oneChar = inputStr.substring(i, i + 1);
         if (oneChar < "0" || oneChar > "9")
         {                  return false;
         }
   }
   return true;
}

// function to determine if value is in acceptable range
function inRange(inputStr)
{
   num = parseInt(inputStr);
   // Machines don't need parenthesis but humans do:
   if (num < 1 || (num > 586 && num < 596) || (num > 599 && num < 700)
        || num > 728)
   {
      return false;
   }
   return true;
}
```

The master validation controller function (named `isValid()` in this application) is also covered in depth in Chapter 46. A statement that wants to know if it should proceed with the lookup

process calls this function. If any one validation test fails, the function returns `false`, and the search does not proceed:

```
// Master value validator routine
function isValid(inputStr)
{
   var msg = " 3 digit positive number";
   var msgPrefix;
   var msgSuffix;
   if (isEmpty(inputStr))
   {
      msgPrefix = "Please enter a";
      msgSuffix = " into the field before clicking the button.";
      alert(msgPrefix + msg + msgSuffix);
      return false;
   }
   else
   {
      if (!isNumber(inputStr))
      {
         msgPrefix = "Please make sure entries are";
         msgSuffix = "s only.";
         alert(msgPrefix + msg + msgSuffix);
         return false;
      }
      else
      {
         if (!inRange(inputStr))
         {
            msgPrefix = "Sorry, the number you entered is not part
                         of our database. Try a";
            msgSuffix = ".";
            alert(msgPrefix + msg + msgSuffix);
            return false;
         }
      }
   }
   return true;
}      // **END DATA VALIDATION FUNCTIONS**
```

The `search()` function is invoked by two different event handlers. The two direct calls come from the input field's `onchange` event handler and the Search button's `onclick` event handler.

To search the database, the script repeatedly compares each succeeding entry of the `ssn[]` array against the value entered by the user. For this process to work, a little bit of preliminary work is needed. First comes an initialization of a variable, `foundMatch`, which comes into play later. Initially set to `false`, the variable is set to `true` only if there is a successful match — information you need later to set the value of the result text object correctly for all possible conditions:

```
function search()
{
   var foundMatch = false;
   var inputStr = stripZeros(oEntry.value);
```

```
            if (isValid(inputStr))
            {
               inputValue = inputStr;
               for (var i = 0; i < ssn.length; i++)
               {
                  if (inputValue <= ssn[i])
                  {
                     foundMatch = true;
                     break;
                  }
               }
            }
         oResult.value = (foundMatch) ? geo[i] : "";
         oEntry.focus();
         // delay so IE may select
         setTimeout("oEntry.select()", 100);
      }
```

Next comes all the data preparation. After the entry is passed through the zero stripper, a copy is dispatched to the master validation controller, which, in turn, sends copies to each of its special-purpose minions. If the master validator detects a problem from the results of any of those minions, it returns `false` to the condition that wants to know if the input value is valid. Should the value not be valid, processing skips past the `for` loop and proceeds immediately to an important sequence of three statements.

The first is a conditional statement that relies on the value of the `foundMatch` variable that was initialized at the start of this function. If `foundMatch` is still `false`, that means that something is wrong with the entry and it cannot be processed. To prevent any incorrect information from appearing in the result field, that field is set to an empty string if `foundMatch` is `false`. The next two statements set the focus and selection to the entry field, inviting the user to try another number. You'll recall in Chapter 26, "Generic HTML Element Objects," that IE sometimes fails to `select()` immediately after a `focus()` due to an internal timing problem, so `setTimeout()` adds a small delay to get around the problem.

On the other hand, if the entry is a valid number, the script finally gets to perform its lookup task. Looping through every entry of the `ssn[]` array starting with entry 0 and extending until the loop counter reaches the last item (based on the array's length property), the script compares the input value against each entry's value. If the number is less than or equal to a particular entry, the value of the loop counter (`i`) is frozen, the `foundMatch` variable is set to `true`, and execution breaks out of the `for` loop.

This time through the conditional expression, with `foundMatch` being `true`, the statement plugs the corresponding value of the `geo[]` array (using the frozen value of `i`) into the result field. Focus and selection are set to the entry field to make it easy to enter another value.

Further Thoughts

If we were doing this type of application for production purposes, we would turn each pairing of range high number and geographical location into separate objects and store the objects in an

array. Making that technique work requires one extra function and a different way of populating the data. The following is an example using the same variable names as the preceding listing:

```
// specify an array entry with two items
function dataRecord(ssn, geo)
{
   this.ssn = ssn;
   this.geo = geo;
   return this;
}

// initialize basic array
var numberState = new Array(57);

// populate main array with smaller arrays
numberState[0] = new dataRecord(3,"New Hampshire");
numberState[1] = new dataRecord(7,"Maine");
numberState[2] = new dataRecord(9,"Vermont");
```

The other changes (marked in boldface) occur in the `search()` function, which must address this data in a slightly different way than it did before:

```
function search()
{
   var foundMatch = false;
   var inputStr = stripZeros(oEntry.value);
      if (isValid(inputStr))
      {
         inputValue = inputStr;
         for (var i = 0; i < numberState.length; i++)
         {
            if (inputValue <= numberState[i].ssn)
            {
               foundMatch = true;
               break;
            }
         }
      }
   oResult.value = (foundMatch) ? numberState[i].geo : "";
   oEntry.focus();
   // delay so IE may select
   setTimeout("oEntry.select()", 100);
}
```

All references to data are to the `numberState[]` array and properties of its objects (either `ssn` or `geo`). With the data for each record arranged in a comma-delimited fashion, it may be easier to transfer data exported from an existing database to your script with less copying and pasting or dragging and dropping.

Another possibility would be to use JavaScript's capability to load `.js` files that have the arrays already populated or have variables preloaded with comma-delimited values. By using the

`string.split()` method (see Chapter 15, "The String Object"), you can easily assign data in this format to an array.

This application presents its results in a text box form control. But with today's browsers, you have the luxury of replacing segments of regular body content at will. Therefore, you could revise the script and HTML to include a placeholder element whose content is updated with the result of the array lookup.

We truly believe that server-less data lookups offer a great opportunity to many creative JavaScripters.

CHAPTER

54

Application: A Poor Man's Order Form

IN THIS CHAPTER

Live math on table rows and columns

Number formatting

Code reusability

We hesitate to call the application described in this chapter an order form because it is not in any way intended for use as a client-side shopping cart or some of the more advanced e-commerce applications you see on the Web. No, the goal here is to demonstrate how JavaScript can be used to assist users with column-and-row arithmetic, very much like the kinds of arithmetic needed to calculate the total for an order of goods.

Although this order form is not linked to any particular online catalog, some or all of it can be used as a piece for a small e-commerce site. The form in the example here requires that users input product descriptions and prices, but there is no reason that a client-side JavaScript shopping cart can't accumulate the shopper's choices from catalog pages, and then present them in an order form with product descriptions and prices hard-wired into the table. There still are entry boxes for quantity and selecting local sales tax rates. But all the arithmetic products and sums are calculated quickly on the client with JavaScript.

Along the way, you should also discover how to design code — more specifically, JavaScript data structures — in such a way that they are easily editable by non-scripters who are responsible for updating the embedded data. Therefore, even if you prefer to leave professional e-commerce order processing to server applications, you may still pick up a scripting tip or two from this "poor man's" version of an order form.

Defining the Task

We doubt that any two order forms on the Web are executed precisely the same way. Much of the difference has to do with the way an application on the server wants to receive the data on its way to an order-entry system or database. The rest has to do with how clever the HTML programmer is.

To come up with a generalized demonstration, we had to select a methodology and stay with it.

Because the intended goal of this demonstration is to focus on the rows and columns of an order form, we omit the usual name-and-address input elements. Instead, the code deals exclusively with the tabular part of the form, including the footer "stuff" of a form for subtotals, sales tax, shipping, and the grand total.

Another goal is to design the order form with an eye to as much reusability as possible. In other words, we may design the form for one page, but we also want to adapt it to another order form quickly without having to muck around too deeply in complicated HTML and JavaScript code. One giant annoyance that this approach eliminates is the normal HTML repetition of row after row of tags for input fields and table cells. JavaScript can certainly help you out there.

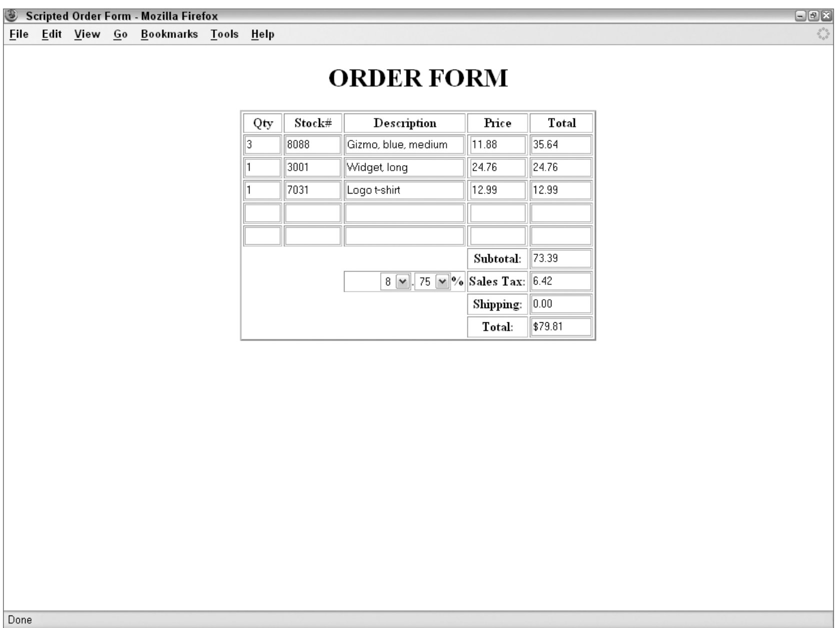
The order form code also demonstrates how to perform math and display results in two decimal places, use the `String.split()` method to make it easy to build arrays of data from comma-delimited lists, and enable JavaScript arrays to handle tons of repetitive work.

The Form Design

Figure 54-1 shows a rather simplified version of an order form as provided in the listings. Many elements of the form are readily adjustable by changing only a few characters near the top of the JavaScript listing. At the end of the chapter, we provide several suggestions for improving the user experience of a form, such as this one.

FIGURE 54-1

The order form display.



Form HTML and Scripting

Because this form is generated as the document loads, JavaScript writes most of the document to reflect the variable choices made in the reusable parts of the script. In fact, in this example, only the document heading is hard-wired in HTML.

The order form example page starts innocently enough:

```
<!DOCTYPE html>
<html>
  <head>
     <meta http-equiv="content-type" content="text/html;charset=utf-8">
<title>Scripted Order Form</title>
```

Global adjustments

The first important section of the example is the start of the JavaScript statements and functions that do most of the work. The script begins by initializing three very important global variables. This location is where the author, defining the details for the order form, also enters information about the column headings, column widths, and number of data entry rows:

```
<script type="text/javascript">
   // ** BEGIN GLOBAL ADJUSTMENTS ** //
   // Order form columns and rows specifications
   // **Column titles CANNOT CONTAIN PERIODS
   var columnHeads = "Qty,Stock#,Description,Price,Total".split(",");
   var columnWidths = "3,7,20,7,8".split(",");
   var numberOfRows = 5;
```

The first two assignment statements perform double duty. Not only do they provide the location for customized settings to be entered by the HTML author, but they use the `string.split()` method to literally create arrays out of their series of comma-delimited strings. At first, this may seem to be a roundabout way to generate an array, because you can also create the array directly with

```
var columnHeads = new Array("Qty","Stock",...);
```

But the way shown here minimizes the possibility of goofing up the quotes and commas when modifying the data, especially if modification might be attempted by a non-scripter.

So much of the repetitive work to come in this application is built around arrays that it will prove to be extraordinarily convenient to have the column title names and column widths in parallel arrays. The number-of-rows value also plays a role in not only drawing the form, but calculating it as well.

Notice the caveat about periods in column heading strings. You will soon see that these column names are assigned as text object names, which, in turn, are used to build object references to text boxes. Object names cannot have periods in them, so for these column headings to perform their jobs, you have to leave periods out of their names.

As part of the global adjustment area, the `extendRow()` method requires knowledge about which columns are to be multiplied to reach a total for any row:

```
// data entry row math
function extendRow(form,rowNum)
{
   // **change 'Qty' and 'Price' to match your column names
   var rowSum = form.Qty[rowNum].value * form.Price[rowNum].value;
   // **change 'Total' to match your corresponding column name
   form.Total[rowNum].value = rowSum.toFixed(2);
}
```

This example uses the `Qty`, `Price`, and `Total` fields for math calculations. Those field names are inserted into the references within this function. To calculate the total for each row, the function receives the form object reference and the row number as parameters. As described later, the order form is generated as a kind of array. Each field in a column intentionally has the same name. This scheme enables scripts to access a given field in that column by row number when using the row number as an index to the array of objects bearing the same name. For example, for the first row (row 0), you calculate the total by multiplying the quantity field of row 0 (`form.Qty[0].value`) times the price field of row 0 (`form.Price[0].value`). You then format that value to two places to the right of the decimal and plug that number into the value of the total field for row 0 (`form.Total[0].value`). More on the `number.toFixed()` method in a moment.

The final place where you have to worry about customized information is in the function that adds up the total columns. The function must know the name that you assigned to the total column:

```
function addTotals(form)
{
   var subTotal = 0;
   for (var i = 0; i < numberOfRows; i++)
   {
      // **change 'Total' in both spots to match your column name
      subTotal += (form.Total[i].value != "") ?
         parseFloat(form.Total[i].value) : 0;
   }
   form.subtotal.value = subTotal.toFixed(2);
   form.tax.value = (getTax(form,subTotal)).toFixed(2);
   form.total.value = "$"
                    + (parseFloat(form.subtotal.value)
                    + parseFloat(form.tax.value)
                    + parseFloat(form.shipping.value)).toFixed(2);
}
// ** END GLOBAL ADJUSTMENTS ** //
```

The `addTotals()` function receives the form reference as a parameter, which it uses to read and write data around the form. The first task is to add up the values of the total fields from each of the data-entry rows. Here you need to be specific about the name you assign to that column. To keep code lines to a minimum, you use a conditional expression inside the `for` loop to make additions to the `subTotal` amount only when a value appears in a row's total field. Because all

values from text fields are strings, you use `parseFloat()` to convert the values to floating-point numbers before adding them to the `subTotal` variable.

Three more assignment statements fill in the subtotal, tax, and total fields. The subtotal is nothing more than a formatted version of the amount reached at the end of the `for` loop. The task of calculating the sales tax is passed off to another function (described in a following section), but its value is also formatted before being plugged into the sales tax field. For the grand total, you add floating-point-converted values of the subtotal, tax, and shipping fields before slapping a dollar sign in front of the result. Even though the three fields contain values formatted to two decimal places, any subsequent math on such floating-point values incurs the minuscule errors that send formatting out to 16 decimal places. Thus, you must reformat the results after the addition.

Do the math

As you can see from Figure 54-1, the user interface for entering the sales tax is a pair of `select` elements. This type of interface minimizes the possibility of users entering the value in all kinds of weird formats that, in some cases, would be impossible to parse. The function that calculates the sales tax of the subtotal looks to these select objects for their current settings:

```
function getTax(form,amt)
{
   var chosenPercent = form.percent[form.percent.selectedIndex].value;
   var chosenFraction = form.fraction[form.fraction.selectedIndex].value;
   var rate = parseFloat(chosenPercent
                      + "."
                      + chosenFraction) / 100;
   return amt * rate;
}
```

After receiving the form object reference and subtotal amount as parameters, the function reads the two values chosen in the `select` elements. The string `value` properties of the `select` objects are temporarily stored in local variables. To arrive at the actual rate, you concatenate the two portions of the string (joined by an artificial decimal point) and `parseFloat()` the string to get a number that you can then divide by 100. The product of the subtotal times the rate is returned to the calling statement (in the preceding `addTotals()` function).

All the calculation that ripples through the order form is controlled by a single `calculate()` function:

```
function calculate(form,rowNum)
{
   extendRow(form,rowNum);
   addTotals(form);
}
```

This function is called by any object that affects the total of any row. Such a request includes both the form object reference and the row number. This information lets the single affected row, and then the totals column, be recalculated. Changes to some objects, such as the sales tax

select objects, affect only the totals column, so they will call addTotals() function directly rather than this function (the rows don't need recalculation).

Number formatting, as explained in Chapter 16, "The Math, Number, and Boolean Objects," is a detail that is addressed in the order form with relative ease thanks to the number.toFixed() method, which is thankfully now supported in modern browsers. In this case you need to trim down all monetary figures to exactly two decimal places. The number.toFixed() method offers precisely this functionality; you simply call the method on a number and pass along the number of fractional digits as the only argument. Here's an example:

```
total2D = total.toFixed(2);
```

You'll end up passing 2 to the toFixed() method for all monetary calculations that require two decimal places, but you may find it helpful to pass other values to the toFixed() method in other situations where fractional precision beyond two decimals is desired.

Cooking up some HTML

As we near the end of the scripting part of the document's Head section, we come to two functions that are invoked later to assemble some table-oriented HTML based on the global settings made at the top. One function assembles the row of the table that contains the column headings:

```
function makeTitleRow()
{
   var titleRow = "<tr>";
   for (var i = 0; i < columnHeads.length; i++)
   {
      titleRow += "<th>"
               + columnHeads[i]
               + "<\/th>";
   }
   titleRow += "<\/tr>";
   return titleRow;
}
```

The heart of the makeTitleRow() function is the for loop, which makes simple <th> tags out of the text entries in the columnHeads array defined earlier. All this function does is assemble the HTML. A document.write() method in the Body puts this HTML into the document.

```
function makeOneRow(rowNum)
{
   var oneRow = "<tr>";
   for (var i = 0; i < columnHeads.length; i++)
   {
      oneRow += "<td align=middle><input type=text size="
             + columnWidths[i]
             + " name=\'"
             + columnHeads[i]
```

```
                + "\' onchange='calculate(this.form,"
                + rowNum
                + ")'><\/td>";
      }
      oneRow += "<\/tr>";
      return oneRow;
   }
```

Creating a row of entry fields is a bit more complex, but not much. Instead of assigning just a word to each cell, you assemble an entire `<input>` object definition. You use the `columnWidths` array to define the size for each field (which therefore defines the width of the table cell in the column). `columnHead` values are assigned to the field's `name` attribute. Each column's fields have the same name, no matter how many rows exist. Finally, the `onchange` event handler invokes the `calculate()` method, passing the form and, most importantly, the row number, which comes into this function as a parameter (see the following section).

The next block of code closes up the head, opens up the body, and prepares the page for a table to hold the order form:

```
   </script>
</head>
<body>
   <center>
      <h1>ORDER FORM</h1>
      <form>
         <table border='2'>
```

Tedium lost

Believe it or not, all of the rows of data-entry fields in the table are defined by the handful of JavaScript statements that follow:

```
<script type="text/javascript">
   document.write(makeTitleRow());
   // order form entry rows
   for (var i = 0; i < numberOfRows; i++)
   {
      document.write(makeOneRow(i));
   }
```

The first function to be called is the `makeTitleRow()` function, which returns the HTML for the table's column headings. Then a very simple `for` loop writes as many rows of the field cells as defined in the global value near the top of the document. Notice how the index of the loop, which corresponds to the row number, is passed to the `makeOneRow()` function, so that it can assign that row number to its relevant statements. Therefore, these few statements generate as many entry rows as you need.

Tedium regained

What follows in the script writes the rest of the form to the screen. To make these fields as intelligent as possible, the scripts must take the number of columns into consideration. A number of empty-space cells must also be defined (again, calculated according to the number of columns). Finally, the code-consuming `select` element definitions must also be in this segment of the code:

```
document.write(makeTitleRow());
// order form entry rows
for (var i = 0; i < numberOfRows; i++)
{
   document.write(makeOneRow(i));
}

// order form footer stuff (subtotal, sales tax, shipping, total)
var colSpacer = "<tr><td colspan="
              + (columnWidths.length - 2)
              + "><\/td>";
document.write(colSpacer);
document.write("<th>Subtotal:<\/th>");
document.write("<td><input type=text size="
               + columnWidths[columnWidths.length - 1]
               + " name=subtotal><\/tr>");
document.write("<tr><td colspan="
               + (columnWidths.length - 3)
               + "><\/td>");
var tax1 = "<select name=percent onchange='addTotals(this.form)'>";
tax1 += "<option value=0>0";
tax1 += "<option value=1>1<option value=2>2<option value=3>3";
tax1 += "<option value=4>4<option value=5>5<option value=6>6";
tax1 += "<option value=7>7<option value=8>8<option value=9>9";
tax1 += "<\/select>";
var tax2 = "<select name=fraction onchange='addTotals(this.form)'>";
tax2 += "<option value=0>00<option value=25>25";
tax2 += "<option value=5>50<option value=75>75<\/select>";
document.write("<th align=right>"
               + tax1
               + "."
               + tax2
               + "\%<\/th>");
document.write("<th align=right>Sales Tax:<\/th>");
document.write("<td><input type=text size="
               + columnWidths[columnWidths.length - 1]
               + " name=tax value=0.00><\/tr>");
document.write(colSpacer);
document.write("<th>Shipping:<\/th>");
document.write("<td><input type=text size="
               + columnWidths[columnWidths.length - 1]
               + " name=shipping value=0.00 "
               + "onchange='addTotals(this.form)'><\/tr>");
document.write(colSpacer);
document.write("<th>Total:<\/th>");
```

```
                document.write("<td><input type=text size="
                               + columnWidths[columnWidths.length - 1]
                               + " name=total><\/tr>");
            </script>
            </table>
          </form>
       </center>
      </body>
   </html>
```

To gain a better understanding of how the script assembles the HTML for this part of the table, start by looking at the `colSpacer` variable. This variable contains a table cell definition that must span all but the rightmost two columns. Thus, the `colspan` attribute is calculated based on the length of the `columnWidths` array (minus two for the columns we need for data). Therefore, to write the line for the subtotal field, you start by writing one of these column spacers, followed by the `<th>` type of cell with the label in it. For the actual field, you must size it to match the fields for the rest of the column. That's why you summon the value of the last `columnWidths` value for the `size` attribute. You use similar machinations for the Shipping and Total lines of the form footer material.

In between these locations, you define the Sales Tax `select` objects (and a column spacer that is one cell narrower than the other one you used). To reduce the risk of data-entry error and to allow for a wide variety of values without needing a 40-item pop-up list, we divided the choices into two components and then display the decimal point and percentage symbol in hard copy. Both `select` objects trigger the `addTotals()` function to recalculate the rightmost column of the form.

Sometimes, it seems odd that you can script 4 lines of code to get 20 rows of a table, yet it takes 20 lines of code to get only 4 more complex rows of a table. Such are the incongruities of the JavaScripter's life.

Further Thoughts

Depending on the catalog of products or services being sold through this order form, the first improvement we would make is to automate the stock number and description entries. For example, if the list of all product numbers isn't that large, you may want to consider dropping a `select` element into each cell of the Description column. Then, after a user makes a selection, the `onchange` event handler performs a lookup through a product array and automatically plugs in the description and unit price. In any version of this form, you also need to perform data validation for crucial calculation fields, such as quantity.

Some of the other online order forms we've seen include reset buttons for every row or a column of checkmarks that lets users select one or more rows for deletion or resetting. Remember that people make mistakes and change their minds while ordering online. Give them plenty of opportunity to recover easily. If getting out of a jam is too much trouble, they will head for the History list or Back button, and that valued order will be, well, history.

CHAPTER

55

Application: Outline-Style Table of Contents

IN THIS CHAPTER

- Multiple frames
- Clickable images
- Persistent data
- Dynamic HTML positioning
- Reading XML data via Ajax

In your web surfing, you may have encountered sites that implement an expandable, outline-type table of contents. I've long thought that these elements were great ideas, especially for sites with lots of information. An outline, such as the Windows Explorer or the text-style Macintosh Finder windows, enables the author to present a large table of contents in a way that doesn't necessarily take up a ton of page space or bandwidth. From listings of top-level entries, a user can drill down to reveal only those items of interest.

No matter how much I like the idea, however, I dislike visiting most of these sites. Usually, a server program responds to each click, chews on my selection, and then sends back a completely new screen, showing my choice expanded or collapsed. After working with outlines in the operating system and outliner programs on personal computers, the delays in this processing seem interminable. It occurred to me that implementing the outline interface as a client-side JavaScript can significantly reduce the delay problem and make outlines a more viable interface to a site's table of contents. This chapter documents the process that went into a JavaScript-powered outliner, which works with all modern browsers.

The Implementation Plan

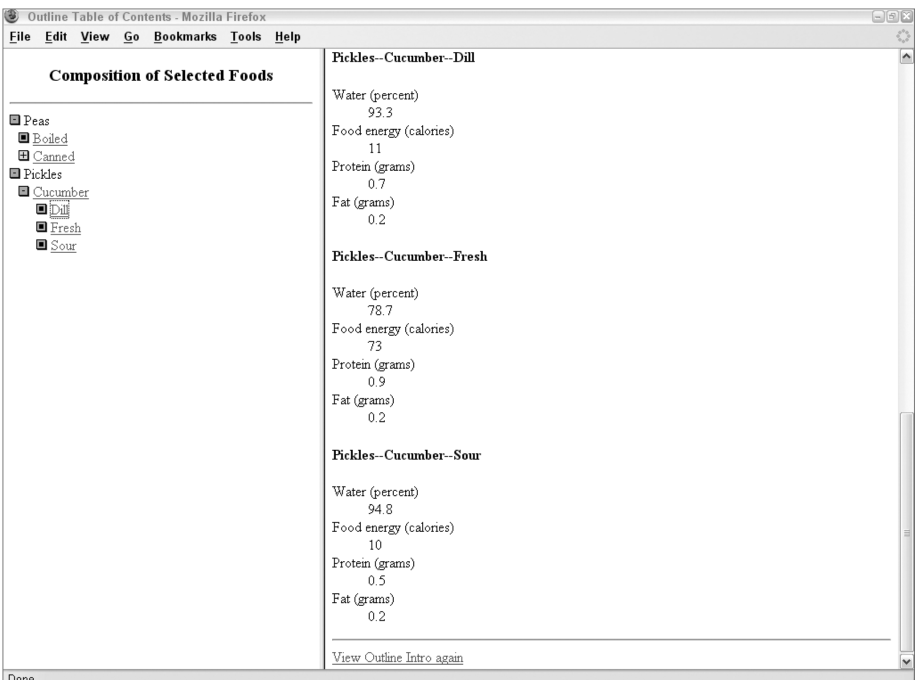
I admit to approaching the outline technique the first time without a specific data-display goal in mind — not always the best way to go about it. In search of some logical and public domain data that I could use as an example, I came upon the tables of information about food composition (grams of protein, fat, calories, and so on) published by the U.S. government. For this demonstration, I created one HTML document containing data for two hierarchical categories of foods: peas and pickles.

At the beginning of each food category, I assigned an anchor to which the text entries of the outline point.

My design for this implementation calls for two frames set up as columns (see Figure 55-1). The narrower left column houses the outline interface. After the frameset loads, the wider right frame initially shows an introductory HTML document. Clicking any of the links in the outline changes the view of the right-hand frame from the introductory document to the food data document. A link at the bottom of the food data document enables the user to view the introductory document again in the same frame, if desired.

FIGURE 55-1

The outline in the left frame is dynamic and local.



Earlier editions of this book included versions of this example that targeted legacy browsers, and were therefore limited in some ways. Modern browsers gave me reason to make some other improvements to the outliner over older versions. They include:

- Adjustable indentation spacing
- Easier specification of widget art files
- Easier way to specify a target frame for the results
- Additional array field for status bar display text

All adapter-adjustable elements appear near the top of the script to make it easy for scripters without a lot of experience to modify the application for their own sites.

The Code

All files for this implementation of the outline are on the CD-ROM accompanying this book, so I display here only the code for the framesetting document (`index.html`) and the outline (`toc.html`).

Setting the frames

To establish the frames, the HTML creates a two-column format, assigning 35 percent of the page as a column to contain the outline:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
<title>Outline Table of Contents</title>
   </head>
   <frameset cols="35%,*">
      <noframes>
         <body>
            <h1>It's really cool...</h1>
            <h2>...but only if you have a frames-capable browser.</h2>
            <hr />
            <a href="index.html">Back</a>
         </body>
      </noframes>
      <frame name="Frame1" src="toc.html" />
      <frame name="Frame2" src="intro.html" />
   </frameset>
</html>
```

The names that I assign to the two frames aren't very original or clever, but they help me remember which frame is which. Because the nature of the contents of the second frame changes (either the introductory document or the data document), I couldn't think of a good name to reflect its purpose.

Outline code

Now we come to some lengthy code for the outline (in file `toc.html`). Much of the code deals with managing the binary representation of the current state of the outline. For each line of the completely exploded outline, the code designates a `0` for a line that has no nested items showing, and a `1` for a line that has a nested item showing. This sequence of `0`s and `1`s (as one string) is the road map that the script follows when redrawing the outline. Cues from the `0` and `1` settings let the script know whether it should display a nested item (if one exists) or leave that item collapsed.

To help me visualize the inner workings of these scripts, I developed a convention that calls any item with nested items beneath it a *mother*. Any nested item is that mother's *daughter*. A daughter can also be a mother if it has an item nested beneath it. You see how this plays out in the code shortly.

The food outline document starts out simply enough, with three CSS styles for the amount of indentation required by the three indentation levels of my sample outline. If the outline were to include more levels, you could simply add styles accordingly.

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Outline Style JavaScript TOC</title>
      <style type="text/css">
         .heading
         {
            text-align:center;
         }       div.indent0
         {
            margin-left:0px;
         }
         div.indent1
         {
            margin-left:10px;
         }
         div.indent2
         {
            margin-left:20px;
         }
      </style>
```

Scripting begins by setting up a global variable that keeps track of the state of the outline:

```
<script type="text/javascript">
   // global variables
   var CSScurrState;
```

The `toggle()` function is called by the `href` attribute of the links surrounding the widget icon art in the outline. This approach continues some of the legacy implementations, in which `img` elements were not capable of recognizing click events and required a link to handle the event (a version later in the chapter shows a more modern approach). A variable number of parameters are passed to this function, so that the parameters are extracted and analyzed through the `arguments` property of the function. Inside the large `for` loop, the setting of the `style.display` property is dynamically changed. The image of the toggled widget is then swapped. As a final touch, the window is given focus so that WinIE browsers lose the dotted rectangle around the clicked image:

```
// **function that updates persistent storage of state**
// toggles an outline mother entry, storing new value
function toggle()
```

```
{
   var newString = "";
   var expanded, n;
   // get all <DIV> tag objects in W3C DOMs
   var allDivs = document.getElementsByTagName("div");
   var currState = CSScurrState; // of whole outline
   // assemble new state string based on parameters passed from link
   for (var i = 0; i < arguments.length; i++)
   {
      n = arguments[i];
      expanded = currState.charAt(n); // of clicked item
      newString += currState.substring(0,n);
      newString += expanded ^ 1; // Bitwise XOR clicked item
      newString += currState.substring(n+1,currState.length);
      currState = newString;
      newString = "";
      // dynamically change display style without reloading
         if (expanded == "0")
         {
            allDivs[n].style.display = "block";
         }
         else
         {
            allDivs[n].style.display = "none";
         }
   }
   CSScurrState = currState; // store the new state
   // swap images in CSS versions
   var img = document.images["widget" + (arguments[0]-1)];
   img.src = (img.src.indexOf("plus.gif") != -1) ?
         "minus.gif" : "plus.gif";
   window.focus();
}
```

A prerequisite for loading the page to begin with is setting the initial value of the state. This is the only part of the script that must be hard-wired based on the structure of the outline — the string assigned to `initState` will be different with each outline. The goal here is to set each block assigned to the `indent0` style class to `1` while all others are set to `0`. These settings allow the first display of the outline to show all the root nodes, with all other items collapsed:

```
// initialize 'current state' storage field
if (!CSScurrState)
{
   // must be hard-wired to outline structure with "1" for
   // each indent0 class item, "0" for all others
   initState = "1000010000";
   CSScurrState = initState;
}
```

Initial settings of the `display` property can be done programmatically only after the document loads (the tags must exist before their properties can be adjusted). The following `init()`

function is called from the `onload` event handler. The `style.display` properties for hidden blocks are set to `none`:

```
            // initialize flagged tags to style display = "none"
            function init()
            {
               var visState = CSScurrState;
               for (var i = 0; i < visState.length; i++)
               {
                  if (visState.charAt(i) == "0")
                  {
                     document.getElementById("a" + i).style.display = "none";
                  }
               }
            }
         </script>
      </head>
      <body onload="init()">
         <div class="heading">
            <h3>Composition of Selected Foods</h3>
            <hr />
         </div>
```

The `init()` function reveals how the display status of outline entries is initially set. To find out if an entry should be displayed, the script performs a test to see if the visibility state of the entry is `0`.

Assembling outline content

Now begins the HTML that defines the content of the outline. For readability, I have formatted the `<div>` tag sets to follow the indentation of the outline data (this listing looks much better if you open the file from the CD-ROM in your text editor with word-wrap turned off). Each tag includes a `class` attribute pointing to a class defined in the first `<style>` tag of the page. Each tag also includes an `id` attribute whose name begins with the letter *a* and a sequential serial number, starting with zero. The `id` attributes are used to help assign `display` property settings during each reload.

Each outline entry includes an image (surrounded by a clickable link) and a text entry (which may or may not be a link to a document). The link around the image includes a `javascript:` URL for the `href` attribute. When a link is for a widget that is a mother item, the parameters to the `toggle()` function are the serial numbers (IDs) of the immediate children whose display properties are to be adjusted in the `toggle()` function. These passed items only need to be in the immediate children, because any of their children inherit the `display` property of their parents. For example, the first widget toggles items 1 and 2 (IDs `a1` and `a2`). Item 2 happens to be a parent to items 3 and 4. But when the `display` property of item 2 is set to `none`, none of its children (items 3 and 4) are displayed, no matter how their display properties are set.

`img` elements associated with each toggled `div` are named along similar lines, with the name starting with *widget* and the same serial number as the containing `div`. If you look at the end of the `toggle()` function again, you'll see that the name for the `img` element is derived from

the first parameter received by the `toggle()` function. That first parameter will always be one number higher than the serial number for the widget image to swap. To help you visualize the numbering scheme used within the example, the numbered identifiers and methods that relay associated numbers are shown in boldface:

```
<div class="indent0" id="a0">
   <a href="javascript:toggle(1,2)"
      onmouseover="status='Click to expand/collapse nested
                       items';return true"
      onmouseout="status='';return true"><img alt="image" name="widget0"
      src="plus.gif" height="12" width="12" border="0" /></a>
    Peas
   <br />
   <div class="indent1" id="a1">
      <a href="javascript:void(0)"
         onmouseover="status='No further items';return true"
         onmouseout="status='';return true"><img alt="image" src="end.gif"
         height="12" width="12" border="0" /></a>
       <a href="foods.html#boiled" target="Frame2">Boiled</a>
      <br />
   </div>
   <div class="indent1" id="a2">
      <a href="javascript:toggle(3,4)"
        onmouseover="status='Click to expand/collapse nested
                       items';return true"
        onmouseout="status='';return true"><img alt="image" name="widget2"
         src="plus.gif" height="12" width="12" border="0" /></a>
       <a href="foods.html#canned" target="Frame2">Canned</a>
      <br />
      <div class="indent2" id="a3">
         <a href="javascript:void(0)"
            onmouseover="status='No further items';return true"
            onmouseout="status='';return true"><img alt="image"
            src="end.gif" height="12" width="12" border="0" /></a>
          <a href="foods.html#alaska" target="Frame2">Alaska</a>
         <br />
      </div>
      <div class="indent2" id="a4">
        <a href="javascript:void(0)"
            onmouseover="status='No further items';return true"
            onmouseout="status='';return true"><img alt="image"
            src="end.gif" height="12" width="12" border="0" /></a>
         <a href="foods.html#losodium" target="Frame2">Low-Sodium</a>
        <br />
      </div>
   </div>
</div>
<div class="indent0" id="a5">
   <a href="javascript:toggle(6)"
      onmouseover="status='Click to expand/collapse nested
                       items';return true"
      onmouseout="status='';return true"><img alt="image" name="widget5"
```

```
            src="plus.gif" height="12" width="12" border="0" /></a>
          Pickles<br />
         <div class="indent1" id="a6">
            <a href="javascript:toggle(7,8,9)"
              onmouseover="status='Click to expand/collapse nested
                                    items';return true"
              onmouseout="status='';return true"><img alt="image" name="widget6"
              src="plus.gif" height="12" width="12" border="0" /></a>
               <a href="foods.html#cucumber" target="Frame2">Cucumber</a>
            <br />
            <div class="indent2" id="a7">
               <a href="javascript:void(0)"
                 onmouseover="status='Click to expand nested items';return true"
                 onmouseout="status='';return true"><img alt="image"
                 src="end.gif" height="12" width="12" border="0" /></a>
                <a href="foods.html#dill" target="Frame2">Dill</a>
               <br />
            </div>
            <div class="indent2" id="a8">
               <a href="javascript:void(0)"
                  onmouseover="status='No further items';return true"
                  onmouseout="status='';return true"><img alt="image"
                  src="end.gif" height="12" width="12" border="0" /></a>
                <a href="foods.html#fresh" target="Frame2">Fresh</a>
               <br />
            </div>
            <div class="indent2" id="a9">
               <a href="javascript:void(0)"
                  onmouseover="status='No further items';return true"
                  onmouseout="status='';return true"><img alt="image"
                  src="end.gif" height="12" width="12" border="0" /></a>
                <a href="foods.html#sour" target="Frame2">Sour</a>
               <br />
            </div>
         </div>
      </div>
   </body>
</html>
```

Note

The property assignment event handling technique used in this example and the next, is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." ■

Note how the `href` attribute of outline entries is set to call the `toggle()` function, passing the number of the entry within the outline database. Perhaps more important is the use of the CSS `class` attribute to set the indentation of each outline entry. By tinkering with this example in a web browser, you should be able to figure out quickly how to modify the outline content to house your own unique outline data.

This example assumes that a site will be using only one outline-style table of contents. Of course, you can have multiple outlines for different sections of a web site or application. But if the outlines all share the same cookie data, the state of the most recent outline will be applied to the next one that loads. Items will be magically opened. And if the number of items between the two outlines is different, the cookie data can get a bit messy.

To solve this problem, assign a different cookie label for each outline. That prevents one outline's state from stepping on another.

An Ajax (XML) Outline

Most modern browsers are now capable of working directly with XML data. Therefore, I've modernized the scriptable outliner described earlier in this chapter to use the `XMLHttpRequest` object described in Chapter 39, "Ajax, E4X, and XML Objects." The data for this Ajax outline version is set apart in a more easily maintainable XML data file. At the same time, I've prettied up the hierarchical interface of the outliner display. Be aware that at the very least, you need to put the XML file on a server in order for the code in this section to render, as discussed later in this chapter.

Birth of an XML specification

Collapsible outlines provide convenient ways to organize hierarchical information all around us. You'd be hard-pressed to find a more active proponent of the outline than Dave Winer, founder of UserLand Software, Inc. (`www.userland.com`). Dave is a veteran software developer, as well as an author and outspoken web publisher. His `www.scripting.com` site is a popular destination if you want to find out the latest Internet and computing technology buzz.

As an outgrowth of development for his company's web tools, Dave looked to the XML structure to assist in representing outline content in a shareable, easily parseable format. The result is a specification called Outline Processor Markup Language, or OPML for short. You can read all about the formal specification at `http://www.opml.org/spec`. Like virtually all XML, OPML is intended to be written by software, not humans (although humans input the data via a user-friendly front-end provided by the software). Even so, the format of an OPML outline is extremely readable by humans, and, with little more trouble than it would take to write basic HTML tags manually, you can represent an outline in this format yourself.

A plain OPML file, saved as an `.xml` file, can be viewed through the native XML parsers of modern browsers such as IE5+ and NN6+/Moz1+. These parsers automatically render XML tags in the same hierarchical fashion in which OPML encourages outlines to be structured. But such rendering is under strict control of the browser, unless you also get involved with XML style sheets (the XSL and XSLT standards), at which point, browser implementation incompatibilities can make the going tough.

I liked the OPML data format when I first saw it, and I think it's a convenient way to convey an outline's data to the client, at which point JavaScript and the browser's DOM can take over to

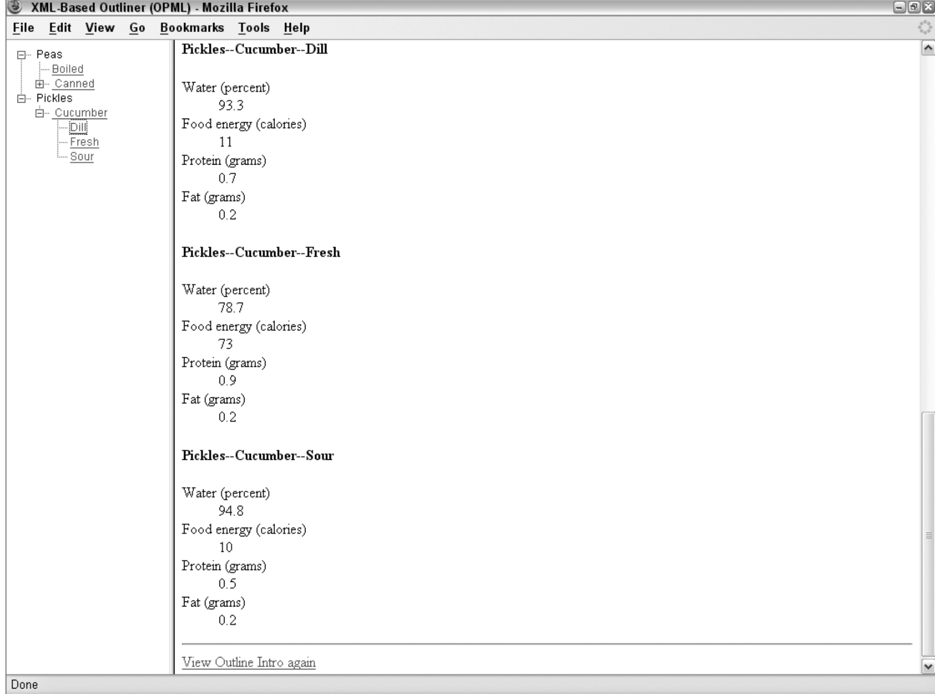
provide interesting visuals for, and interaction with, the content. Thus was born this last example of the chapter, in which the outliner's data is delivered, but not in the form of scripted arrays or hard-wired HTML `div` elements. Instead, the data arrives in its native XML (OPML) format from a separate file. Scripts take over to do the rest.

OPML outliner prep

The appearance of widgets and text for the new outliner has changed to more closely emulate the kinds of outline presentations that you see in some Windows programs (see Figure 55-2). For demonstration purposes, the same frameset structure and outline content from the earlier example is used for the OPML version so that you can more easily see the differences in implementations and grasp the new concepts presented here.

FIGURE 55-2

OPML-based outliner style.



Each OPML outline entry is nothing more than a tag. An entry that does not have any nested child nodes can use the XML shortcut of combining a start and end tag inside one set of angle brackets:

```
<tagName attribute="value" ... />
```

And any entry that has nested nodes contains the nested nodes between its start and end tags, as shown here, with the actual tag names used in OPML (indentation is optional, but increases readability and is therefore considered a best practice):

```
<outline text="text">
   <outline text="text" />
   <outline text="text" />
</outline>
```

If you want to associate more information about an entry, simply add an attribute. For example, if an entry is to behave as a link, you can convey that information with an attribute whose name you determine. When the time comes for your scripts to render the content in HTML, the scripts access the attribute values and generate the associated HTML for the attributes (you see an example of this in the code).

The true beauty of the OPML structure (and XML in general) is that the parent–child relationships are automatically implied by the element containment. The XML containment hierarchy implicitly specifies how many levels deep an entry is, and whether it has any child nodes. Suddenly, all of the W3C DOM gobbledygook about nodes, child nodes, and attributes becomes your friend, as your scripts convert the element hierarchy into a renderable hierarchy of your design.

The XML and HTML code

Because our focus is so tight on the outliner content, the first code to view is that of the XML document, named `outlineData.xml`:

```
<?xml version="1.0" ?>
<opml version="1.0">
   <head>
      <title>A Modern Outline</title>
      <dateCreated>Thu, 13 Nov 2003 02:40:00 GMT</dateCreated>
      <dateModified>Fri, 19 Dec 2003 19:35:00 GMT</dateModified>
      <ownerName>Danny Goodman</ownerName>
      <ownerEmail>dannyg@dannyg.com</ownerEmail>
      <expansionState></expansionState>
      <vertScrollState>1</vertScrollState>
      <windowTop></windowTop>
      <windowLeft></windowLeft>
      <windowBottom></windowBottom>
      <windowRight></windowRight>
   </head>
   <body>
      <outline text="Peas">
         <outline text="Boiled" uri="foods.html#boiled"/>
         <outline text="Canned" uri="foods.html#canned">
            <outline text="Alaska" uri="foods.html#alaska"/>
            <outline text="Low-Sodium" uri="foods.html#losodium"/>
         </outline>
      </outline>
```

```
         <outline text="Pickles">
            <outline text="Cucumber" uri="foods.html#cucumber">
               <outline text="Dill" uri="foods.html#dill"/>
               <outline text="Fresh" uri="foods.html#fresh"/>
               <outline text="Sour" uri="foods.html#sour"/>
            </outline>
         </outline>
      </body>
   </opml>
```

This file is a textbook OPML version 1.0 form. Notice that the OPML syntax reuses element names that are found in all HTML files (for example, `head`, `title`, `body`). This element name duplication makes it essential to isolate the XML from any HTML rendering area (such as an `iframe`), which would automatically add its own `body` element and thus destroy the OPML node tree.

The HTML body of the `toc.html` file is sparse, to say the least:

```
<body onload="init('outlineData.xml')">
   <div id="content"></div>
</body>
```

The only other HTML delivered in the document body is an empty `div` element, which is used as the container for the outline HTML that the scripts generate as a result of the `onload` event handler's invocation of the `init()` function.

Setting the scripted stage

All scripts for this page are in the `head` (although they could also be linked in from an external `.js` file). First on the docket is establishing several global variables that get used a lot within the rest of the code and make it easy to customize important visible properties, especially widget art. Due to the art choices made for this version, there are separate versions for items that appear as first, middle, and end items for different nesting states:

```
<script type="text/javascript">
   // global variables
   // art files and sizes for widget styles and spacers
   // (all images must have same height/width)
   var collapsedWidget = "oplus.gif";
   var collapsedWidgetStart = "oplusStart.gif";
   var collapsedWidgetEnd = "oplusEnd.gif";
   var expandedWidget = "ominus.gif";
   var expandedWidgetStart = "ominusStart.gif";
   var expandedWidgetEnd = "ominusEnd.gif";
   var nodeWidget = "onode.gif";
   var nodeWidgetEnd = "onodeEnd.gif";
   var emptySpace = "oempty.gif";
   var chainSpace = "ochain.gif";
   var widgetWidth = "20";
   var widgetHeight = "16";
```

```
var currState = "";
var displayTarget = "Frame2";
```

The `init()` function, invoked by the `onload` event handler, sets the content creation in motion. In actuality, all this function does is call the `loadXMLDoc()` function to handle the details of loading the XML document and building the outline:

```
// initialize first time
function init(outlineDataURL)
{
   loadXMLDoc(outlineDataURL);
}
```

Loading the XML file and populating the outline is performed in the `loadXMLDoc()` function. The function also handles alerts to users due to a missing XML file, connection problems, or lack of support for the feature:

```
// XML document
var xDoc;

// retrieve XML document as document object
function loadXMLDoc(url)
{
   var req = null;
   try
   {
      req = new XMLHttpRequest();
      req.overrideMimeType("text/xml");
   }
   catch(e)
   {
      req = new ActiveXObject("Msxml2.XMLHTTP");
   }
   if (req)
   {
      xDoc = null;
      req.open("GET", url, true);
      req.onreadystatechange = function()
         {
            if (req.readyState == 4)
            {
               if (req.status == 200)
               {
                xDoc = req.responseXML;
                if (xDoc &&
                    typeof xDoc.childNodes != "undefined" &&
                    xDoc.childNodes.length == 0)
                {
                   xDoc = null;
                }
                else
                {
```

```
                  // demo how to get outline head elements
                  var hdr = xDoc.getElementsByTagName("head")[0];
                  // get outline body elements for iteration
                  // and conversion to HTML
                  var ol = xDoc.getElementsByTagName("body")[0];
                  // wrap whole outline HTML in a span
                  var olHTML = "<span id='renderedOL'>"
                             + makeHTML(ol)
                             + "</span>";
                 // throw HTML into 'content' div for display
                 document.getElementById("content").innerHTML =
olHTML;

                 initExpand();
               }
            }
            else
            {
              alert("There was a problem retrieving the XML data:\n"
                    + req.statusText);
            }
         }
      }
     req.send(null);
   }
  }
```

The XMLHttpRequest object is available in IE as the Msxml2.XMLHTTP object, so the first thing you'll see is a try/catch block that instantiates the appropriate object. Both objects support the same properties and methods (see Chapter 39). If the XML file is not found on the server, the status property will not return a 200 (it will return a 0), and the responseXML property will be null. So, the code execution falls through with an error message to the user.

The loadXMLDoc() function uses the standard Ajax approach of establishing a callback function that waits for the XML document to be loaded, and then does something meaningful with it once the load has succeeded. The external XML data is loaded into a scripted document object global variable (named xDoc). If the data loads successfully, a reference to the Body portion of the outline data is retrieved so that many other functions are able to dive into the outliner hierarchy. The reference to the OPML body element is passed to the makeHTML() function, which returns the entire outline HTML, to be assigned to the innerHTML property of the empty div element, which is delivered with the document.

Note

As handy as it may be, in a strict W3C approach to JavaScript, you wouldn't use the innerHTML property since it isn't officially part of the W3C standard. However, it is often too powerful a convenience property to ignore, as much of the code throughout this book is a testament. The book does show the W3C node manipulation alternative to innerHTML in some examples. Refer to Chapter 29, "The Document and Body Objects," for a thorough explanation, and examples of the W3C alternative to innerHTML. ■

Accumulating the HTML

From the `loadXMLDoc()` function, a call to the `makeHTML()` function starts the most complex actions of the scripts on this page. This function walks the node hierarchy of the outline's `body` elements, deciphering which ones are containers and which ones are end points.

Two global variables are used to keep track of how far the node walk progresses, because this function calls itself from time to time to handle nested branches of the node tree. Because a reflexive call to a function starts out with new values for local variables, the global variables operate as pointers to let statements in the function know which node is being accessed. The numbers get applied to an `id` attribute assigned to the `div` elements holding the content.

One of the fine points of the design of this outline is the way space to the left of each entry is assembled. Unlike the earlier outlines in this chapter, this one displays vertical dotted lines connecting nodes at the same level. There isn't a vertical line for every clickable node appearing above the item, because a clickable node may have no additional siblings — meaning that the space is blank. To see what I mean, open the OPML example, and expand the Peas and Canned nodes (or refer to Figure 55-2). The Canned node is the end of the second column, so the space beneath the icon is blank. That's what some of the code in the `makeHTML()` named prefix is dealing with: Accumulating just the right combination of dotted line (`chain.gif`) and blank (`empty.gif`) images in sequence before the outline entry.

Another frequent construction throughout this function is a three-level conditional expression. This construction is used to determine whether the image just to the left of the item's text should be a start, middle, or end version of the image. The differences among them are subtle (having to do with how the vertical dotted line extends above or below the widgets). All of these decisions are made from information revealed by the inherent structure of the OPML element nesting. The listing in the book looks longer than it truly is because so many long or deeply nested lines must be wrapped to the next line. Viewing the actual file in your text editor should calm your fears a bit.

```
// counters for reflexive calls to makeHTML()
var currID = 0;
var blockID = 0;
// generate HTML for outline
function makeHTML(ol, prefix)
{
   var output = "";
   var nestCount, link, nestPrefix;
   prefix = (prefix) ? prefix : "";
   for (var i = 0; i < ol.childNodes.length ; i++)
   {
      if (ol.childNodes[i].nodeType != 1)
      {
         continue;
      }
      nestCount = ol.childNodes[i].childNodes.length;
      output += "<div class='row' id='line" + currID++ + "'>\n";
      if (nestCount > 0)
```

```
{
   output += prefix;
   output += "<img id='widget"
          + (currID-1)
          + "' src='"
          + ((i== ol.childNodes.length-1) ?
               collapsedWidgetEnd : (blockID==0) ?
                   collapsedWidgetStart : collapsedWidget);
   output += "' height="
          + widgetHeight
          + " width="
          + widgetWidth;
   output += " title='Click to expand/collapse nested items.'"
          + " onclick='toggle(this,"
          + blockID
          + ")'>";
   link =  (ol.childNodes[i].getAttribute("uri")) ?
               ol.childNodes[i].getAttribute("uri") : "";
   if (link)
   {
      output += " <a href='"
             + link
             + "' class='itemTitle' title='"
             + link
             + "' target='"
             + displayTarget
             + "'>";
   }
   else
   {
      output += " <a class='itemTitle' title='"
             + link
             + "'>";
   }
   output += " "
          + ol.childNodes[i].getAttribute("text")
          + "</a>";
   currState += calcBlockState(currID-1);
   output += "<span class='OLBlock' blocknum='"
          + blockID
          + "' id='OLBlock"
          + blockID++
          + "'>";
   nestPrefix = prefix;
   nestPrefix += (i == ol.childNodes.length - 1) ?
      "<img src='" + emptySpace + "' height=16 width=20>" :
      "<img src='" + chainSpace + "' height=16 width=20>";
   output += makeHTML(ol.childNodes[i], nestPrefix);
   output += "</span></div>\n";
}
else
{
   output += prefix;
```

```
            output += "<img id='widget"
                  + (currID-1)
                  + "' src='"
                  + ((i == ol.childNodes.length - 1) ?
                             nodeWidgetEnd : nodeWidget);
            output += "' height="
                  + widgetHeight
                  + " width="
                  + widgetWidth
                  + ">";
            link =  (ol.childNodes[i].getAttribute("uri")) ?
                     ol.childNodes[i].getAttribute("uri") : "";
            if (link)
            {
               output += " <a href='"
                     + link
                     + "' class='itemTitle' title='"
                     + link
                     + "' target='"
                     + displayTarget
                     + "'>";
            }
            else
            {
               output += " <a class='itemTitle' title='"
                     + link
                     + "'>";
            }
            output += ol.childNodes[i].getAttribute("text")
                  + "</a>";
            output += "</div>\n";
         }
      }
      return output;
   }
```

As with the HTML assembly code of the first outliner, if you were to add attributes to `outline` elements in an OPML outline (for example, a URL for an icon to display in front of the text), it is in `makeHTML()` that the values would be read and applied to the HTML being created.

The only other function invoked by the `makeHTML()` function is `calcBlockState()`. This function looks into one of the OPML outline's `head` elements, called `expansionstate`. This element's values can be set to a comma-delimited list of numbers, corresponding to nodes that are to be shown expanded when the outline is first displayed. The `calcBlockState()` function is invoked for each parent element. The element's location is compared against values in the `expansionstate` element, if there are any, and returns the appropriate `1` or `0` value for the state string being assembled for the rendered outline:

```
// apply default expansion state from outline's header
// info to the expanded state for one element to help
// initialize currState variable
function calcBlockState(n)
```

```
{
   var ol = xDoc.getElementsByTagName("body")[0];
   var outlineLen = ol.getElementsByTagName("outline").length;
   // get OPML expansionState data
   var expandElem = xDoc.getElementsByTagName("expansionState")[0];
   var expandedData = (expandElem.childNodes.length) ?
         expandElem.firstChild.nodeValue.split(",") : null;
   if (expandedData)
   {
      for (var j = 0; j < expandedData.length; j++)
      {
         if (n == expandedData[j] - 1)
         {
            return "1";
         }
      }
   }
   return "0";
}
```

The final act of the initialization process is a call to the `initExpand()` function. This function loops through the `currState` global variable (whose value was written in `makeHTML()` with the help of `calcBlockState()`) and sets the `display` property to `block` for any element designed to be expanded at the outset. HTML element construction in `makeHTML()` is performed in such a way that each parent `div` has a `span` nested directly inside of it; and inside that `span` are all the child nodes. The `display` property of the `span` determines whether all of those children are seen or not.

```
// expand items set in expansionState XML tag, if any
function initExpand()
{
   for (var i = 0; i < currState.length; i++)
   {
      if (currState.charAt(i) == 1)
      {
         document.getElementById("OLBlock" + i).style.display =
"block";
      }
   }
}
```

By the time the `initExpand()` function has run — a lot of setup code that executes pretty quickly — the rendered outline is in a steady state. Users can now expand or collapse portions by clicking the widget icons.

Toggling node expansion

All of the widget images in the outline have `onclick` event handlers assigned to them. The handlers invoke the `toggle()` function, passing parameters consisting of a reference to the `img`

element object receiving the event, and the serial number of the span block nested just inside the div that holds the image. With these two pieces of information, the toggle() function sets in motion the act of inverting the expanded/collapsed state of the element and the plus or minus version of the icon image. The blockNum parameter corresponds to the position within the currState string of 1s and 0s holding the flag for the expanded state of the block. With the current value retrieved from currState, the value is inverted through swapState(). Then, based on the new setting, the display property of the block is set accordingly, and widget art is changed through two special-purpose functions:

```
// toggle an outline mother entry, storing new state value;
// invoked by onclick event handlers of widget image elements
function toggle(img, blockNum)
{
   var newString = "";
   var expanded, n;
   // modify state string based on parameters from img
   expanded = currState.charAt(blockNum);
   currState = swapState(currState, expanded, blockNum);
   // dynamically change display style
   if (expanded == "0")
   {
     document.getElementById("OLBlock" + blockNum).style.display =
"block";
     img.src = getExpandedWidgetState(img.src);
   }
   else
   {
     document.getElementById("OLBlock" + blockNum).style.display = "none";
     img.src = getCollapsedWidgetState(img.src);
   }
}
```

Swapping the state of the currState variable utilizes the same XOR operator employed by the first outliner in this chapter. The entire currState string is passed as a parameter. The indicated digit is segregated and inverted, and the string is reassembled before being returned to the calling statement in toggle():

```
// invert state
function swapState(currState, currVal, n)
{
   var newState = currState.substring(0,n);
   newState += currVal ^ 1; // Bitwise XOR item n
   newState += currState.substring(n+1,currState.length);
   return newState;
}
```

As mentioned earlier, each of the clickable widget icons (plus and minus) can be one of three states, depending on whether the widget is at the start, middle, or end of a vertical-dotted chain. The two image-swapping functions find out (by inspecting the URLs of the images currently occupying the img element) which version is currently in place so that, for instance, a starting

"plus" (collapsed) widget is replaced with a starting "minus" (expanded) widget. This is a case of going the extra mile for the sake of an improved user interface:

```
          // retrieve matching version of 'minus' images
          function getExpandedWidgetState(imgURL)
          {
             if (imgURL.indexOf("Start") != -1)
             {
                return expandedWidgetStart;
             }
             if (imgURL.indexOf("End") != -1)
             {
                return expandedWidgetEnd;
             }
             return expandedWidget;
          }

          // retrieve matching version of 'plus' images
          function getCollapsedWidgetState(imgURL)
          {
             if (imgURL.indexOf("Start") != -1)
             {
                return collapsedWidgetStart;
             }
             if (imgURL.indexOf("End") != -1)
             {
                return collapsedWidgetEnd;
             }
             return collapsedWidget;
          }
        return collapsedWidget;
   }
```

Wrap up

There's no question that the amount and complexity of the code involved for the OPML version of the outliner are significant. The pain associated with developing an application such as this is all up front. After that, the outline content is easily modifiable in the OPML format (or perhaps by some future editor that produces OPML output).

Even if you don't plan to implement an OPML outline, the explanation of how this example works should drive home the importance of designing data structures that assist not only the visual design, but also the scripting that you use to manipulate the visual design.

Further Thoughts

The advent of CSS and element positioning has prompted numerous JavaScripters to develop another kind of hierarchical system of pop-up or drop-down menus that don't require as much scripting because of their reliance of CSS. You can find examples of this interface at many of the JavaScript source web sites listed in Appendix E.

Most of the code you find, however, will require a fair amount of tweaking to blend the functionality into the visual design that you have, or are planning, for your web site. Finding two implementations on the Web that look or behave the same way is rare. As long as you're aware of what you'll be getting yourself into, you are encouraged to check out these interface elements. By hiding menu choices except when needed, valuable screen real estate is preserved for more important static content.

CHAPTER

56

Application: Calculations and Graphics

IN THIS CHAPTER

Pre-cached images

Math calculations

CGI-like image assembly

When the scripting world had its first pre-release peeks at JavaScript (while Netscape was still calling the language LiveScript), the notion of creating interactive HTML-based calculators captured the imaginations of many page authors. Somewhere on the World Wide Web, you can find probably every kind of special-purpose calculation normally done by scientific calculators and personal computer programs — leaving only weather-modeling calculations to the supercomputers of the world.

In the search for my calculator gift to the JavaScript universe, I looked around for something more graphical. Numbers, by themselves, are pretty boring; so any way the math could be enlivened was fine by me. Having been an electronics hobbyist since I was a kid, I recalled the color-coding of electronic resistor components. The values of these gizmos aren't printed in plain numbers anywhere. You have to know the code and the meaning of the location of the colored bands to arrive at the value of each one. I think that this calculator will be fun to play with, even if you don't know what a resistor is.

The Calculation

To give you an appreciation for the calculation that goes into determining a resistor's value, here is the way the system works. Colored bands are printed on the surface of a resistor to encode its resistance value in ohms. The first (leftmost) band is the tens digit; the second (middle) band is the ones digit. Each color has a number from 0 through 9 assigned to it (black = 0, brown = 1, and so on). Therefore, if the first band is brown and the second band

is black, the number you start off with is 10. The third band is a multiplier. Each color determines the power of ten by which you multiply the first digits. For example, the red color corresponds to a multiplier of 10^2, so that $10 \infty 10^2$ equals 1,000 ohms.

A fourth band, if present, indicates the tolerance of the component — how far, plus or minus, the resistance measurement can fluctuate due to variations in the manufacturing process. Gold means a tolerance of plus-or-minus 5 percent; silver means plus-or-minus 10 percent; and no band means a 20 percent tolerance. A pinch of extra space typically appears between the main group of three-color bands and the one tolerance band.

User Interface Ideas

The quick-and-dirty, non-graphical approach for a user interface was to use a single frame with four `select` elements defined as pop-up menus (one for each of the four color bands on a resistor), a button to trigger calculation, and a field to show the numeric results.

How dull.

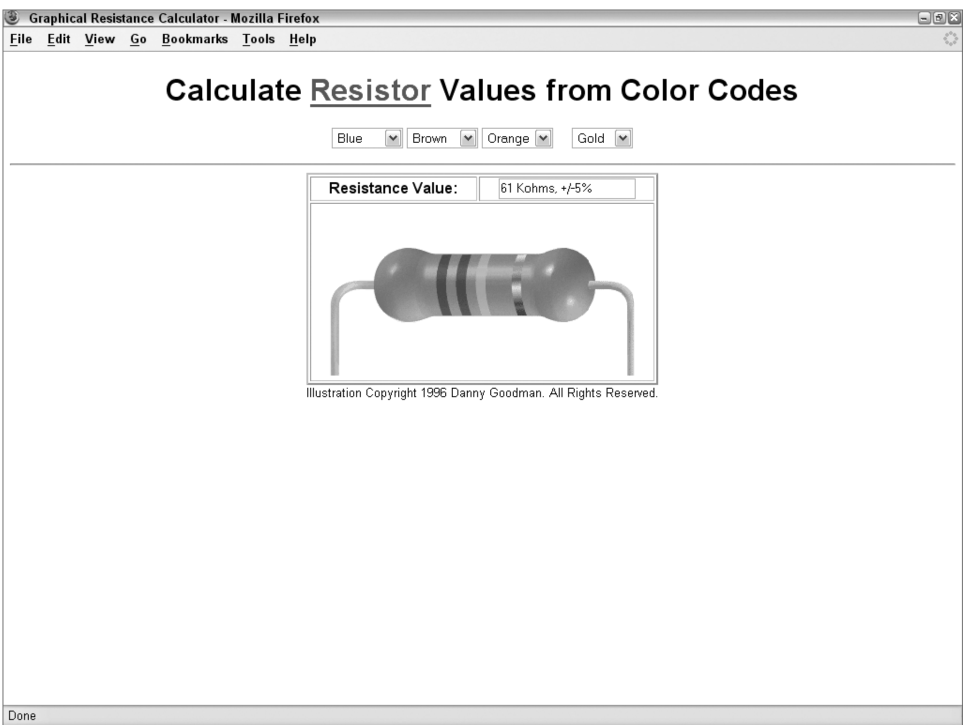
It occurred to me that if I design the art carefully, I can have JavaScript assemble an updated image of the resistor consisting of different slices of art: static images for the resistor's left and right ends, and variable slivers of color bands for the middle. Rather than use the brute force method of creating an image for every possible combination of colors (3,600 images total!), a far more efficient approach is to have one image file for each color (12 colors plus 1 empty) and enable JavaScript to call them from the server, as needed, in the proper order. If not for client-side JavaScript, a script on the server would have to handle this kind of intelligence and user interaction. But with this system, any dumb server can dish up the image files as called by the JavaScript script with no special server-side processing.

The first generation of this resistor calculator used two frames, primarily because I needed a second frame to update the calculator's art dynamically while keeping the pop-up color menus stationary. Images couldn't be swapped back in those frontier days, so the lower frame had to be redrawn for each color choice. Fortunately, modern browsers enabled me to update individual image objects in a loaded document without any document reloading. Moreover, with all the images precached in memory, page users experience no (or virtually no) delay in making a change from one value to another.

The design for the modern version is a simple, single-document interface (see Figure 56-1). Four pop-up menus let you match colors of a resistor, whereas the `onchange` event handler in each menu automatically triggers an image and calculation update. To hold the art together on the page, a table border surrounds the images on the page, whereas the numeric value of the component appears in a text field.

FIGURE 56-1

The Resistor Calculator with images inside a table border.



The Code

All the action takes place in the file named `resistor.html`. A second document is an introductory HTML text document that explains what a resistor is and why you need a calculator to determine a component's value. The article, called *The Path of Least Resistance*, can be viewed in a secondary window from a link in the main window. Here you will be looking only at `resistor.html`.

The document begins in the traditional way without any surprises other than a CSS style to change the font of the body text. Notice that the `onload` event is bound to the window using the `addEvent` function (as described in Chapter 32, "Event Objects").

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Graphical Resistance Calculator</title>
```

```
<style type="text/css">
   body
   {
      font-family:Arial, Helvetica, serif;
   }
   .copyright
   {
      font-size:small;
   }
</style>
<script type="text/javascript" src="../jsb-global.js"></script>
<script type="text/javascript">
   // initialize when the page has loaded
   addEvent(window, "load", calcOhms);
```

Basic arrays

In calculating the resistance, the script needs to know the multiplier value for each color. If not for the last two multiplier values actually being negative multipliers (for example, 10-1 and 10-2), I could have used the index values without having to create this array. But the two out-of-sequence values at the end mean that it's easier to work with an array than to try special-casing these instances in later calculations:

```
// create array listing all the multiplier values
var multiplier = new Array();
multiplier[0] = 0;
multiplier[1] = 1;
multiplier[2] = 2;
multiplier[3] = 3;
multiplier[4] = 4;
multiplier[5] = 5;
multiplier[6] = 6;
multiplier[7] = 7;
multiplier[8] = 8;
multiplier[9] = 9;
multiplier[10] = -1;
multiplier[11] = -2;

// create array listing all tolerance values
var tolerance = new Array();
tolerance[0] = "+/-5%";
tolerance[1] = "+/-10%";
tolerance[2] = "+/-20%";
```

Although the script doesn't do any calculations with the tolerance percentages, it needs to have the strings corresponding to each color for display in the pop-up menu. The `tolerance` array is there for that purpose. This is in contrast with the `multiplier` array, which contains numeric values instead of strings; the `multiplier` array is used to calculate the resistor value.

Calculations and formatting

Before the script displays the resistance value, it needs to format the numbers into values that are meaningful to those who know about these values. Just like measures of computer storage bytes, high quantities of ohms are preceded with "kilo" and "meg" prefixes, commonly abbreviated with the "K" and "M" letters. The `format()` function determines the order of magnitude of the final calculation (from another function shown in the following section) and formats the results with the proper unit of measure:

```
// format large values into kilo and meg
function format(ohmage)
{
   if (ohmage >= 1e6)
   {
      ohmage /= 1e6;
      return "" + ohmage + " Mohms";
   }
   else
   {
      if (ohmage >= 1e3)
      {
         ohmage /= 1e3;
         return "" + ohmage + " Kohms";
      }
      else
      {
         return "" + ohmage + " ohms";
      }
   }
}
```

The selections from the pop-up menus meet the calculation formulas of resistors in the `calcOhms()` function. Because this function is triggered indirectly by each of the `select` objects, sending any of their parameters to the function is a waste of effort. Moreover, the `calcOhms()` function is invoked by the `onload` event handler, which is not tied to the form or its controls. Therefore, the function obtains the reference to the form and then extracts the necessary values of the four `select` objects by using explicit (named) references. Each value is stored in a local variable for convenience in completing the ensuing calculation.

Recalling the rules used to calculate values of the resistor bands, the first statement of the calculation multiplies the "tens" pop-up value times 10 to determine the tens digit, and then adds the ones digit. From there, the combined value is multiplied by the exponent value of the selected multiplier value. Notice that the expression first assembles the value as a string to concatenate the exponent factor and then evaluates it to a number. Although I try to avoid the `eval()` function because of its slow performance, the one call per calculation is not a performance issue. The evaluated number is passed to the `format()` function for proper formatting (and setting of order of magnitude). In the meantime, the tolerance value is extracted from its array, and the

combined string is plugged into the `result` text field (which is in a separate form, as described later):

```
// calculate resistance and tolerance values
function calcOhms()
{
   var form = document.forms["input"];
   var d1 = form.tensSelect.selectedIndex;
   var d2 = form.onesSelect.selectedIndex;
   var m = form.multiplierSelect.selectedIndex;
   var t = form.toleranceSelect.selectedIndex;
   var ohmage = (d1 * 10) + d2;
   ohmage = eval("" + ohmage + "e" + multiplier[m]);
   ohmage = format(ohmage);
   var tol = tolerance[t];
   document.forms["output"].result.value = ohmage + ", " + tol;
}
```

Preloading images

As part of the script that runs when the document loads, the next group of statements precaches all possible images that can be displayed for the resistor art. For added scripting convenience, the color names are loaded into an array. With the help of that just-created array of color names, you then create another array (`imageDB`), which both generates `Image` objects for each image file, and assigns a URL to each image. Notice an important subtlety about the index values being used to create each entry of the `imageDB` array: Each index is a `colorArray` entry, which is the name of the color. As you found out in Chapter 18, "The Array Object," if you create an array element with a named index, you must use that style of index to retrieve the data thereafter; you cannot switch arbitrarily between numeric indexes and names. As you see in a moment, this named index provides a critical link between the choices a user makes in the pop-up lists and the image objects being updated with the proper image file.

```
// pre-load all color images into image cache
var colorArray = new Array("Black","Blue","Brown","Gold","Gray",
   "Green","None","Orange","Red","Silver","Violet","White","Yellow");
var imageDB = new Array();
for (i = 0; i < colorArray.length; i++)
{
   imageDB[colorArray[i]] = new Image(21,182);
   imageDB[colorArray[i]].src = colorArray[i] + ".gif";
}
```

The act of assigning a URL to the `src` property of an `Image` object instructs the browser to pre-load the image file into memory. This preloading happens as the document is loading, so another few seconds of delay won't be noticed by the user.

Changing images on-the-fly

The next four functions are invoked by their respective `select` object's `onchange` event handler. For example, after a user makes a new choice in the first `select` object (the "tens" value

color selector), that `select` object reference is passed to the `setTens()` function. Its job is to extract the text of the choice and use that text as the index into the `imageDB` array. Alternatively, the color name can also be assigned to the `value` attribute of each `option`, and the `value` property read here. You need this connection to assign the `src` property of that array entry to the `src` property of the image that you see on the page (defined in the following section). This assignment is what enables the images of the resistor to be updated instantaneously — just the one image "slice" affected by the user's choice in a `select` object:

```
function setTens(choice)
{
   var tensColor = choice.options[choice.selectedIndex].value;
   document.getElementById("tens").src = imageDB[tensColor].src;
   calcOhms();
}
function setOnes(choice)
{
   var onesColor = choice.options[choice.selectedIndex].value;
   document.getElementById("ones").src = imageDB[onesColor].src;
   calcOhms();
}
function setMult(choice)
{
   var multColor = choice.options[choice.selectedIndex].value;
   document.getElementById("mult").src = imageDB[multColor].src;
   calcOhms();
}
function setTol(choice)
{
   var tolColor = choice.options[choice.selectedIndex].value;
   document.getElementById("tol").src = imageDB[tolColor].src;
   calcOhms();
}
```

The rest of the script for the Head portion of the document merely provides the statements that open the secondary window to display the introductory document:

```
        function showIntro()
        {
            window.open("resintro.htm","","width=400,height=320,
                left=100,top=100");
        }
      </script>
   </head>
```

Creating the select objects

A comparatively lengthy part of the document is consumed with the HTML for the four `select` objects. Remember that the `onload` event was bound to the window object at the beginning of the script. This handler calculates the results of the currently selected choices whenever the document loads or reloads. If it weren't for this event handler, you would not see the resistor

art when the document first appears. Also, because many browsers maintain their form controls' settings while the page is in history, a return to the page later must display the images previously selected in the form:

```
<body>
   <center>
      <h1>Calculate
         <a href="javascript:showIntro()"
            onmouseover="status='An intro to the resistor electronic
                               component...';return true">
            Resistor
         </a> Values from Color Codes         <form name="input">
         <select name="tensSelect" onchange="setTens(this)">
            <option value="Black" selected="selected">Black</option>
            <option value="Brown">Brown</option>
            <option value="Red">Red</option>
            <option value="Orange">Orange</option>
            <option value="Yellow">Yellow</option>
            <option value="Green">Green</option>
            <option value="Blue">Blue</option>
            <option value="Violet">Violet</option>
            <option value="Gray">Gray</option>
            <option value="White">White</option>
         </select>
         <select name="onesSelect" onchange="setOnes(this)">
            <option value="Black" selected="selected">Black</option>
            <option value="Brown">Brown</option>
            <option value="Red">Red</option>
            <option value="Orange">Orange</option>
            <option value="Yellow">Yellow</option>
            <option value="Green">Green</option>
            <option value="Blue">Blue</option>
            <option value="Violet">Violet</option>
            <option value="Gray">Gray</option>
            <option value="White">White</option>
         </select>
         <select name="multiplierSelect" onchange="setMult(this)">
            <option value="Black" selected="selected">Black</option>
            <option value="Brown">Brown</option>
            <option value="Red">Red</option>
            <option value="Orange">Orange</option>
            <option value="Yellow">Yellow</option>
            <option value="Green">Green</option>
            <option value="Blue">Blue</option>
            <option value="Violet">Violet</option>
            <option value="Gray">Gray</option>
            <option value="White">White</option>
            <option value="Gold">Gold</option>
            <option value="Silver">Silver</option>
         </select>
             
         <select name="toleranceSelect" onchange="setTol(this)">
            <option value="Gold" selected="selected">Gold</option>
```

```
      <option value="Silver">Silver</option>
      <option value="None">None</option>
   </select>
</form>
<hr />
```

Note

The property assignment event handling technique in this example is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods, as was done earlier in the code for the `onload` event. The modern cross-browser event handling technique used earlier is explained in detail in Chapter 32. ■

Drawing the initial images

The balance of the document, mostly in JavaScript, is devoted to creating the table and image objects whose `src` properties will be modified with each choice of a `select` object. The act of assembling the HTML for the image table occurs right after the `select` objects have rendered. References to those `select` elements are required in order to extract the currently selected values. If the `form` element that holds the `select` elements is not closed, you can't build a valid reference to the `select` elements. Therefore, the page contains two forms: One for the `select` elements; one for the output text box inside the table:

```
<script type="text/javascript">
   var form = document.forms["input"];
   var tensDigit = form.tensSelect.selectedIndex;
   var tensColor = form.tensSelect.options[tensDigit].value;
   var onesDigit = form.onesSelect.selectedIndex;
   var onesColor = form.onesSelect.options[onesDigit].value;
   var multDigit = form.multiplierSelect.selectedIndex;
   var multColor = form.multiplierSelect.options[multDigit].value;
   var tolDigit = form.toleranceSelect.selectedIndex;
   var tolColor = form.toleranceSelect.options[tolDigit].value;

   var table ="<table border='2'><form name='output'>";
   table += "<tr><th align='middle'>Resistance Value:<\/th>";
   table +=" <th align='middle'>";
   table +="<input type='text' name='result' size=20
            onfocus='this.blur()'>";
   table +="<\/th><\/tr><tr><td colspan=2> ";
   table +="<img SRC='resleft.gif' width=127 height=182><img"
         + " SRC='" + tensColor
         + ".gif' id='tens' width=21 height=182><img"
         + " SRC='" + onesColor
         + ".gif' id='ones' width=21 height=182><img"
         + " SRC='" + multColor
         + ".gif' id='mult' width=21 height=182><img"
         + " SRC='spacer.gif' width=17 height=182><img"
         + " SRC='" + tolColor
         + ".gif' id='tol' width=21 height=182><img"
         + " SRC='resright.gif' width=127 height=182>";
```

```
            table += " <\/td><\/tr><\/form><\/table>";
            document.write(table);
         </script>
         <div class="copyright">Illustration Copyright 1996 Danny Goodman.
            All Rights Reserved.
         </div>
      </center>
   </body>
</html>
```

As you can see, the resistor images appear in one table cell (in the second row) that contains all seven image objects smashed against each other. To keep the images flush, there can be no spaces or carriage returns between `<img>` tags.

Further Thoughts

Although this example works quite well, annoying differences still exist among different platforms. At one point in the design process, I considered trying to align the pop-up menus with images of the resistor (or callout line images), but the differences in platform rendering of pop-up menus made that idea impractical. At best, I now separate the three left `select` objects from the right one by way of hard-coded spaces (` `).

You should notice from this exercise that I look for ways to blend JavaScript object data structures with my own data's structure. For example, the `select` objects serve multiple duties in these scripts. Not only does the text of each option point to an image file of the same name, but the index values of the same options are applied to the calculations. Things don't always work out that nicely, but whenever your scripts bring together user interface elements and data elements, look for algorithmic connections involving names or index integers that you can leverage to create elegant, concise code.

One last thought regarding this example involves the possible usage of the `canvas` object, which you learned about in Chapter 31, "Image, Area, Map, and Canvas Objects." The `canvas` object makes it possible to forego images altogether and render the resistor purely through graphics methods. In other words, you could use the `canvas` object to draw the static parts of the resister via lines and circles, and then draw each colored stripe as a rectangle. Granted, it would be tough getting the nifty shaded 3D effect, but you could eliminate the entire issue of relying on images.

CHAPTER

57

Application: Intelligent "Updated" Flags

IN THIS CHAPTER

Temporary and persistent cookies

World time calculations

CGI-like intelligence

It happens to every active web user all the time: You visit a site periodically and never know for sure what material is new since your last visit. Often, web page authors may flag items with "New" or "Updated" iconic images after they update those items themselves. But if you fail to visit the site over a few modification sessions, the only items you find flagged are those that are new as of the most recent update by the page's author. Several new items from a few weeks back may be of vital interest to you, but you won't have the time to look through the whole site in search of material that is more recent than *your* last visit. Even if the items display their modification dates, do you remember for sure the date and time of your last visit to the page?

As much as we might expect a server-side program and database on a web site to keep track of my last visit, that really is asking a great deal of the web site. Besides, not every web site has the wherewithal to build such a database system — if it can even utilize server applications. Plus, some users won't visit sites if they need to identify themselves or register.

After surveying the way scriptable browsers store cookie information and how time calculations are performed under popular web browsers, I found that a feasible alternative is to build this functionality into HTML documents and let the scripting manage the feature for users. The goal is to save the date and time of the last visit to a page in the visitor's cookie file, and then use that point as a measure against items that have an authorship time stamp in the HTML document.

The Cookie Conundrum

Managing the cookie situation in this application is a bit more complicated than you may think. The reason is that you have to take into account the possible ways visitors may come and go from your site while surfing the

Web. You cannot use just one cookie to store the last time a user visits the site, because you cannot predict when you should update that information with today's date and time. For example, if you have a cookie with the previous visit in it, you eventually need to store today's visit. But you cannot afford to overwrite the previous visit immediately (say, in `onload`) because your scripts need that information to compare against items on the page not only right now, but even after the visitor vectors off from a link and comes back later. That also means you cannot update that last visit cookie solely via an `onunload` event handler, because that, too, would overwrite information that you need when the visitor comes back a minute later.

To solve the problem, I devised a system of two cookies. One is written to the cookie that is given an expiration date of some time out in the future — the *hard cookie,* I call it. The other is a temporary cookie — the *soft cookie* — which stays in cookie memory but is never written to the file. Such temporary cookies are automatically erased as the browser quits.

The hard cookie stores the time stamp when a visitor first loads the page since the last launch of the browser. In other words, the hard cookie contains a time stamp of the current visit. Before the previous entry is overwritten, however, it is copied into the soft cookie. That soft cookie maintains the time stamp of the previous visit and becomes the measure against which author time stamps in the HTML document are compared. To guard against inadvertent overwriting of both cookies, a function triggered by the document's `onload` event handler looks to see if the soft cookie has any data in it. If so, the function knows that the visitor has been to this page in the current session and leaves the current settings alone. Thus, the visitor can come to the site and see what's new, vector off to some other location, come back to see the same new items flagged, and pick up from there.

One potential downside to this system is that if a user never quits the browser (or if the browser quits only by crashing), the cookies will never be updated. If you discover that a great deal of your users keep their computers and browsers running all the time, you can build in a kind of timeout that invalidates the soft cookie if the hard cookie is more than, say, 12 hours old.

Time's Not on Your Side

Thanks to more than 17 years' experience programming applications that involve tracking time, I am overly sensitive to the way computers and programming languages treat time on a global basis. This issue is a thorny one, what with the vagaries of Daylight Savings Time and time zones in some parts of the world that differ from their neighbors by increments other than whole hours.

To accomplish a time tracking scheme for this application, I had to be aware of two times: the local time of the visitor and the local time of the page author. Making times match up in what can be widely disparate time zones, I use one time zone — GMT — as the reference point.

When a visitor arrives at the page, the browser needs to save that moment in time so that it can be the comparison measure for the *next* visit. Fortunately, whenever you create a new date object in JavaScript, it does so internally as the GMT date and time. Even though the way you attempt

to read the date and time created by JavaScript shows you the results in your computer's local time, the display is actually filtered through the time zone offset as directed by your computer's time control panel. In other words, the millisecond value of every date object you create is maintained in memory in its GMT form. That's fine for the visitor's cookie value.

For the page author, however, I was presented with a different problem. Rather than force the author to convert the time stamps throughout the document to GMT, I wanted to let the author enter dates and times in local time. Besides the fact that many people have trouble doing time zone conversions, it is much easier on the scripter's side to look at an existing item in the HTML with a local time stamp and recognize when it was last updated.

The problem, then, is how to let the visitor's browser know what time the author's time stamp is in GMT terms. To solve the issue, the author's time stamp needs to include a reference to the author's time zone relative to GMT. An Internet convention provides a couple of ways to do this: specifying the number of hours and minutes difference from GMT or, where supported by the browser, the abbreviation of the time zone. In JavaScript, you can create a new date object out of one of the specially formatted strings containing the date, time, and time zone. Three examples follow for the Christmas Eve dinner that starts at 6 p.m. in the Eastern Standard Time zone of North America:

```
var myDate = new Date("24 Dec 2010 23:00:00 GMT");
var myDate = new Date("24 Dec 2010 18:00:00 GMT-0500");
var myDate = new Date("24 Dec 2010 18:00:00 EST");
```

The first assumes you know the Greenwich Mean Time for the date and time that you want to specify. But if you don't, you can use the GMT designation and offset value. The syntax indicates that the date and time is in a time zone exactly five hours west of GMT (values to the east would be positive numbers) in `hhmm` format. Browsers also know all of the time zone abbreviations for North America (EST, EDT, CST, CDT, MST, MDT, PST, and PDT, where "S" is for standard time and "D" is for daylight time).

When a user visits a page with this application embedded in it, the visitor's browser converts the author's time stamp to GMT (with the help of the author's zone offset parameter), so that both the author time stamp and last visit time stamp (in the soft cookie) are comparing apples to apples.

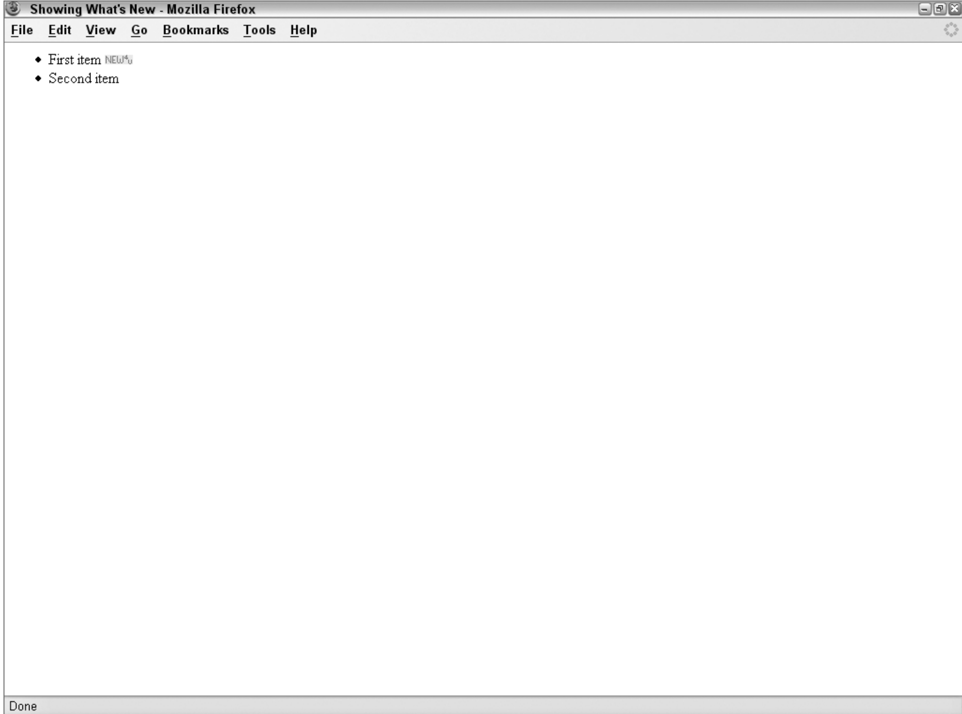
The Application

All of this discussion may make the application sound complicated. That may be true, internally. But the goal, as in most of the samples in this book, is to make the application easy to use on your site, even if you're not sure how everything works inside.

The sample page described in this chapter and on the CD-ROM (`whatsnew.html`) is pretty boring to look at, because the power all lies in the scripting that users don't see (see Figure 57-1). Though this figure may be the most uninspired graphic presentation of the book, the functionality may be the most valuable addition that you make to your web site.

FIGURE 57-1

An item flagged as being new since my last visit to the page.



When you first open the document (do so from a copy on your hard disk so that you can modify the author time stamp in a moment), all you see are the two items on the page without any flags. Although both entries have author time stamps that pre-date the time you're viewing the page, a soft cookie does not yet exist against which to compare those times. But the act of making the first visit to the page has created a hard cookie of the date and time.

Note

Testing the sample page requires that cookies are enabled in your browser. Also, be aware that if you are testing with Google Chrome, your code will not work unless the files are coming from an HTTP server. Chrome intentionally disables cookies on `file:///` documents. See Chapter 29, "The Document and Body Objects," for a discussion of cookies. ■

Quit the browser to get that hard cookie officially written to the cookie file. Then open the `whatsnew.html` file in your script editor. Scroll to the bottom of the document, where you see the `<body>` tag and the interlaced scripts that time stamp anything that you want on the page. This application is designed to display a special `.gif` image that says "NEW 4U" whenever an item has been updated since your last visit.

Each interlaced script looks like this:

```
<script type="text/javascript">
   document.write(newAsOf("12 Oct 2010 13:36:00 PDT"))
</script>
```

The `document.write()` method writes to the page whatever HTML comes back from the `newAsOf()` function. The parameter to the `newAsOf()` function is what holds the author time stamp and zone offset information. The time stamp value must be in the string format, as shown in the preceding example, with the date and time following the exact order "`dd mmm yyyy hh:mm:ss`". Month abbreviations are in English (Jan, Feb, Mar, Apr, May, Jun, Jul, Aug, Sep, Oct, Nov, Dec).

As you see in the code that follows, the `newAsOf()` function returns an `<img>` tag with the "NEW 4U" image if the author time stamp (after appropriate conversion) is later than the soft cookie value. This image can be placed anywhere in a document. For example, at my web site, I sometimes place the image before a contents listing rather than at the end. This means, too, that if part of your page is written by `document.write()` methods, you can just insert the `newAsOf()` function call as a parameter to your own `document.write()` calls.

If you want to see the author time stamping work, edit one of the time stamps in the `whatsnew.html` file to reflect the current time. Save the document and relaunch the browser to view the page. The item whose author time stamp you modified should now show the bright "NEW 4U" image.

The Code

The HTML file for the sample page is simple enough. I have you create a simple bulleted list of two entries, imaginatively called "First item" and "Second item." Interlaced into the HTML are scripts that are ready to insert the "NEW 4U" image if the author time stamp is new enough:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Showing What's New</title>
      <script type="text/javascript" src="whatsnew.js"></script>
   </head>
   <body>
      <ul>
         <li>First item
            <script type="text/javascript">
               document.write(newAsOf("19 Jan 2010 19:55:00 PST"))
            </script>
         </li>
         <li>Second item
            <script type="text/javascript">
               document.write(newAsOf("15 Jan 2010 13:36:00 PST"))
            </script>
```

```
         </li>
      </ul>
   </body>
</html>
```

The JavaScript file for the sample page starts by initializing three global variables that are used in the statements that follow. One variable is a Boolean value indicating whether the visitor has been to the page before. Another variable, `lastVisit`, holds the value of the soft cookie whenever the visitor is at this page:

```
// globals
var repeatCustomer = false;
var lastVisit = 0; // to hold date & time of previous access in GMT milliseconds
```

For reading and writing cookie data, I'm including an expiration date, because I want this cookie to hang around in the cookie file for a while — at least until the next visit, whenever that may be:

```
// shared cookie functions
var mycookie = document.cookie;
// read cookie data
function getCookieData(name)
{
   var label = name + "=";
   var labelLen = label.length;
   var cLen = mycookie.length;
   var i = 0;
   while (i < cLen)
   {
      var j = i + labelLen;
         if (mycookie.substring(i,j) == label)
         {
            var cEnd = mycookie.indexOf(";",j);
               if (cEnd == -1)
               {
                  cEnd = mycookie.length;
               }
            return unescape(mycookie.substring(j,cEnd));
         }
      i++;
   }
   return "";
}

// write cookie data
function setCookieData(name,dateData,expires)
{
   mycookie = document.cookie = name + "=" + dateData
                              + "; expires=" + expires;
}
```

Notice that the `setCookieData()` function still maintains a level of reusability by requiring a name for the cookie to be passed as a parameter, along with the data and expiration date. I could have hard-wired the name into this function, but that goes against my philosophy of designing for reusability.

Setting the stage

Functions in the next part of the script get your cookies all in a row. The first function (`saveCurrentVisit()`) deals with the visitor's local time, converting it to a form that will be useful on the next visit. Although one of the local variables is called `nowGMT`, all the variable does is take the new date object and convert it to the GMT milliseconds value (minus any `dateAdjustment` value) by invoking the `getTime()` method of the date object. I use this name in the variable to help me remember what the value represents:

```
// write date of current visit (in GMT time) to cookie
function saveCurrentVisit()
{
   var visitDate = new Date();
   var nowGMT = visitDate.getTime();
   var expires = (nowGMT + (180 * 24 * 60 * 60 *1000));
   expires = new Date(expires);
   expires = expires.toGMTString();
   setCookieData("lastVisit", nowGMT, expires);
}
```

From the current time, I create an expiration date for the cookie. The example shows a date roughly six months (180 days, to be exact) from the current time. I leave the precise expiration date up to your conscience and how long you want the value to linger in a user's cookie file.

The final act of the `saveCurrentVisit()` function is to pass the relevant values to the function that actually writes the cookie data. I assign the name `lastVisit` to the cookie. If you want to manage this information for several different pages, assign a different cookie name for each page. This setup can be important in case a user gets to only part of your site during a visit. On the next visit, the code can point to page-specific new items.

The "temporary" cookie also needs to set an expiration date for itself. Normally, temporary cookies disappear when the user quits the browser. But these days, it's not uncommon for users to keep their computers and applications running for days (with fewer crashes than not too long ago). To force the browser to visit the site after awhile, as if coming fresh (to look for new flags), the `nextPrevVisit` cookie is set to expire one hour after it is set:

```
// set cookie with next previous visit with one-hour expiration
function saveNextPrevVisit(lastStoredVisit)
{
   var visitDate = new Date();
   var nowGMT = visitDate.getTime();
   var expires = (nowGMT + (60*1000));
   expires = new Date(expires);
```

```
      expires = expires.toGMTString();
      setCookieData("nextPrevVisit", lastStoredVisit, expires);
   }
```

The bulk of what happens in this application takes place in an initialization function. All the cookie swapping occurs there, as well as the setting of the `repeatCustomer` global variable value:

```
// set up global variables and establish whether user is repeat customer
function initialize()
{
   var lastStoredVisit = getCookieData("lastVisit");
   var nextPrevStoredVisit = getCookieData("nextPrevVisit");

   if (!lastStoredVisit)
   { // never been here before
      saveCurrentVisit();
      repeatCustomer = false;
   }
   else
   { // been here before...
      if (!nextPrevStoredVisit)
      {  // but first time this session
         saveNextPrevVisit(lastStoredVisit); // expires in one hour
         lastVisit = parseFloat(lastStoredVisit);
         saveCurrentVisit();
         repeatCustomer = true;
      }
      else
      { // back again during this session (perhaps reload or Back)
         lastVisit = parseFloat(nextPrevStoredVisit);
         repeatCustomer = true;
      }
   }
}

initialize();
```

The first two statements retrieve both hard (`lastVisit`) and soft (`nextPrevVisit`) cookie values. After calling the function that sets any necessary date adjustment, the script starts examining the values of the cookies to find out where the visitor stands upon coming to the page.

The first test is whether the person has ever been to the page before. You do this by checking whether a hard cookie value (which would have been set in a previous visit) exists. If no such cookie value exists, the current visit time is written to the hard cookie and `repeatCustomer` is set to `false`. These actions prepare the visitor's cookie value for the *next* visit.

Should a user already be a repeat customer, you have to evaluate whether this visit is the user's first visit since launching the browser. You do that by checking for a value in the soft cookie. If that value doesn't exist, it means the user is here for the first time "today." You then grab the hard cookie and drop it into the soft cookie before writing today's visit to the hard cookie.

For repeat customers who have been here earlier in this session, you update the `lastVisit` global variable from the cookie value. The variable value will have been destroyed when the user left the page just a little while ago, whereas the soft cookie remains intact, enabling you to update the variable value now.

Outside of the function definition, the script automatically executes the `initialize()` function by that single statement. This function runs every time the page loads.

The date comparison

Every interlaced script in the body of the document calls the `newAsOf()` function to find out if the author's time stamp is after the user's last visit to the page. This function is where the time zone differences between visitor and author must be neutralized so that a valid comparison can be made:

```
function newAsOf(authorDate)
{
   authorDate = new Date(authorDate);
   var itemUpdated = authorDate.getTime();
   return ((itemUpdated > lastVisit) && repeatCustomer)
           ? "<img src='updated.gif' height=10 width=30 \/>" : "";
}
```

As you saw earlier, calls to this function require one parameter: a specially formatted date string that includes time zone information. The first task in the function is to re-cast the author's date string to a date object. You reuse the variable name (`authorDate`) because its meaning is quite clear. The date object created here is stored internally in the browser in GMT time, relative to the time zone data supplied in the parameter. To assist in the comparison against the `lastVisit` time (stored in milliseconds), the `getTime()` method converts `authorDate` to GMT milliseconds.

The last statement of the function is a conditional expression that returns the `<img>` tag definition for the "NEW 4U" image only if the author's time stamp is later than the soft cookie value, and the visitor has been here before. Otherwise, the function returns an empty string. Any `document.write()` method that calls this function and executes via this branch writes an empty string — nothing — to the page.

Further Thoughts

You can, perhaps, go overboard with the way that you use this technique on a web site. Like most features in JavaScript, I recommend using it in moderation and confining the flags to high-traffic areas that repeat visitors frequent. For example, it makes a great callout for new entries in a blog, since blog updates are often time sensitive. One hazard is that you can exceed the number of cookies a browser allows if you have too many page-specific listings. Although some modern browsers (Safari and Chrome) don't have a limit, others do. The fewest number

of cookies allowed on some browsers (IE6 and legacy) is 20. Other browsers allow a varying number of cookies.

You can share the same cookie among documents in related frames. Copy all the functions from the `head` section of the script in this chapter into a `head` section of a framesetting document. Then, modify the call to the `newAsOf()` function by pointing it to the parent:

```
document.write(parent.newAsOf("18 Nov 2006 17:40:00 PDT"));
```

That way, one cookie can take care of all documents that you display in that frameset.

CHAPTER

58

Application: Decision Helper

IN THIS CHAPTER

Multiple frames

Multiple-document applications

Multiple windows

Persistent storage (cookies)

Scripted image maps

Scripted charts

The list of key concepts for this chapter's application looks like the grand finale to a fireworks show. As JavaScript implementations go, this application is, in some respects, over the top, yet not out of the question for presenting a practical interactive application on a web site without any server programming.

The Application

I wanted to implement a classic application often called a *decision support system*. My experience with the math involved here goes back to the first days of Microsoft Excel. Rather than design a program that had limited appeal (covering only one possible decision tree), I set out to make a completely user-customizable decision helper. All the user has to do is enter values into fields on a series of screens; the program performs the calculations to let the user know how the various choices rank against each other.

Although I won't be delving too deeply into the math inside this application, you will find it helpful to understand how a user approaches this program and what the results look like. The basic scenario is a user who is trying to evaluate how well a selection of choices measure up to his or her expectations of performance. User input includes:

- The name of the decision
- The names of up to five alternatives (people, products, ideas, and so on)
- The factors or features of concern to the user
- The importance of each of the factors to the user
- A user ranking of the performance of every alternative in each factor

What makes this kind of application useful is that it forces the user to rate and weigh a number of often-conflicting factors. By assigning hard numbers to these elements, the computer calculates a decision based on the rates and weights of the various factors.

Results come in the form of floating-point numbers between 0 and 100. As an extra touch, I've added a graphical charting component to the results display.

The Design

With so much user input necessary for this application, conveying the illusion of simplicity is important. Rather than lump all text objects onto a single scrolling page, I decided to break them into five pages, each consisting of its own HTML document. As an added benefit, I could embed information from early screens into the HTML of later screens, which would help to establish a more intuitive user interface. This "good idea" presented one opportunity and one rather large challenge.

The opportunity was to turn the interface for this application into something resembling a multimedia application using multiple frames. The largest frame would contain the forms the user fills out, as well as the results page. Another frame would contain a navigation panel with arrows for moving forward and backward through the sequence of screens, plus buttons for going back to a home page and getting information about the program. I also thought a good idea would be to add a frame that provides instructions or suggestions for the users at each step. And so, the three-frame window was born, as shown in the first entry screen in Figure 58-1.

Using a navigation bar also enables me to demonstrate how to script a client-side image map — not an obvious task with JavaScript. Also notice in the figure how there is a helpful text message appearing just above the navigation bar. This "tooltip"-style message appears thanks to the use of several handy `onmouseover` and `onmouseout` event handlers, which you learn about a bit later in the chapter.

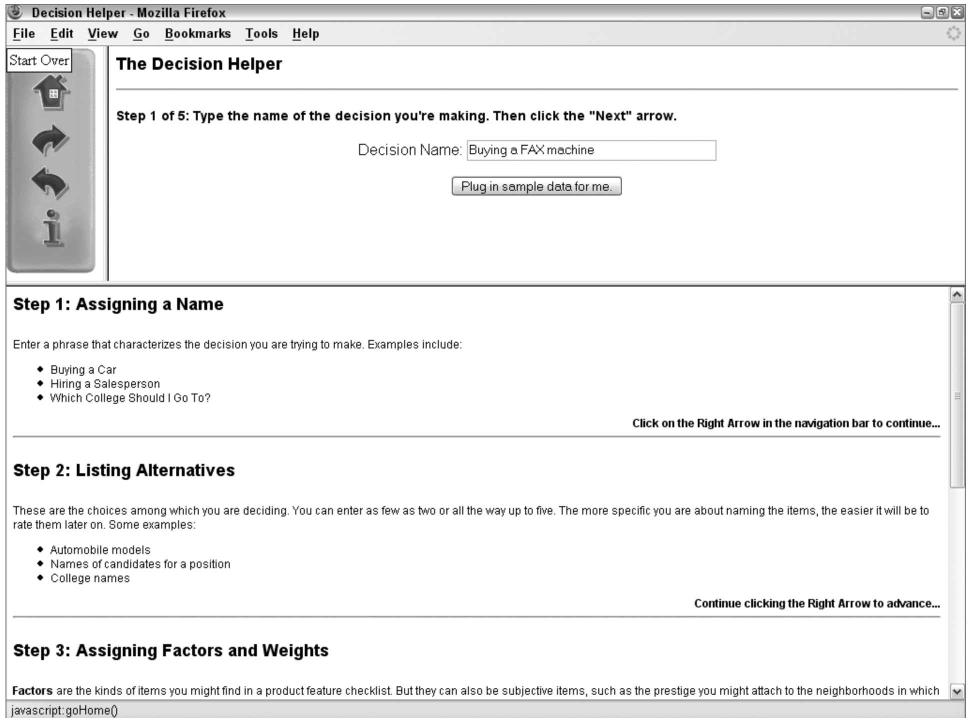
On the challenge side of this design, finding a way to maintain data globally, as the user navigates from screen to screen, was necessary. Every time one of the entry pages unloads, none of its text fields is available to a script. My first attack at this problem was to store the data as global variable data (mostly arrays) in the parent document that creates the frames. Because JavaScript enables you to reference any parent document's object, function, or variable (by preceding the reference with `parent`), I thought this task would be a snap. But a hazard exists in that a reload of the frameset could erase the current state of those variables.

My next hope was to use the `document.cookie` as the storage bin for the data. A major problem I faced was that this program needs to store a total of 41 individual data points, yet no more than 20 uniquely-named cookies can be allotted to a given domain. (While some modern browsers don't have a limit, other modern browsers and legacy browsers allow between 20 and 50 cookies.) But the cookie proved to be the primary solution for this application. (See the "Further Thoughts" section at the end of the chapter about a non-cookie version on the

CD-ROM.) For some of the data points (which are related in an array-like manner), I fashioned my own data structures so that one named cookie could contain up to five related data points. That reduced my cookie demands to 17.

FIGURE 58-1

The Decision Helper window consists of three frames.



Note

Testing the sample application obviously requires that cookies be enabled in your browser. Be aware that if you are testing with Google Chrome, your code will not work unless the files are coming from an HTTP server. Chrome intentionally disables cookies on `file:///` documents. See Chapter 29, "The Document and Body Objects," for a discussion of cookies. ■

The Files

Before I get into the code, let me explain the file structure of this application. Table 58-1 gives a rundown of the files used in the Decision Helper.

TABLE 58-1

Files Comprising the Decision Helper Application

File	Description
index.html	Framesetting parent document
dhNav.html	Navigation bar document for the upper-left frame that contains some scripting
dhNav.gif	Image displayed in dhNav.html
dh1.html	First Decision Helper entry page
dh2.html	Second Decision Helper entry page
dh3.html	Third Decision Helper entry page
dh4.html	Fourth Decision Helper entry page
dh5.html	Results page
chart.gif	Tiny image file used to create bar charts in dh5.html
dhHelp.html	Sample data and instructions document for the lower frame
dhAbout.html	Document that loads into a second window

A great deal of interdependence exists among these files. As you see later, assigning the names to some of these files was strategic for the implementation of the image map.

The Code

With so many JavaScript-enhanced HTML documents in this application, you can expect a great deal of code. To best grasp what's going on here, first try to understand the structure and interplay of the documents, especially the way the entry pages rely on functions defined in the parent document. My goal in describing this structure is not to teach you how to implement this application, but rather how to apply the lessons I learned while building this application to the more complex ideas that may be aching to get out of your head and into JavaScript.

index.html

Taking a top-down journey through the JavaScript and HTML of the Decision Helper, start at the document that loads the frames. Unlike a typical framesetting document, however, this one contains JavaScript code in its head section — code that many other documents rely on:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Decision Helper</title>
```

An important consideration to remember is that in a multiple-frame environment, the title of the parent window's document is the name that appears in the window's title bar, no matter how many other documents are open inside its subframes.

The first items of the script control a global variable, `currTitle`, which is set by a number of the subsidiary files as the user navigates through the application. This variable ultimately helps the navigation bar buttons do their jobs correctly. Because this application relies on the `document.cookie` so heavily, the cookie management functions (slightly modified versions of Bill Dortch's cookie functions — see Chapter 29) are located in the parent document so they load only once. I simplified the cookie-writing function because this application uses default settings for pathname and expiration. With no expiration date, the cookies don't survive the current browser session, which is perfect for this application:

```
<script type="text/javascript">
   // global variable settings of current dh document number
   var currTitle = "";
   function setTitleVar(titleVal)
   {
      currTitle = "" + titleVal;
   }
   function getCookieVal(offset)
   {
      var endstr = document.cookie.indexOf (";", offset);
         if (("" + endstr) == "" || endstr == -1)
         {
            endstr = document.cookie.length;
         }
      return unescape(document.cookie.substring(offset, endstr));
   }

   function getCookie(name)
   {
      var arg = name + "=";
      var alen = arg.length;
      var clen = document.cookie.length;
      var i = 0;
      while (i < clen)
      {
         var j = i + alen;
            if (document.cookie.substring(i, j) == arg)
            {
               return getCookieVal (j);
            }
         i = document.cookie.indexOf(" ", i) + 1;
            if (i == 0)
            {
               break;
            }
      }
      return null;
   }
```

```
function setCookie(name, value)
{
   document.cookie = name + "=" + escape (value) + ";";
}
```

When this application loads (or a user elects to start a new decision), it's important to grab the cookies you need and initialize them to the basic values that the entry screens will use to fill fields when the user first visits them. All statements inside the `initializeCookies()` function call the `setCookie()` function, defined in the preceding listing. The parameters are the name of each cookie and the initial value — mostly empty strings. Before going on, study the cookie labeling structure carefully. I refer to it often in discussions of other documents in this application:

```
function initializeCookies()
{
   setCookie("decName","");
   setCookie("alt0","");
   setCookie("alt1","");
   setCookie("alt2","");
   setCookie("alt3","");
   setCookie("alt4","");
   setCookie("factor0","");
   setCookie("factor1","");
   setCookie("factor2","");
   setCookie("factor3","");
   setCookie("factor4","");
   setCookie("import","0");
   setCookie("perf0","");
   setCookie("perf1","");
   setCookie("perf2","");
   setCookie("perf3","");
   setCookie("perf4","");
}
```

The following functions should look familiar to you. They were borrowed either wholesale or with minor modification from the data-entry validation section of the Social Security number database lookup in Chapter 53, "Application: A Lookup Table." I'm glad I wrote these as generic functions, making them easy to incorporate into this script. Because many of the entry fields on two screens must be integers between 1 and 100, I brought the data validation functions to the parent document rather than duplicating them in each of the subdocuments:

```
// JavaScript sees numbers with leading zeros
// as octal values, so strip zeros
function stripZeros(inputStr)
{
   var result = inputStr;
   while (result.substring(0,1) == "0")
   {
      result = result.substring(1,result.length);
   }
   return result;
}
```

```
// general purpose function to see if a suspected numeric
// input is a positive integer
function isNumber(inputStr)
{
   for (var i = 0; i < inputStr.length; i++)
   {
      var oneChar = inputStr.substring(i, i + 1);
         if (oneChar < "0" || oneChar > "9")
         {
            return false;
         }
   }
   return true;
}

// function to determine if value is in acceptable
// range for this application
function inRange(inputStr)
{
   num = parseInt(inputStr);
   if (num < 1 || num > 100)
   {
      return false;
   }
   return true;
}
```

To control the individual data entry validation functions in the master controller, I again was able to borrow heavily from the application in Chapter 53:

```
// Master value validator routine
function isValid(inputStr)
{
   if (inputStr != "" )
   {
      inputStr = stripZeros(inputStr);
      if (!isNumber(inputStr))
      {
         alert("Please make sure entries are numbers only.");
         return false;
      }
      else
      {
         if (!inRange(inputStr))
         {
            var msg="Entries must be numbers between 1 and 100.";
            msg += " Try another value.";
            alert(msg);
            return false;
         }
      }
   }
   return true;
}
```

Each of the documents containing entry forms retrieves and stores information in the cookie. Because all cookie functions are located in the parent document, it simplifies coding in the subordinate documents to have functions in the parent document acting as interfaces to the primary cookie functions. For each category of data stored as cookies, the parent document has a pair of functions for getting and setting data. The calling statements pass only the data to be stored when saving information; the interface functions handle the rest, such as storing or retrieving the cookie with the correct name.

In the following pair of functions, the decision name (from the first entry document) is passed back and forth between the cookie and the calling statements. Not only must the script store the data, but if the user returns to that screen later for any reason, the entry field must retrieve the previously entered data:

```
function setDecisionName(str)
{
   setCookie("decName",str);
}
function getDecisionName()
{
   return getCookie("decName");
}
```

The balance of the storage and retrieval pairs does the same thing for their specific cookies. Some cookies are named according to index values (`factor1`, `factor2`, and so on), so their cookie-accessing functions require parameters for determining which of the cookies to access, based on the request from the calling statement. Many of the cookie retrieval functions are called to fill in the data in tables of later screens during the user's trip down the decision path:

```
function setAlternative(i,str)
{
   setCookie("alt" + i,str);
}
function getAlternative(i)
{
   return getCookie("alt" + i);
}
function setFactor(i,str)
{
   setCookie("factor" + i,str);
}
function getFactor(i)
{
   return getCookie("factor" + i);
}
function setImportance(str)
{
   setCookie("import",str);
}
function getImportance(i)
{
```

```
      return getCookie("import");
   }
   function setPerformance(i,str)
   {
      setCookie("perf" + i,str);
   }
   function getPerformance(i)
   {
      return getCookie("perf" + i);
   }
```

One sequence of code that runs when the parent document loads is the one that looks to see if a cookie structure is set up. If no such structure is set up (the retrieval of a designated cookie returns a `null` value), the script initializes all cookies via the function described earlier:

```
   if (getDecisionName() == null)
   {
      initializeCookies();
   }
```

The last part of the script is a function that's called if the user wants to plug in a canned example by clicking a button in the file (`dh1.html`) that is the first data entry screen in the upper-right frame:

```
   // plug in sample code if user wants
   function doSample(form)
   {
      setCookie("decName","Buying a FAX machine");
      setCookie("alt0","Fax-O-Matic 1000");
      setCookie("alt1","InkyFax 300");
      setCookie("alt2","LazyFax LX");
      setCookie("alt3","Loose Cannon M-200");
      setCookie("alt4","");
      setCookie("factor0","Cost");
      setCookie("factor1","Size");
      setCookie("factor2","Paper Handling");
      setCookie("factor3","Warranty");
      setCookie("factor4","");
      setCookie("import","80.40.60.70..");
      setCookie("perf0","60.80.40.20..");
      setCookie("perf1","80.60.50.30..");
      setCookie("perf2","80.55.75.70..");
      setCookie("perf3","70.70.80.70..");
      setCookie("perf4","");
      parent.entryForms.document.forms[0].decName.value
                               = "Buying a FAX machine";
   }
 </script>
</head>
```

The balance of the parent document source code defines the frameset for the browser window. It establishes some hard-wired pixel sizes for the navigation panel. This ensures that the entire

`.gif` file is visible whenever the frameset loads, without a ton of unwanted white space if the browser window is large:

```
      <frameset rows="250,*">
         <frameset cols="104,*">
            <frame name="navBar" src="dhNav.html" scrolling="no" marginheight="2"
                   marginwidth="1" />
            <frame name="entryForms" src="dh1.html" />
         </frameset>
         <frameset rows="100%">
            <frame name="instructions" src="dhHelp.html" />
         </frameset>
         <noframes>
            <body>
               <h1>It's really cool...</h1>
               <h2>...but only if your browser handles frames</h2>
               <hr />
               <a href="/index.html">Back</a>
            </body>
         </noframes>
      </frameset>
   </html>
```

It's worth pointing out that some older browsers do not respond to changes in framesetting size attributes through a simple reload of the page. Modern browsers appear to have resolved this problem; however if you seem to be making changes, but reloading the frameset doesn't make the changes appear, try reopening the browser window or — as a last resort — restarting the browser.

dhNav.html

Because of its crucial role in controlling the activity around this program, look into the navigation bar's document next. To accomplish the look and feel of a multimedia program, this document was designed as a client-side image map that has four regions scripted, corresponding to the locations of the four buttons (see Figure 58-1). The trick to the tooltip mechanism is the showing and hiding of a `div` element that contains the text to be displayed. This element has its own style class, `tipStyle`, which is responsible for establishing the white rectangular text box with a thin black border.

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Navigation Bar</title>
      <style type="text/css">
         body
         {
            background-color:white;
         }
         .tipStyle
         {
            position:absolute;
```

```
        background-color:#FFFFFF;
        border:solid 1px #000000;
        padding:2px;
        visibility: hidden;
    }
</style>
```

One function is connected to each button. The first function is linked to the graphical Home button. For the listing here, I just present an alert dialog box replicating the action of navigating back to a real web site's home page:

```
<script type="text/javascript">
   function goHome()
   {
      alert("Navigate back to home page on a real site.");
   }
```

Each of the arrow navigation buttons brings the user to the next or previous entry screen in the sequence. To facilitate this without building tables of document titles and names, you call upon the `currTitle` global variable in the parent document. This value contains an integer in the range between 1 and 5, corresponding to the main content documents `dh1.html`, `dh2.html`, and so on. As long as the offset number is no higher than the next-to-last document in the sequence, the `goNext()` function increments the index value by one and concatenates a new location for the frame. At the same time, the script advances the help document (in the bottom frame) to the anchor corresponding to the chosen entry screen by setting the `location.hash` property of that frame. Similar action navigates to the previous screen of the sequence through the `goPrev()` function. This time, the index value is decremented by one, and an alert warns the user if the current page is already the first in the sequence:

```
   function goNext()
   {
      var currOffset = parseInt(parent.currTitle);
         if (currOffset <= 4)
         {
            ++currOffset;
            parent.entryForms.location.href = "dh"
                                            + currOffset
                                            + ".html";
            parent.instructions.location.hash = "help"
                                              + currOffset;
         }
         else
         {
            alert("This is the last form.");
         }
   }
   function goPrev()
   {
      var currOffset = parseInt(parent.currTitle);
         if (currOffset > 1)
```

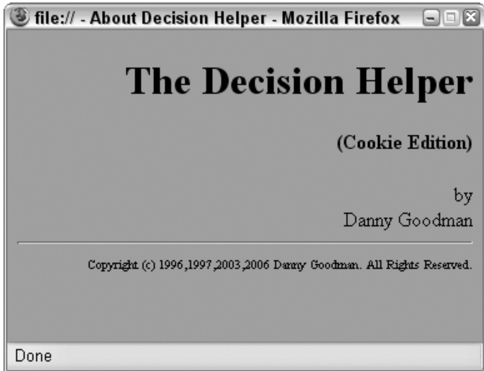
```
            {
               --currOffset;
               parent.entryForms.location.href = "dh"
                                                + currOffset
                                                + ".html";
               parent.instructions.location.hash = "help"
                                                + currOffset;
            }
            else
            {
               alert("This is the first form.");
            }
      }
```

Clicking the Info button displays a smaller window containing typical About-box data for the program (see Figure 58-2):

```
function goInfo()
{
   var newWindow =
       window.open("dhAbout.html","","height=250,width=380");
}
```

FIGURE 58-2

The About Decision Helper screen appears in a separate window.



The last pair of functions, `showTip()` and `hideTip()`, are used to show and hide, respectively, the tooltip text that appears when the mouse hovers over one of the navigation buttons. The `showTip()` function accepts the text to be shown in the tooltip as its only argument:

```
function showTip(tipMsg)
{
   var obj = document.getElementById("tip");
   obj.style.visibility = "visible";
```

```
      while(obj.firstChild)
         obj.removeChild(obj.firstChild);
      obj.appendChild(document.createTextNode(tipMsg));
   }
   function hideTip()
   {
      var obj = document.getElementById("tip");
      obj.style.visibility = "hidden";
   }
   </script>
```

The body of the navigation document contains the part that enables you to script a client-side image map. Mouse click events weren't available to area elements in legacy browsers and are not available in all modern browsers, so to inject a bit of backward compatibility, mouse action is converted to script action by assigning a javascript: pseudo-URL to the HREF attribute for each area element. Instead of pointing to an entirely new URL (as area elements usually work), the attributes point to the JavaScript functions defined in the head portion of this document. After a user clicks the rectangle specified by an <area> tag, the browser invokes the function instead.

```
<body>
      <div id="tip" class="tipStyle"></div>
      <map id="navigation" name="navigation">
         <area shape="rect" coords="23,22,70,67"
               href="javascript:goHome()"
               onmouseover="showTip('Start Over')"
               onmouseout="hideTip()"/>
         <area shape="rect" coords="25,80,66,116"
               href="javascript:goNext()"
               onmouseover="showTip('Next Step')"
               onmouseout="hideTip()"/>
         <area shape="rect" coords="24,125,67,161"
               href="javascript:goPrev()"
               onmouseover="showTip('Previous Step')"
               onmouseout="hideTip()"/>
         <area shape="rect" coords="35,171,61,211"
               href="javascript:goInfo()"
               onmouseover="showTip('Get Info')"
               onmouseout="hideTip()"/>
      </map>
      <img alt="image" src="dhNav.gif" height="240" width="96"
          border="0" usemap="#navigation" />
   </body>
</html>
```

Revealed here is the other component of the tooltip feature you learned about earlier (revisit the upper-left corner of Figure 58-1). Each area element within the image map has two mouse event handlers that take care of showing and hiding the tooltip text, based upon the mouse hovering above the navigation area.

Note

The property assignment event handling technique used throughout this example is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` **(NN6+/Moz/W3C) or** `attachEvent()` **(IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32.** ■

dh1.html

Of the five documents that display in the main frame, `dh1.html` is the simplest (refer to Figure 58-1). It contains a single entry field in which the user is invited to enter the name for the decision.

The function `loadDecisionName` summons one of the cookie interface functions in the parent window. A test is located here in case there is a problem with initializing the cookies. Rather than show `null` in the field, the conditional expression substitutes an empty string:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>DH1</title>
      <style type="text/css">
         body
         {
            font-family:Arial, Helvetica, serif;
         }
         h2
         {
            font-size:18px;
         }
         h4
         {
            font-size:14px;
         }
         .form
         {
            text-align:center;
         }
      </style>
      <script type="text/javascript" src="../../jsb-global.js"></script>
      <script type="text/javascript">
         // initialize when the page has loaded
         addEvent(window, "load", initialize);

         function initialize()
         {
            parent.setTitleVar(1);
            loadDecisionName();
            document.forms[0].decName.focus();
         }
         function loadDecisionName()
```

```
      {
         var result = parent.getDecisionName();
         result = (result == null) ? "" : result;
         document.forms[0].decName.value = result;
      }
   </script>
</head>
```

After the document loads, it performs three tasks (in the `onload` event handler bound to the `window` object in the first part of the script). The first task is to set the global variable in the parent to let it know which number of the five main documents is currently loaded. Next, the script must fill the field with the decision name stored in the cookie. This task is important because users will want to come back to this screen to review what they entered previously. A third statement sets the focus of the entire browser window to the one text object. This task is especially important in a multi-frame environment, such as this design. After a user clicks on the navigation panel, that frame has the focus. To begin typing into the field, the user has to tab (repeatedly) or click the text box to give it focus for typing. By setting the focus in the script when the document loads, you save the user time and aggravation:

```
<body>
   <h2>The Decision Helper</h2>
   <hr />
   <h4>Step 1 of 5: Type the name of the decision you're making. Then
      click the "Next" arrow.
   </h4>
```

In the text field itself, an `onchange` event handler saves the value of the field in the parent's cookie for the decision name. No special Save button or other instruction is necessary here because any navigation that the user does via the navigation bar automatically causes the text field to lose focus and triggers the `onchange` event handler:

```
<div class="form">
   <form>
      Decision Name:
      <input type="text" name="decName" size="40"
             onchange="parent.setDecisionName(this.value)" />
```

The balance of this file has a (commented out) `textarea` object that you can use for debugging cookie data. This is followed by a button that, when clicked, calls a function in the parent (`index.html`). This allows the user to choose to plug in sample data:

```
<p>
   <script type="text/javascript">
      // un-comment next lines to show textarea that
      // monitors cookie values
      // document.write("<textarea rows='6' cols='50'"
      //                + " name='showcookie' wrap='HARD'>"
      //                + parent.document.cookie
      //                + "<\/textarea>");
   </script>
</p>
```

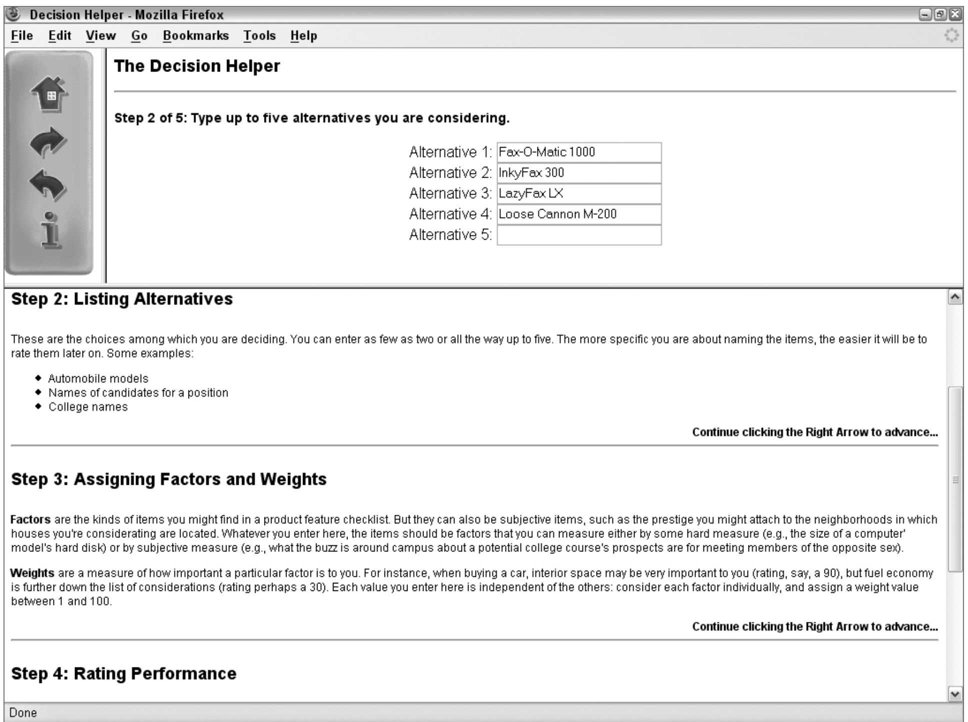
```
            <p><input type="button" value="Plug in sample data for me."
                      onclick="parent.doSample()" />
            </p>
         </form>
      </div>
   </body>
</html>
```

dh2.html

For the second data entry screen (shown in Figure 58-3), five fields invite the user to enter descriptions of the alternatives under consideration. As with the decision name screen, the scripting for this page must both retrieve and save data displayed or entered in the fields.

FIGURE 58-3

The second data entry screen.



In one function, the script retrieves the alternative cookies (five total) and stuffs them into their respective text fields (as long as their values are not `null`). This function uses a `for` loop to cycle through all five items — a common process throughout this application. Whenever a cookie is one of a set of five, the parent function has been written (in the following example) to

store or extract a single cookie, based on the index value. Text objects holding like data (defined in the following listing) are all assigned the same name, so that JavaScript lets you treat them as array objects — greatly simplifying the placement of values into those fields inside a `for` loop:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>DH2</title>
      <style type="text/css">
         body
         {
            font-family:Arial, Helvetica, serif;
         }
         h2
         {
            font-size:18px;
         }
         h4
         {
            font-size:14px;
         }
         .form
         {
            text-align:center;
         }
      </style>
      <script type="text/javascript" src="../../jsb-global.js"></script>
      <script type="text/javascript">
         // initialize when the page has loaded
         addEvent(window, "load", initialize);

         function initialize()
         {
            parent.setTitleVar(2);
            loadAlternatives();
            document.forms[0].alternative[0].focus();
         }
         function loadAlternatives()
         {
            for (var i = 0; i < 5; i++)
            {
               var result = parent.getAlternative(i);
               result = (result == null) ? "" : result;
               document.forms[0].alternative[i].value = result;
            }
         }
      </script>
   </head>
```

After the document loads, the `onload` event (bound to the `window` object at the beginning of the script) does three things: the document number is sent to the parent's global variable, its

fields are filled by the function defined in the `head`, and the first field is handed the focus to assist the user in entering data the first time.

Any change that a user makes to a field is stored in the corresponding cookie. Each `onchange` event handler passes its indexed value (relative to all like-named fields), plus the value entered by the user, as parameters to the parent's cookie-saving function:

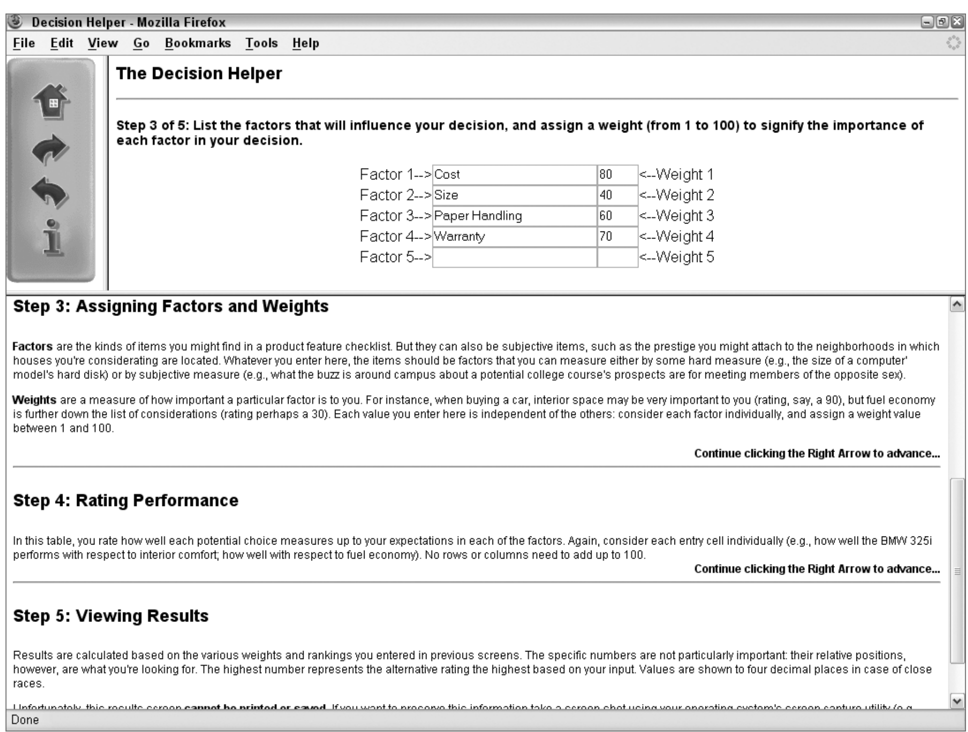
```
   <body>
      <h2>The Decision Helper</h2>
      <hr />
      <h4>Step 2 of 5: Type up to five alternatives you are considering.</h4>
      <div class="form">
         <form>
            Alternative 1:
            <input type="text" name="alternative" size="25"
                   onchange="parent.setAlternative(0,this.value)" />
            <br />
            Alternative 2:
            <input type="text" name="alternative" size="25"
                   onchange="parent.setAlternative(1,this.value)" />
            <br />
            Alternative 3:
            <input type="text" name="alternative" size="25"
                   onchange="parent.setAlternative(2,this.value)" />
            <br />
            Alternative 4:
            <input type="text" name="alternative" size="25"
                   onchange="parent.setAlternative(3,this.value)" />
            <br />
            Alternative 5:
            <input type="text" name="alternative" size="25"
                   onchange="parent.setAlternative(4,this.value)" />
            <br />
         </form>
      </div>
   </body>
</html>
```

dh3.html

With the third screen, the complexity increases a bit. Two factors contribute to this increase in difficulty. One is that the limitation on the number of cookies available for a single domain forces you to combine into one cookie the data that might normally be distributed among five cookies. Second, with the number of text objects on the page (see Figure 58-4), it becomes more efficient (from the standpoint of tedious HTML writing) to let JavaScript deploy the fields. The fact that two sets of five related fields exist facilitates using `for` loops to lay out and populate them.

FIGURE 58-4

Screen for entering decision factors and their weights.



The `onload` event is bound to the `window` object. The only tasks that the `onload` event handler needs to do are to update the parent global variable about the document number, and to set the focus on the first entry field of the form. The `getdh3Factor()` function is reminiscent of `head` functions in previous entry screens. This function retrieves a single factor cookie from the set of five cookies:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>DH3</title>
      <style type="text/css">
         body
         {
            font-family:Arial, Helvetica, serif;
         }
```

```
      h2
      {
         font-size:18px;
      }
      h4
      {
         font-size:14px;
      }
   </style>
   <script type="text/javascript" src="../../jsb-global.js"></script>
   <script type="text/javascript">
      // initialize when the page has loaded
      addEvent(window, "load", initialize);

      function initialize()
      {
         parent.setTitleVar(3);
         document.forms[0].factor[0].focus();
      }

      function getdh3Factor(i)
      {
         var result = parent.getFactor(i);
            if (result == null)
            {
            return "";
            }
         return result;
      }
```

Values for the five possible weight entries are stored together in a single cookie. To make this work, I had to determine a data structure for the five "fields" of a single cookie "record." Because all entries are integers, any nonnumeric character would work. I arbitrarily selected the period:

```
function setdh3Importance()
{
   var oneRecord = "";
   for (var i = 0; i < 5; i++)
   {
      var dataPoint = document.forms[0].importance[i].value;
         if (!parent.isValid(dataPoint))
         {
            document.forms[0].importance[i].focus();
            document.forms[0].importance[i].select();
            return;
         }
      oneRecord += dataPoint + ".";
   }
   parent.setImportance(oneRecord);
   return;
}
```

The purpose of the `setdh3Importance()` function is to assemble all five values from the five Weight entry fields (named `importance`) into a period-delimited record that is ultimately sent to the cookie for safekeeping. Another of the many `for` loops in this application cycles through each of the fields, checking for validity and then appending the value with its trailing period to the variable (`oneRecord`) that holds the accumulated data. As soon as the loop finishes, the entire record is sent to the parent function for storage.

Although the function shows two `return` statements, the calling statement does not truly expect any values to be returned. Instead, I use the `return` statement inside the `for` loop as a way to break out of the `for` loop without any further execution whenever an invalid entry is found. Just prior to that, the script sets the `focus` and `select` to the field containing the invalid entry. JavaScript, however, is sensitive to the fact that a function with a `return` statement in one possible outcome doesn't have a `return` statement for other outcomes (an error message to this effect appears in some browsers if you try the function without balanced returns). By putting a `return` statement at the end of the function, all other possibilities are covered to the browser's satisfaction.

The inverse of storing the weight entries is retrieving them. Because the `parent.getImportance()` function returns the entire period-delimited record, this function must break apart the pieces and distribute them into their corresponding Weight fields. A combination of string methods determines the offset of the period and how far the data extraction should go into the complete record. Before the `for` loop repeats each time, it is shortened by one "field's" data. In other words, as the `for` loop executes, the copy of the cookie data returned to this function is pared down one entry at a time, as each entry is stuffed into its text object for display:

```
         function getdh3Importance()
         {
            var oneRecord = parent.getImportance();
               if (oneRecord != null)
               {
                  for (var i = 0; i < 5; i++)
                  {
                     var recLen = oneRecord.length;
                     var offset = oneRecord.indexOf(".");
                     var dataPoint = (offset >= 0 )
                                   ? oneRecord.substring(0,offset) : "";
                     document.forms[0].importance[i].value = dataPoint;
                     oneRecord = oneRecord.substring(offset+1,recLen);
                  }
               }
         }
      </script>
   </head>
```

Assembling the HTML for the form and its 10 data entry fields needs only a few lines of JavaScript code. Performed inside a `for` loop, the script assembles each line of the form, which consists of a label for the Factor (and its number), the factor input field, the importance input

field, and the label for the Weight (and its number). A `document.write()` method writes each line to the document:

```
      <body>
         <h2>The Decision Helper</h2>
         <hr />
         <h4>Step 3 of 5: List the factors that will influence your decision, and
            assign a weight (from 1 to 100) to signify the importance of each
            factor in your decision.
         </h4>
         <p>
            <script type="text/javascript">
               var output = "<center><form>";
               for (i = 0; i < 5; i++)
               {
                  output += "Factor "
                         + (i+1)
                         + "--><input type='text' name='factor' size='25' ";
                  var eHandler = " onchange=\'parent.setFactor("
                               + i
                               + ",this.value)\'";
                  output += eHandler
                         + "value='"
                         + getdh3Factor(i)
                         + "'>";
                  output += "<input type='text' name='importance' size='3' ";
                  var eHandler = " onchange=\'setdh3Importance()\'";
                  output += eHandler + "value=''>";

                  output += "<--Weight " + (i+1) + "<br \/>";
                  document.write(output);
                  output = "";
               }
               document.write("<\/form><\/center>");
               getdh3Importance();
            </script>
         </p>
      </body>
   </html>
```

Each of the scripted text objects has an event handler. Notice that each event handler is first defined as a variable on a statement line just above its insertion into the string being assembled for the `input` object definition. One reason for this is that the nested quote situation gets quite complex when you are doing these tasks all in one massive assignment statement. Rather than mess with matching several pairs of deeply nested quotes, I found it easier to break out one portion (the event handler definition) as a variable value and then insert that preformatted expression into the concatenated string for the `input` definition.

Notice, too, how the different ways of storing the data in the cookies influence the ways the existing cookie data is filled into the fields as the page draws itself. For the factors, which have one cookie each, the `value` attribute of the field is set with a specific indexed call to the parent factor cookie retriever, one factor at a time. But, for the importance values, which are stored

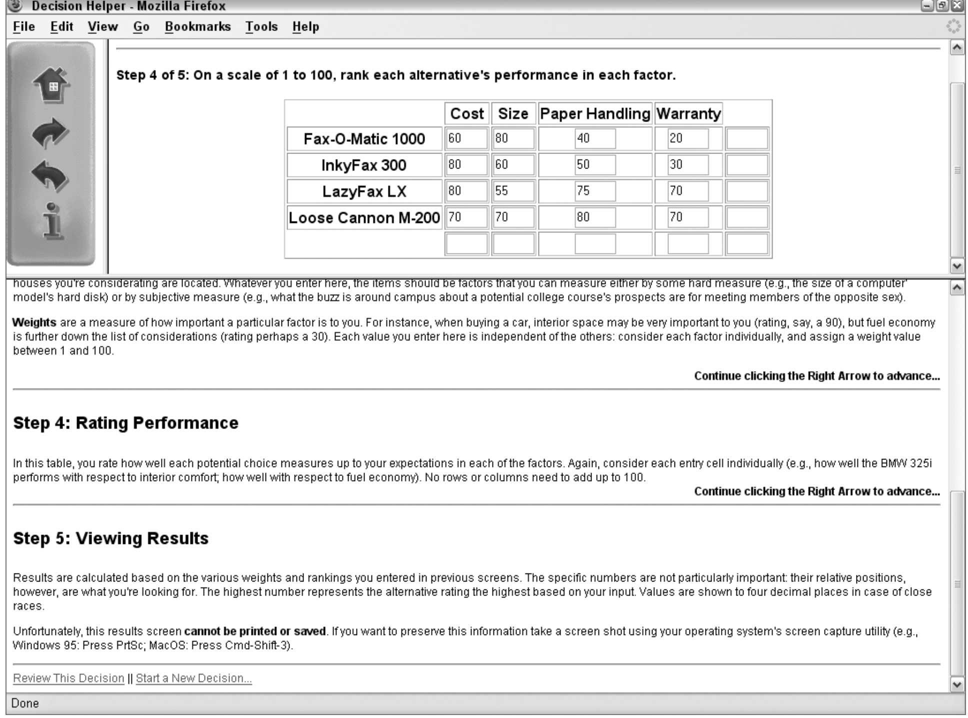
together in the period-delimited chunk, a separate function call (`getdh3Importance()`) executes after the fields are already drawn (with initial values of empty strings) and fills all the fields in a batch operation.

dh4.html

Step 4 of the decision process (shown in Figure 58-5) is the most complex step because of the sheer number of entry fields: 25 in all. Notice that this screen retrieves data from two of the previous screens (or rather, from the cookies preserving the entries) and embeds the values into the fixed parts of the table. All these tasks are possible when you create those tables with JavaScript.

FIGURE 58-5

A massive table includes label data from earlier screen entries.



Functions for getting and setting performance data are complex because of the way I was forced to combine data into five "field" records. In other words, one parent cookie exists for each row of data cells in the table. To extract cell data for storage in the cookie, I use nested `for` loop constructions. The outer loop counts the rows of the table, whereas the inner loop (with the `j` counter variable) works its way across the columns for each row.

Because all cells are named identically, they are indexed with values from 0 to 24. Calculating the row (`i * 5`), plus the column number, establishes the cell index value. After you check for

validity, each cell's value is added to the row's accumulated data. Each row is then saved to its corresponding cookie. As in the code for `dh3.html`, the `return` statement is used as a way to break out of the function if an entry is deemed invalid.

Retrieving the data and populating the cells for the entire table requires an examination of each of the five performance cookies — and, for each labeled cookie's data, a parsing for each period-delimited entry. After a given data point is in hand (one entry for a cell), it must go into the cell with the proper index:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>DH4</title>
      <style type="text/css">
         body
         {
            font-family:Arial, Helvetica, serif;
         }
         h2
         {
            font-size:18px;
         }
         h4
         {
            font-size:14px;
         }
      </style>
      <script type="text/javascript" src="../../jsb-global.js"></script>
      <script type="text/javascript">
         // initialize when the page has loaded
         addEvent(window, "load", initialize);

         function initialize()
         {
            parent.setTitleVar(4);
            document.forms[0].ranking[0].focus();
         }

         function getdh4Performance()
         {
            var oneRecord = "";
            var recLen = 0;
            var offset = 0;
            var dataPoint = "";
            var cellNum = 0;
            for (var i = 0; i < 5; i++)
            {
               oneRecord = parent.getPerformance(i);
                  if (oneRecord == null)
                  {
                     continue;
                  }
```

```
            for (var j = 0; j < 5; j++)
            {
               recLen = oneRecord.length;
               offset = oneRecord.indexOf(".");
               dataPoint = oneRecord.substring(0,offset);
               cellNum = j + (i * 5);
               document.forms[0].ranking[cellNum].value = dataPoint;
               oneRecord = oneRecord.substring(offset+1,recLen);
            }
         }
      }
      function setdh4Performance()
      {
         var oneRecord = "";
         var cellNum = 0;
         var dataPoint = "";
         for (var i = 0; i < 5; i++)
         {
            oneRecord = "";
            for (var j = 0; j < 5; j++)
            {
               cellNum = j + (i * 5);
               dataPoint = document.forms[0].ranking[cellNum].value;
               if (!parent.isValid(dataPoint))
               {
                  document.forms[0].ranking[cellNum].focus();
                  document.forms[0].ranking[cellNum].select();
                  return;
               }
               oneRecord += dataPoint + ".";
            }
            parent.setPerformance(i,oneRecord);
         }
         return;
      }
   </script>
</head>
```

After the document is loaded, the `onload` event handler (bound to the `window` object at the beginning of the script) sends the document number to the parent global variable and brings focus to the first field of the table.

To lessen the repetitive HTML for all tables, JavaScript again assembles and writes the HTML that defines the tables. In the first batch, the script uses yet another `for` loop to retrieve the factor entries from the parent cookie, so that the words can be embedded into `<th>` tags of the first row of the table. If every factor field is not filled in, the table cell is set to empty:

```
<body>
   <h2>The Decision Helper</h2>
   <hr />
   <h4>Step 4 of 5: On a scale of 1 to 100, rank each alternative's
      performance in each factor.
   </h4>
```

```
<p>
   <script type="text/javascript">
      var output = "<div align='center'>";
      output += "<form name='perfRankings'>";
      output += "<table border='1'>";
      output += "<tr><td><\/td>";
      for (var i = 0; i < 5; i++)
      {
         var oneFactor = parent.getFactor(i);
         oneFactor = (oneFactor == null) ? "" : oneFactor;
         output += "<th>"
                + oneFactor
                + "<\/th>";
      }
```

Next comes the assembly of subsequent rows of the table. The first column displays the name of each alternative (within `<th>` tags). The remaining columns are text boxes, all with the same name and event handler. As each row of table definition is completed, it is written to the document. After the table and form closing tags are also written, the `getdh4Performance()` function retrieves all cookie data for the fields and distributes it accordingly:

```
            for (var i = 0; i < 5; i++)
            {
               var oneAlt = parent.getAlternative(i);
               oneAlt = (oneAlt == null) ? "" : oneAlt;
               output += "<tr><th>" + oneAlt + "<\/th>";
               for (var j = 0; j < 5; j++)
               {
                  output += "<td align='center'>";
                  output += "<input type='text' size='3'"
                         + " name='ranking' value=''"
                         + " onchange='setdh4Performance()'>";
                  output += "<\/td>";
               }
               output += "<\/tr>";
               document.write(output);
               output = "";
            }
            document.write("<\/table><\/form><\/div>");
            getdh4Performance();
         </script>
      </p>
   </body>
</html>
```

dh5.html

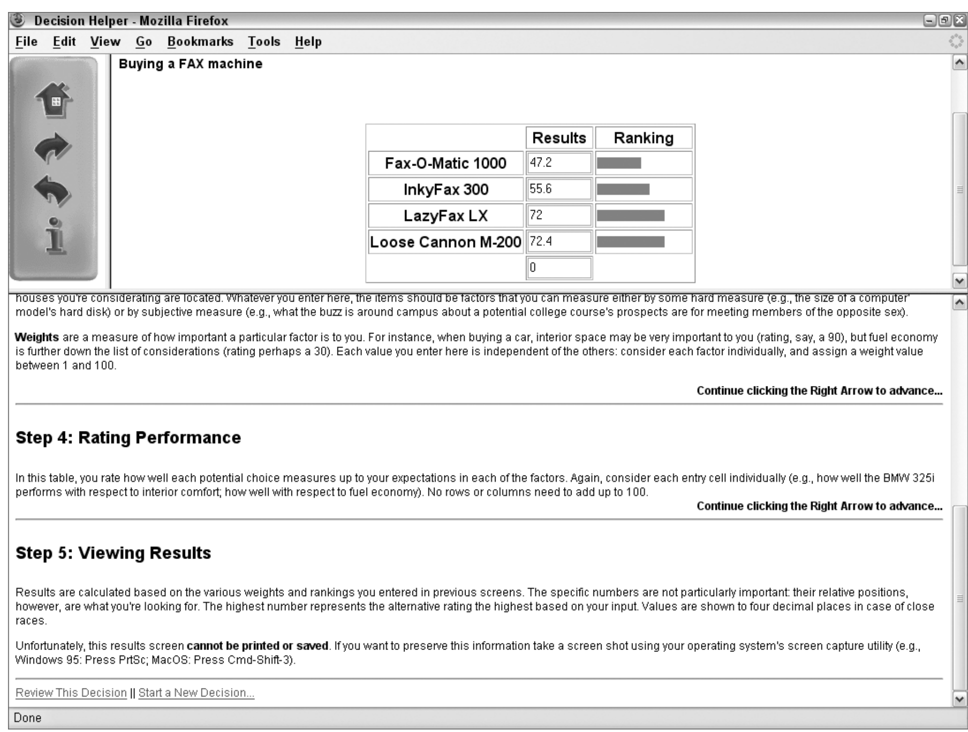
From a math standpoint, dh5.html's JavaScript gets pretty complicated. But because the complexity is attributed to the decision support calculations that turn the user's entries into results,

I treat the calculation script shown here as a black box. You're free to examine the details, if you're so inclined.

Results appear in the form of a table (see Figure 58-6) with columns showing the numeric results and an optional graphical chart.

FIGURE 58-6

The results screen for a decision.



For the purposes of this example, you only need to know a couple of things about the `calculate()` function. First, this function calls all the numeric data stored in parent cookies to fulfill values in its formulas. Second, results are tabulated and placed into a five-entry indexed array called `itemTotal[i]`. This array is defined as a global variable, so that its contents are available to scripts coming up in the `body` portion of the document:

```
<!DOCTYPE html>
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>DH5</title>
      <style type="text/css">
```

```
   body
   {
      font-family:Arial, Helvetica, serif;
   }
   h2
   {
      font-size:18px;
   }
   h4
   {
      font-size:14px;
   }
</style>
<script type="text/javascript" src="../../jsb-global.js"></script>
<script type="text/javascript">
   // initialize when the page has loaded
   addEvent(window, "load", initialize);
   function initialize()
   {
      parent.setTitleVar(5);
   }

   var itemTotal = new Array();

   function calculate()
   {
      var scratchpad = "";
      var importanceSum = 0;
      var oneRecord = parent.getImportance();
      var weight = new Array();
      for (i = 0; i < 5; i++)
      {
         var recLen = oneRecord.length;
         var offset = oneRecord.indexOf(".");
         scratchpad = oneRecord.substring(0,offset);
         importanceSum += (scratchpad == "" || scratchpad == "NaN")
               ? 0 : parseInt(scratchpad);
         oneRecord = oneRecord.substring(offset+1,recLen);
      }
      oneRecord = parent.getImportance();
      for (i = 0; i < 5; i++)
      {
         recLen = oneRecord.length;
         offset = oneRecord.indexOf(".");
         scratchpad = oneRecord.substring(0,offset);
         weight[i] = (scratchpad == "" || scratchpad == "NaN")
               ? 0 : parseInt(scratchpad)/importanceSum * 100;
         oneRecord = oneRecord.substring(offset+1,recLen);
      }

      for (i = 0; i < 5; i++)
      {
         oneRecord = parent.getPerformance(i);
```

```
                if (oneRecord == null)
                {
                   continue;
                }
             scratchpad = 0;
             for (var j = 0; j < 5; j++)
             {
                var recLen = oneRecord.length;
                var offset = oneRecord.indexOf(".");
                var dataPoint = oneRecord.substring(0,offset);
                scratchpad += (dataPoint != "" || dataPoint == "NaN")
                   ? parseInt(dataPoint) * weight[j] / 100 : 0;
                oneRecord = oneRecord.substring(offset+1,recLen);
             }
             itemTotal[i] = scratchpad;
          }
       }
       calculate();
    </script>
 </head>
```

Constructing this function served up many reminders about keeping data types straight. Because the data stored in cookies was in the form of strings, when it comes time to do some real math with those values, careful placement of the `parseInt()` function is essential for getting the math operators to work.

An `onload` event handler (bound to the `window` object at the beginning of the script) sends the document number to the global variable, as usual. The results displayed in this document rely heavily on stored and calculated values, so the table is constructed entirely out of JavaScript. This also means it can redisplay the decision name as part of the page:

```
<body>
   <h2>The Decision Helper</h2>
   <hr />
   <script type="text/javascript">
      document.write("<h4>"
                   + parent.getDecisionName()
                   + "<\/h4><br \/><br \/>");
      var output = "<div align='center'>";
      output += "<form name='Results'><table border='1'>";
      output += "<tr><td><\/td><th>Results<\/th><th>Ranking<\/th>";
      document.write(output);
      output = "";
```

I need to break up the discussion of the `for` loop that produces the results because there are two distinct parts of this HTML assembly. The first, shown in the following script segment, assembles the first two cells of each row of the table. The first cell contains an embedded listing of the alternative name (in `<th>` tags). To highlight the calculated values — and enable the `size` attribute to do the artificial job of truncating the floating-point number — the results are shown in text boxes. For each row, the corresponding result in `itemTotal[i]` is inserted as the `value`

attribute of the text box. The `size` attribute is set to 7, which allows the typical double-digit results, a decimal point, and four digits to the right of the decimal:

```
        for (var i = 0; i < 5; i++)
        {
           var oneAlt = parent.getAlternative(i);
           oneAlt = (oneAlt == null || oneAlt == "") ? "" : oneAlt;
           itemTotal[i] = (oneAlt == "") ? 0 : itemTotal[i];
           output += "<tr><th>" + oneAlt + "<\/th>";
           output += "<td align='center'>";
           output += "<input type='text' size='7' name='ranking' value="
                  + itemTotal[i]
                  + "><\/td>";
```

For extra pizzazz, a third column "draws" a bar chart within a 100-pixel-wide cell. The bars are actually scalings of a one-pixel-wide `.gif` file (an orange line, 12 pixels tall). A single-color `.gif` image scales to fill whatever width is assigned in the `width` attribute. This method is faster, and far better, than a more tedious method (tedious from the web page author's point of view) of creating 100 different `.gif` files, one for each possible width of the bar. I also could have used a one-pixel square `.gif` file with equal ease:

```
           output += "<td width='100'>";
           chartWidth = Math.round(itemTotal[i]);
              if (chartWidth > 0)
              {
                 output += "<img src='chart.gif' height='12' width='"
                        + chartWidth
                        + "' \/>";
              }
           output += "<\/td><\/tr>";
           document.write(output);
           output = "";
        }
        document.write("<\/table><\/form><\/div>");
     </script>
  </body>
</html>
```

dhHelp.html

The only other code worth noting in this application is in the `dhHelp.html` document, which appears in the lower frame of the window. At the end of this document are two links that call separate JavaScript functions in this document's `head` section. The `head` functions are as follows:

```
<!DOCTYPE html>
<html xmlns="http://www.w3.org/1999/xhtml">
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Decision Helper Help</title>
      <style type="text/css">
```

```
        body
        {
           font-family:Arial, Helvetica, serif; font-size:12px;
        }
        h4
        {
           font-size:18px;
        }
        .continue, .term, .warning
        {
           text-align:right; font-weight:bold;
        }
     </style>
     <script type="text/javascript">
        function goFirst()
        {
           parent.entryForms.location = "dh1.html";
           self.location.hash = "help1";
        }
        function restart()
        {
           if (confirm("Erase current decision and start a new one?"))
           {
              parent.initializeCookies();
              parent.entryForms.location = "dh1.html";
              self.location.hash = "help1";
           }
        }
     </script>
  </head>
```

One function merely returns the user to the beginning of the sequences for both the entry screens and the help screen. The second function is a rare instance in which a confirm dialog box makes sense: It is about to erase all entered data. If the user says it's okay to go ahead, the parent window's function for initializing all cookies is called, and the navigation for both the entry and help screens goes back to the beginning.

The links at the bottom of the document (see Figure 58-6) are coded to trigger JavaScript functions (rather than navigate to URLs) and include `onmouseover` event handlers to provide more information about the link in the status bar:

```
     <a href="javascript:goFirst()"
        onmouseover="window.status='Go back to beginning
                                    to review data...';return true">
        Review This Decision</a>
     ||
     <a href="javascript:restart()"
        onmouseover="window.status='Erase current data and
                                    start over...';return true">
        Start a New Decision...</a>
```

Further Thoughts

If you've managed to follow through with this application's discussions, you will agree that it's quite a JavaScript workout. But this application proves that, without a ton of code, JavaScript provides enough functionality to add a great deal of interactivity and pseudo-intelligence to an otherwise flat HTML document.

As an alternative to using cookies for data storage, I have also implemented a version of the application that uses text boxes defined in a frame with a row height of 0. This technique further challenges the synchronization of frames during reloading when a user either resizes the browser window or navigates with the Back or Forward browser buttons. This alternate version is located on the CD-ROM for your own investigation and comparison.

Dynamic HTML also offers some possibilities for this application. The entire program can be presented in a no-frame window, with the navigation, interactive content, and instructions frames incorporated into individual positionable objects. The interactive content area can be treated almost like a slide show, with successive pages flying in from one edge.

Another Dynamic HTML possibility for added intelligence would be to create the tables in the fourth and fifth screens (`dh4.html` and `dh5.html`) with HTML, but to use JavaScript to dynamically add however many rows and columns would be needed. This would avoid the display of unneeded rows and columns for the user's decision management process.

Not only is this application instructive for many JavaScript techniques, it is also fun to play with as a user. Some financial web sites have adapted it to assist visitors with investment decisions. You can use it to ponder where to go on a dream vacation, or to help you decide the most ethical of a few paths confronting you in a personal dilemma. There's something satisfying about putting in data, turning a crank, and watching results (with a bar chart to boot!) magically appear on the screen.

CHAPTER 59

Application: Cross-Browser DHTML Map Puzzle

IN THIS CHAPTER

Applying a DHTML API

Scripting, dragging, and layering multiple elements

Accounting for incompatibilities among modern browsers

Dynamic HTML (DHTML) allows scripts to position, overlap, and hide or show elements under the control of style sheets and scripting. To demonstrate modern cross-browser DHTML development techniques, this chapter describes the details of a jigsaw puzzle game using pieces of a map of the lower 48 United States. (I think everyone would guess where Alaska and Hawaii go on a larger map of North America.) I chose this application because it enables me to demonstrate several typical tasks you might want to script in DHTML: hiding and showing elements; handling events for multiple elements; tracking the position of an element with the mouse cursor; absolute positioning of elements; changing the z-order of elements; changing element colors; and animating the movement of elements.

You may wonder why it is necessary to deal with cross-browser issues in the modern browser era, when so many things have now been standardized thanks to the W3C DOM. Although the W3C DOM has certainly bridged many compatibility gaps among browsers, it still isn't quite yet feasible to build highly interactive JavaScript applications without accounting for subtle differences between browsers. The puzzle game examined in this chapter reveals many of these subtle issues and how to go about handling them as cleanly as possible.

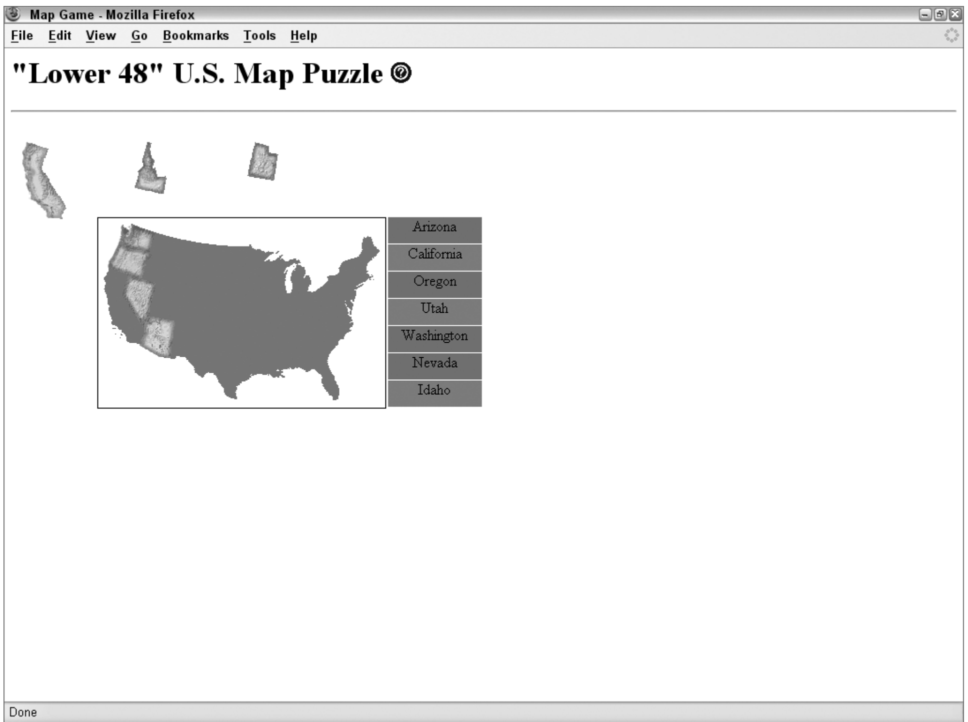
As with virtually any programming task, the example code here is not laid out as the quintessential way to accomplish a particular task. Each author brings his or her own scripting style, experience, and implementation ideas to a design. Very often, you have available several ways to accomplish the same end. If you find other strategies or tactics for the operations performed in these examples, it means you are gaining a good grasp of both JavaScript and DHTML.

The Puzzle Design

Figure 59-1 shows the finished map puzzle with the game in progress. To keep the code to a reasonable length, the example provides positionable state maps for only seven western states; you are free to expand the example to include additional states. Also, the overall design is intentionally Spartan so as to place more emphasis on the positionable elements and their scripting, rather than on fancy design.

FIGURE 59-1

The puzzle map game DHTML example.



(Images courtesy Map Resources — `www.mapresources.com`)

When the page initially loads, all the state maps are presented across the top of the puzzle area. The state labels all have a red background, and the silhouette of the continental United States has no features in it. To the right of the title is a question mark icon. A click of this icon causes a panel of instructions to glide to the center of the screen from the right edge of the browser window. A button on the panel hides it.

To play the game (no scoring or time keeping is in this simplified version), a user clicks and drags a state, with the goal of moving it into its rightful position on the silhouette. While the user drags the state, the background of its label to the right of the main map turns yellow to

highlight the name of the state being worked on. To release the state into its trial position, the user releases the mouse button. If the state is within a 4-pixel square region around its true location, the state snaps into its correct position, and the corresponding label background color turns green. If the state is not dropped close enough to its destination, the label background reverts to red, meaning that the state still needs to be placed.

After the last state map is dropped into its proper place, all the label backgrounds will be green, and a congratulatory message is displayed where the state map pieces originally lay. Should a user then pick up a state and drop it out of position, the congratulatory message disappears.

Implementation Details

Due to the number of different scripted properties being changed in this application, I decided to implement a lot of the scripting as a custom API loaded from an external `.js` file library. The library, whose code is dissected and explained in Chapter 50, "Cross-Browser Dynamic HTML Issues," contains functions for most of the scriptable items you can access in DHTML. Having these functions available simplified what would have been more complex functions in the main part of the application.

Although I frown on using global variables except where absolutely necessary, I needed to assign a few globals for this application. All of them store information about the state map currently picked up by the user and the associated label. This information needs to survive the invocations of many functions between the time the state is picked up and the time it is dropped and checked against the database of state data.

That database is another global object — a global variable that I don't mind using at all. Constructed as a multidimensional array, each record in the database stores several fields about the state, including the coordinates for its destination inside the outline map, and a Boolean field to store whether the state has been correctly placed in position.

The custom API

To begin the analysis of the code, you should be familiar with the API that is linked in from an external `.js` library file. Listing 50-3 contains that code and its description.

The main program

Code for the main program is shown in Listing 59-1. The listing is a long document, so I interlace commentary throughout the listing. Before diving into the code, however, allow me to present a preview of the structure of the document. With two exceptions (the map silhouette and the help panel), all positionable elements have their styles set through style sheets in the `head` of the document. Note the way class and id selectors are used to minimize the repetitive nature of the styles across so many similar items. After the style sheets come two `script` elements pointing to the external general scripts for the page, followed by the `script` element for the embedded scripts particular for the page. All this material is inside the `head`

element. I leave the `body` element to contain the visible content of the page. This approach is an organization style that works well for me, but you can adopt any style you like, provided various elements that support others on the page are loaded before the dependent items (for example, define a style before assigning its name to the corresponding content tag's id attributes).

LISTING 59-1

The Main Program (mapgame.htm)

```
<html>
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8">
      <title>Map Game</title>
```

Most of the positionable elements have their CSS properties established in the `style` element at the top of the document. Positionable elements whose styles are defined here include a text label for each state, a map for each state, a congratulatory message, and some of the pieces for the help panel and the background map. Note that the names of the label and state map objects begin with a two-letter abbreviation of the state. This labeling comes in handy in the scripts when synchronizing the selected map and its label.

The label objects are nested inside the background map object. Therefore, the coordinates for the labels are relative to the coordinate system of the background map, not the page. That's why the first label has a `top` property of zero.

You'll notice that I said "some of the pieces for the help panel and the background map." Although both of these are also positionable elements, scripts need to read the positions of these elements without first setting the values. Recall that in the W3C DOM, the `style` property of an object does not reveal property values that are set in remote style sheet rules. Although there are ways to read the effective style properties applied to an element from style sheets (the `currentStyle` property in IE5+ and the `window.getComputedStyle()` method in NN6+/Moz/Safari1.2+), I elected to specify the style sheet rules for the background map and help panel as `style` attributes in those two elements' tags later in the listing.

```
<style type="text/css">
   .labels { position:absolute;
      Width:100px; height:28px;
      background-color:red; border:none;
      text-align:center;
   }
   #azlabel { left:310px; top:0px;
   }
   #calabel { left:310px; top:29px;
   }
   #orlabel { left:310px; top:58px;
   }
```

```
#utlabel { left:310px; top:87px;
}
#walabel { left:310px; top:116px;
}
#nvlabel { left:310px; top:145px;
}
#idlabel { left:310px; top:174px;
}

#camap { position:absolute; left:20px; top:100px;
}
#ormap { position:absolute; left:45px; top:100px;
}
#wamap { position:absolute; left:100px; top:100px;
}
#idmap { position:absolute; left:140px; top:100px;
}
#nvmap { position:absolute; left:180px; top:100px;
}
#azmap { position:absolute; left:220px; top:100px;
}
#utmap { position:absolute; left:260px; top:100px;
}

#helpImage { height:22px; width:22px; border:none;
}
#help { background-color:#98FB98; border:none;
    top:80px; width:300px;
}
#helpTitle { text-align:center; font-weight:bold;
   margin-top:5px;
}
#helpCloseBtnForm { text-align:center;
}
#helpList { margin-right:20px;
}
#helpRule { height: 0px; border: 0px;
   border-top: 1px solid seagreen;
}

#bgmap { position:absolute;
   width:406px;
}

#usMapImage { width:306px; height:202px;
   border: 1px solid;
}

#congrats { position:absolute; left:20px; top:100px;
   width:1px; color:red; visibility:hidden;
}
```

The next statements load the external `.js` library files that contain the API described in Chapter 50 and the common external `.js` library file that contains the event-handling code used in much of the book. You'll find it in the root script directory on the CD ROM: `jsb-global.js`. I tend to load external library files before listing any other JavaScript code in the page, just in case the main page code relies on global variables or functions in its initializations.

```
<script type="text/javascript" src="../jsb-global.js"></script>
<script type="text/javascript" src="DHTMLapi.js"></script>
```

Note

One of the property assignment event-handling techniques employed in this chapter uses the more modern approach of binding events with the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. This modern cross-browser event-handling technique is explained in detail in Chapter 32, "Event Objects." Another event-handling technique employed in the code in this chapter and much of the book is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events, as we do in this example. ■

Now comes the main script, which contains all the document-specific functions and global variables. Two event handlers discussed later are bound here. The global variables are ready to hold information about the selected state object (and associated details), as well as the offset between the position of a click inside a map object and the top-left corner of that map object. You will see that this offset is important for allowing the map to track the cursor at the same offset position within the map. And because the tracking is done by repeated calls to a function (triggered by numerous mouse events), these offset values must have global scope.

```
<script type="text/javascript">
// initialize when the page has loaded
addEvent(window, "load", init);
addEvent(window, "resize", setWinWidth);
// global declarations
var offsetX = 0;
var offsetY = 0;
var selectedObj;
var states = new Array();
var statesIndexList = new Array();
var selectedStateLabel;
```

You also have the option of creating just one, all-encompassing, custom JavaScript object in the global space, and defining properties of that object with the same names shown here for individual global variables. It means that subsequent references to these values would be written in *objectName.propertyName* form. For this example, however, I'll keep the global variables short and sweet to help you visualize how they are used in later script statements.

As you will see later in the code, an `onload` event handler for the document invokes an initialization function, whose main job is to build the array of objects containing information about each state. The fields for each `state` object record are for the two-letter state abbreviation, the full name (not used in this application, but included for use in a future version), the x and y coordinates (within the coordinate system of the background map) for the exact position of the state, and a Boolean flag to be set to `true` whenever a user correctly places a state. I will come back to the last two statements of the constructor function in a moment.

Calculating the data for the x and y coordinates required some legwork during development. As soon as I had the pieces of art for each state and the code for dragging them around the screen, I disengaged the part of the script that tested for accuracy. Instead, I added a statement to the code that revealed the x and y position of the dragged item in the status bar (rather than being bothered by alerts). When I carefully positioned a state in its destination, I copied the coordinates from the status bar into the statement that created that state record. Sure, it was tedious, but after I had that info in the database, I could adjust the location of the background map and not have to worry about the destination coordinates, because they were based on the coordinate system inside the background map.

```
// object constructor for each state; preserves destination
// position; invokes assignEvents()
function state(abbrev, fullName, x, y)
{
   this.abbrev = abbrev;
   this.fullName = fullName;
   this.x = x;
   this.y = y;
   this.done = false;
   assignEvents(this);
   statesIndexList[statesIndexList.length] = abbrev;
}
// initialize array of state objects
function initArray()
{
   states["ca"] = new state("ca", "California", 7, 54);
   states["or"] = new state("or", "Oregon", 7, 24);
   states["wa"] = new state("wa", "Washington", 23, 8);
   states["id"] = new state("id", "Idaho", 48, 17);
   states["az"] = new state("az", "Arizona", 45, 105);
   states["nv"] = new state("nv", "Nevada", 27, 61);
   states["ut"] = new state("ut", "Utah", 55, 69);
}
```

The act of creating each `state` object causes all statements in the constructor function to execute. Moreover, they were executing within the context of the object being created. That opened up channels for two important processes in this application. One was to maintain a list of abbreviations as its own array. This becomes necessary later on when the script needs to loop through all objects in the `states` array to check their `done` properties. Because the array is set up like a hash table (with string index values), a `for` loop using numeric index values is out of the question. So, this extra `statesIndexList` array provides a numerically indexed array that can be used in a `for` loop; values of that array can then be used as index values of the `states` array. Yes, it's a bit indirect, but other parts of the application benefit greatly by having the state information stored in a hash table–like array.

We now come to the functions that operate while the user interacts with the map puzzle pieces. The first function, acting as a vital behind-the-scenes utility function, is called `setSelectedMap()`. It receives as its sole parameter an event object that is of the proper type for the browser currently running (that's done in the `engage()` function, described next). `setSelectedMap()` has three jobs to do, two of which set global variables. The first global variable, `selectedObj`, maintains a reference to the layer (the puzzle piece) being dragged

by the user. At the same time, the `selectedStateLabel` variable is assigned a value that is a reference to the layer that holds the label (recall that its color changes during dragging and release). All this requires DOM-specific references that are generated through the aid of object-detecting branches of the function. The last job of this function is to set the stacking order of the selected map to a value higher than the others, so that while the user drags the map, it is in front of everything else on the page.

To assist in establishing references to the map and label layers, naming conventions of the HTML objects (shown later in the code) play an important role. In addition to event handlers being assigned to the images, the mouse events are also targeted at the image objects. To assist in associating labels with images, the image objects are assigned uppercase abbreviations of the state names. As `setSelectedMap()` begins to execute, it uses object detection to extract a reference to the element object regarded as the target of the event. To make sure that the event being processed comes from an image, the next statement checks that the `tagName` property of the event target is `img`, in which case a lowercase version of the name is assigned to the `abbrev` local variable. That `abbrev` variable then becomes the basis for the element name used in the reference to the `selectedStateLabel` object.

The presence of a value assigned to `selectedObj` becomes an important case for all three drag-related functions later. That's why the `setSelectedMap()` function nulls out the value if the event comes from some other source.

```
/**************************************************
BEGIN INTERACTION FUNCTIONS
**************************************************/

// set global reference to map being engaged and dragged
function setSelectedMap(evt)
{
   var target = (evt.target)
              ? evt.target : evt.srcElement;
   var abbrev = (target.tagName == "IMG")
              ? target.name.toLowerCase() : "";
   if (abbrev)
   {
      if (document.getElementById)
      {
         selectedObj = target;
         selectedStateLabel =
               document.getElementById(abbrev + "label");
      }
      setZIndex(selectedObj, 100);
      return;
   }
   selectedObj = null;
   selectedStateLabel = null;
   return;
}
```

Next comes the `engage()` function definition. This function is invoked by `mousedown` events inside any of the state map layers (event handler assignment code comes later). W3C DOM

browsers pass an event object as the sole parameter to the function (picked up by the `evt` parameter variable). If that parameter contains a value, it stands as the event object for the rest of the processing; but for IE, the `window.event` object is assigned to the `evt` variable. After setting the necessary object globals through `setSelectedMap()`, the next major task for `engage()` is to calculate and preserve in global variables the number of pixels within the state map layer at which the `mousedown` event occurred. By preserving these values, the `dragIt()` function makes sure that the motion of the state map layer keeps in sync with the mouse cursor at the very same point within the state map. If it weren't for taking the offset into account, the layer would jump unexpectedly to bring the top-left corner of the layer underneath the cursor. That's not how users expect to drag items on the screen.

The calculations for the offsets require a variety of DOM-specific properties. A nested object detection takes place in each assignment statement. The IE branch has some additional branching within each of the assignment statements. These extra branches cover a disparity in the way IE reports the offset properties of an event as related to window scrolling. Later calculations for positioning must take window scrolling into account, so that scrolling is factored into the preserved offset global values if there are indications that the window has scrolled and the values are being affected by the scroll (in which case the offset values go negative). The logic is confusing, and it won't make much sense until you see later how the positioning is invoked. Conceptually, all these offset value calculations may seem like a can of worms, but they are essential, and are performed compactly.

After the offsets are established, the background color of the state's label layer is set to yellow. The function ends with `return false` to make sure that the `mousedown` event doesn't propagate through the page (causing a contextual menu to appear on the Macintosh, for instance).

```
// set relevant globals onmousedown; set selected map
// object global; preserve offset of click within
// the map coordinates; set label color to yellow
function engage(evt)
{
   evt = (evt) ? evt : window.event;
   setSelectedMap(evt);
   if (selectedObj)
   {
      if (evt.pageX)
      {
         offsetX = evt.pageX - selectedObj.offsetLeft;
         offsetY = evt.pageY - selectedObj.offsetTop;
      }
      else if (evt.offsetX || evt.offsetY)
      {
         offsetX = evt.offsetX - document.body.scrollLeft;
         offsetY = evt.offsetY - document.body.scrollTop;
      }
      setBGColor(selectedStateLabel,"yellow");
      return false;
   }
}
```

The `dragIt()` function, compact as it is, provides the main action in the application by keeping a selected state object under the cursor as the user moves the mouse. This function is called repeatedly by the `mousemove` events, although the actual event-handling methodology varies with platform (precisely the same way as with `engage()`, as shown previously). Regardless of the event property detected, event coordinates (minus the previously preserved offsets) are passed the `shiftTo()` function in the API.

Before the dragging action branch of the function ends, the event object's `cancelBubble` property is set to `true`. It's important that this function operate as quickly as possible, because it must execute with each `mousemove` event. Canceling event bubbling helps in a way, but more importantly, the cancellation allows the `mousemove` event to be used for other purposes, as described shortly.

```
// move div on mousemove
function dragIt(evt)
{
   evt = (evt) ? evt : event;
   if (selectedObj)
   {
      if (evt.pageX)
      {
         shiftTo(selectedObj, (evt.pageX - offsetX),
                 (evt.pageY - offsetY));
      }
      else if (evt.clientX || evt.clientY)
      {
         shiftTo(selectedObj, (evt.clientX - offsetX),
                 (evt.clientY - offsetY));
      }
      evt.cancelBubble = true;
      return false;
   }
}
```

When a user drops the currently selected map object, the `release()` function invokes the `onTarget()` function to find out if the current location of the map is within range of the desired destination. If it is in range, the background color of the state label object is set to green, and the `done` property of the selected state's database entry is set to `true`. One additional test (the `isDone()` function call) looks to see if all the `done` properties are `true` in the database. If so, the `congrats` object is shown. But if the map object is not in the right place, the label reverts to its original red color. In case the user moves a state that was previously okay, its database entry is also adjusted. No matter what the outcome, however, the user has dropped the map, so key global variables are set to `null`, and the layer order for the item is set to zero (bottom of the heap) so that it doesn't interfere with the next selected map.

One more condition is possible in the `release()` function. As shown later in the initialization function, the `document` object's `onmousemove` event handler is assigned to the `release()` function (to compare the `onmousemove` events for the state maps, go to `dragIt()`). The reasoning behind this document-level event assignment is that no matter how streamlined the dragging

function may be, it is possible for the user to move the mouse so fast that the map can't keep up. At that point, mousemove events are firing at the document (or other object, eventually bubbling up to the document), and not the state map. If that happens while a state map is registered as the selected object, but the image is no longer the target of the event, the code performs the same act as if the user had released the map. The label reverts to red, and all relevant globals are set to null, preventing any further interaction with the map until the user mouses down again on the map.

```
// onmouseup, see if dragged map is near its destination
// coordinates; if so, mark it as 'done' and color label green
   function release(evt)
   {
      evt = (evt) ? evt : event;
      var target = (evt.target)
                 ? evt.target : evt.srcElement;
      var abbrev = (target.tagName == "IMG")
                 ? target.name.toLowerCase() : "";
      if (abbrev && selectedObj)
      {
         if (onTarget(evt))
         {
            setBGColor(selectedStateLabel, "green");
            states[abbrev].done = true;
            if (isDone())
            {
               show("congrats");
            }
         }
         else
         {
            setBGColor(selectedStateLabel, "red");
            states[abbrev].done = false;
            hide("congrats");
         }

         setZIndex(selectedObj, 0);
      }
      else if (selectedStateLabel)
      {
         setBGColor(selectedStateLabel, "red");
      }
      selectedObj = null;
      selectedStateLabel = null;
   }
```

To find out whether a dropped map is in (or near) its correct position, the onTarget() function first calculates the target spot on the page by adding the location of the bgmap object to the coordinate positions stored in the states database. Because the bgmap object doesn't come into play in other parts of this script, it is convenient to pass merely the object name to the two API functions that get the object's left and top coordinate points.

Next, the script uses platform-specific properties to get the recently dropped state map object's current location. A large `if` condition checks whether the state map object's coordinate points are within a 4-pixel square region around the target point. If you want to make the game easier, you can increase the cushion values of each coordinate point from 2 to 3 or 4. You might make the cushion values even higher if the map is intended as an educational tool for children.

If the map is within the range, the script calls the `shiftTo()` API function to snap the map into the exact destination position, and reports back to the `release()` function the appropriate Boolean value.

```
// compare position of dragged element against the destination
// coordinates stored in corresponding state object; after shifting
// element to actual destination, return true if item is within
// 2 pixels.
function onTarget(evt)
{
   evt = (evt) ? evt : event;
   var target = (evt.target)
            ? evt.target : evt.srcElement;
   var abbrev = (target.tagName == "IMG")
            ? target.name.toLowerCase() : "";
   if (abbrev && selectedObj)
   {
      var x = states[abbrev].x + getObjectLeft("bgmap");
      var y = states[abbrev].y + getObjectTop("bgmap");
      var objX, objY;
      if (selectedObj.style)
      {
         objX = parseInt(selectedObj.style.left);
         objY = parseInt(selectedObj.style.top);
      }
      if ((objX >= x-2 && objX <= x+2)
          && (objY >= y-2 && objY <= y+2))
      {
         shiftTo(selectedObj, x, y);
         return true;
      }
      return false;
   }
   return false;
}
```

A `for` loop cycles through the `states` database (with the help of the hash table values stored indirectly in the `statesIndexList` array) to see if all the done properties are set to `true`. When they are, the `release()` function (which calls the `isDone()` function) displays the congratulatory object.

```
// test whether all state objects are marked 'done'
function isDone()
{
```

```
      for (var i = 0; i < statesIndexList.length; i++)
      {
         if (!states[statesIndexList[i]].done)
         {
            return false;
         }
      }
      return true;
   }
```

The help panel is created differently than the map and label objects (details coming up in a moment). When the user clicks the Help button at the top of the page, the instructions panel slides in from the right edge of the window (see Figure 59-2). The `showHelp()` function begins the process by setting its location to the current right window edge, bringing its layer to the very front of the heap, and showing the object. To assist `moveHelp()` in calculating the center position on the screen, the `showHelp()` function retrieves (just once per showing) the property for the width of the help panel. That value is passed as a parameter to `moveHelp()`, as it is repeatedly invoked through the `setInterval()` mechanism.

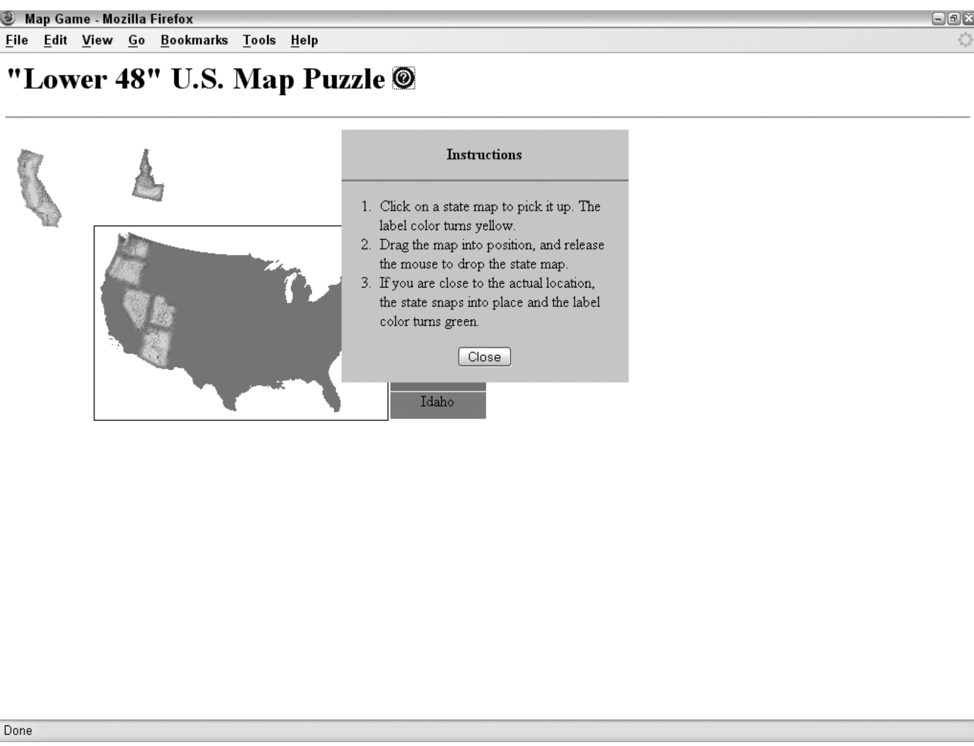
```
/***********************************************
BEGIN HELP ELEMENT FUNCTIONS
************************************************/
// initiate show action
function showHelp()
{
   var objName = "help";
   var helpWidth = 0;
   shiftTo(objName, insideWindowWidth, 80);
   setZIndex(objName,1000);
   show(objName);
   if (document.getElementById)
   {
      if (document.getElementById(objName).offsetWidth >= 0)
      {
         helpWidth = document.getElementById(objName).offsetWidth;
      }
   }
   intervalID = setInterval("moveHelp(" + helpWidth + ")", 1);
}
```

In the `moveHelp()` function, the help object is shifted in 5-pixel increments to the left. The ultimate destination is the spot where the object is in the middle of the browser window. That midpoint must be calculated each time the page loads, because the window may have been resized. The width of the `help` object, received as a parameter to the function, gets a workout in the mid-point calculation.

This function is called repeatedly under the control of a `setInterval()` method in `showHelp()`. But when the object reaches the middle of the browser window, the interval ID is canceled, which stops the animation.

FIGURE 59-2

Instruction panel slides in from left to center screen.



The help object processes a mouse event to hide the object. An extra `clearInterval()` method is called here in case the user clicks the object's Close button before the object has reached mid-window (where `moveHelp()` cancels the interval). The script also shifts the position to the right edge of the window, but this isn't absolutely necessary, because the `showHelp()` method positions the window there.

```
// iterative move helps div to center of window
function moveHelp(w)
{
   shiftBy("help",-5,0);
   var objectLeft = getObjectLeft("help");
   if (objectLeft <= (insideWindowWidth/2) - w/2)
   {
      clearInterval(intervalID);
   }
}
// hide the help div
```

```
function hideMe()
{
   clearInterval(intervalID);
   hide("help");
   shiftTo("help", insideWindowWidth, 80);
}
```

The document's `onload` event handler invokes the `init()` function, which, in turn, calls two functions and assigns the `document` object's mouse event handlers. The first function is `initArray()`, which builds the `states[]` database and assigns event handlers to the state map layers. Because the layers are defined so late in the document, initializing their events after the page has loaded is safest.

For convenience in moving the help window to the center of the browser window, the `setWinWidth()` function sets a global variable (`insideWindowWidth`) to hold the width of the browser window. This function is also invoked by the `onresize` event handler for the window to keep the value up to date.

The most important parts of the `init()` function are the event handler assignments. The trio — engaging the map on `mousedown`, dragging it on `mousemove`, releasing it on `mouseup` — are assigned to the `document` object so that the events track correctly even if the cursor speeds past a puzzle piece's edge on a fast drag action.

```
   // calculate center of window for help div
   function setWinWidth()
   {
      if (window.innerWidth)
      {
         insideWindowWidth = window.innerWidth;
      }
      else if (document.body.scrollWidth)
      {
         insideWindowWidth = document.body.scrollWidth;
      }
   }

   /*************************************************
   INITIALIZE THE APPLICATION
   *************************************************/
   // initialize application
   function init()
   {
      initArray();
      setWinWidth();
      document.onmousedown = engage;
      document.onmousemove = dragIt;
      document.onmouseup = release;
   }
   </script>
</head>
```

Now comes the part of the document that generates the visible content. The question mark icon includes an `onclick` event handler to display the Help panel.

```
<body>
   <h1>"Lower 48" U.S. Map Puzzle
      <a href="javascript:void showHelp()"
         onmouseover="status='Show help panel...';return true"
         onmouseout="status='';return true"><img alt="image"
         src="info.gif" id="helpImage" /></a>
   </h1>
```

Next come tags for all the `div` and `img` elements. The `style` attribute for the `bgmap div`, in combination with the styles set in the embedded style sheet in the `head` section, lets scripts read the positioned values to assist in calculating positions in the `onTarget()` function, as shown previously. The `bgmap` layer also contains all labels, so that if the design calls for moving the map to another part of the page, the labels follow automatically. Notice how the lowercase state abbreviations are part of the names of both the label and map layers. As you saw in a few functions shown previously, a systematic approach to object naming can offer powerful shortcuts in determining references to elements.

```
   <div id="bgmap" style=" left:100px; top:180px;">
      <img alt="image" id="usMapImage" src="us11.gif" /> 
      <div class="labels" id="azlabel">Arizona</div>
      <div class="labels" id="calabel">California</div>
      <div class="labels" id="orlabel">Oregon</div>
      <div class="labels" id="utlabel">Utah</div>
      <div class="labels" id="walabel">Washington</div>
      <div class="labels" id="nvlabel">Nevada</div>
      <div class="labels" id="idlabel">Idaho</div>
   </div>
   <img id="camap" alt="image" name="CA" src="ca.gif"
        width="47px" height="82px" border="0" />
   <img id="ormap" alt="image" name="OR" src="or.gif"
        width="57px" height="45px" border="0" />
   <img id="wamap" alt="image" name="WA" src="wa.gif"
        width="38px" height="29px" border="0" />
   <img id="idmap" alt="image" name="ID" src="id.gif"
        width="34px" height="55px" border="0" />
   <img id="azmap" alt="image" name="AZ" src="az.gif"
        width="38px" height="45px" border="0" />
   <img id="nvmap" alt="image" name="NV" src="nv.gif"
        width="35px" height="56px" border="0" />
   <img id="utmap" alt="image" name="UT" src="ut.gif"
        width="33px" height="41px" border="0" />
   <div id="congrats"><h1>Congratulations!</h1></div>
   <div id="help" onclick="hideMe()"
        style="position:absolute; visibility:hidden;">
      <p id="helpTitle">Instructions</p>
      <hr id="helpRule" />
      <ol id="helpList">
```

```
            <li>Click on a state map to pick it up.
                The label color turns yellow.</li>
            <li>Drag the map into position, and release
                the mouse to drop the state map.</li>
            <li>If you are close to the actual location,
                the state snaps into place and the label
                color turns green.</li>
         </ol>
         <form id="helpCloseBtnForm">
            <input type="button" value="Close" />
         </form>
      </div>
   </body>
</html>
```

This page has a lot of code to digest in one reading. Run the application, study the structure of the source code listing file, and re-read the previous explanations. It may take several readings for a mental picture of the application to form.

Further Thoughts

As soon as the external cross-platform API was in place, it helped frame a lot of the other code in the main program. The APIs provided great comfort in that they encouraged me to reference a complex object fully in the main code as a platform-shared value (for example, the `selectedObj` and `selectedStateLabel` global variables). At the same time, I could reference top-level elements (that is, non-nested objects) simply by their names when passing them to API functions.

It's worth pointing out that the version of the Map Puzzle example game you just saw is considerably cleaner than similar versions found in previous editions of this book. By finally abandoning legacy (version 4 and earlier) browsers and focusing on modern DOMs, it's possible to unify and simplify a lot of the code in the application. Over time, browser vendors will hopefully continue to hammer out their differences so that it is eventually possible to write JavaScript code that has no browser branching hacks at all.

But without a doubt the biggest lesson you learn from working on a project like this is how important it is to test an application on as many browsers and operating systems as possible. Unfortunately, designing a cross-platform application with any degree of complexity on one browser and having it run flawlessly on the other the first time is nearly impossible (at least for now). Be prepared to go back and forth among multiple browsers, breaking and repairing existing working code along the way, until you eventually reach a version that works on every browser that you can test.

CHAPTER 60

Application: Transforming XML Data

IN THIS CHAPTER

Mapping XML data to JavaScript objects with Ajax

Complex JavaScript data structures

Advanced array sorting

Dynamic tables

Chapter 55, "Application: Outline-Style Table of Contents," ends with an example of an interactive outliner whose data arrives from an external XML file, a feature supported by modern browsers. The application described in this chapter picks up from there.

As you recall from the Chapter 55 outline, the node structure of the XML data was used as a guide to the structure for a one-time rendering of HTML elements. There was a one-to-one correlation between XML element nesting and the HTML element nesting. Adjusting style sheet properties for displaying or hiding elements controlled all interactivity. What you're about to see here is a case for converting XML into JavaScript objects that can be used multiple times, as a convenient data source for HTML that is displayed in any number of formats. In particular, you see how JavaScript's array-sorting prowess supplies XML data with extraordinary flexibility in presentation.

You will see a lot of code in this chapter. The code is presented here as a way to demonstrate the potential for rich data handling. At the same time, the code may provide ideas for server-side processing of XML data being output to the client.

Application Overview

Understanding the data is a good place to start in describing this application. The scenario is a small American company (despite its grandiose name: GiantCo) that has divided the country into three sales regions. Two of the regions have two sales representatives, whereas the third region has three reps. The time-frame is the end of the fiscal year, when management wants to review and present the performance of each salesperson. An XML

report (`salesrpt.xml`) delivers the sales forecast and the actual sales per quarter for each sales rep. An HTML and JavaScript page is charged not only with loading the XML data, which displays the raw tabular data, but also with allowing for a variety of views and sorting possibilities, so that management can analyze performance by sales rep and region, as well as by quarter.

A server-based searching and reporting program collects the requested data and outputs each sales rep's record in an XML structure, similar to the following excerpt from the `salesrpt.xml` file:

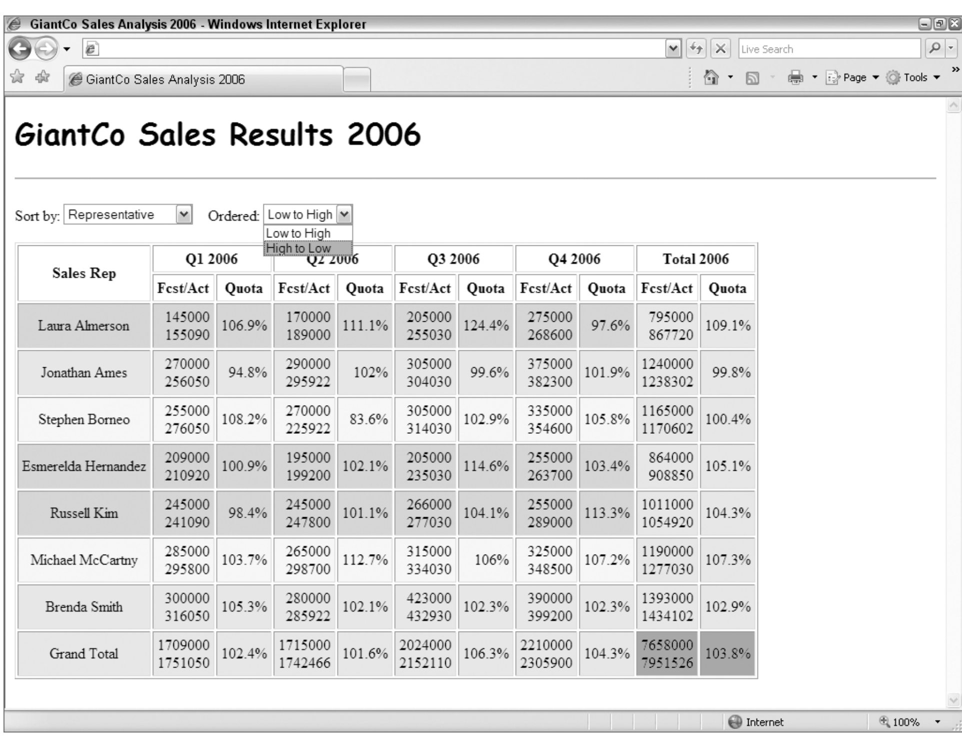
```
<salesrep>
   <employeeid>12345</employeeid>
   <contactinfo>
      <firstname>Brenda</firstname>
      <lastname>Smith</lastname>
      <email>brendas@giantco.com</email>
      <phone>312-555-9923</phone>
      <fax>312-555-9901</fax>
   </contactinfo>
   <manager>
      <employeeid>02934</employeeid>
      <firstname>Alistair</firstname>
      <lastname>Renfield</lastname>
   </manager>
   <region>Central</region>
   <salesrecord>
      <period>
         <id>Q1_2006</id>
         <forecast>300000</forecast>
         <actual>316050</actual>
      </period>
      <period>
         <id>Q2_2006</id>
         <forecast>280000</forecast>
         <actual>285922</actual>
      </period>
      <period>
         <id>Q3_2006</id>
         <forecast>423000</forecast>
         <actual>432930</actual>
      </period>
      <period>
         <id>Q4_2006</id>
         <forecast>390000</forecast>
         <actual>399200</actual>
      </period>
   </salesrecord>
</salesrep>
```

As you can see, the data consists of several larger blocks, such as contact information and a pointer to the rep's manager, and then the details of each quarterly period's forecast and actual

sales. The goal is to present the data in table form with a structure similar to the table shown in Figure 60-1. Not only is the raw data presented, but numerous calculations are also made on the results, such as the percentage of quota attained for each reporting period, plus totals along each axis of the spreadsheet-like table.

FIGURE 60-1

One view of the XML data output.



Sales Rep	Q1 2006		Q2 2006		Q3 2006		Q4 2006		Total 2006	
	Fcst/Act	Quota	Fcst/Act	Quota	Fcst/Act	Quota	Fcst/Act	Quota	Fcst/Act	Quota
Laura Almerson	145000 155090	106.9%	170000 189000	111.1%	205000 255030	124.4%	275000 268600	97.6%	795000 867720	109.1%
Jonathan Ames	270000 256050	94.8%	290000 295922	102%	305000 304030	99.6%	375000 382300	101.9%	1240000 1238302	99.8%
Stephen Borneo	255000 276050	108.2%	270000 225922	83.6%	305000 314030	102.9%	335000 354600	105.8%	1165000 1170602	100.4%
Esmerelda Hernandez	209000 210920	100.9%	195000 199200	102.1%	205000 235030	114.6%	255000 263700	103.4%	864000 908850	105.1%
Russell Kim	245000 241090	98.4%	245000 247800	101.1%	266000 277030	104.1%	255000 289000	113.3%	1011000 1054920	104.3%
Michael McCartny	285000 295800	103.7%	265000 298700	112.7%	315000 334030	106%	325000 348500	107.2%	1190000 1277030	107.3%
Brenda Smith	300000 316050	105.3%	280000 285922	102.1%	423000 432930	102.3%	390000 399200	102.3%	1393000 1434102	102.9%
Grand Total	1709000 1751050	102.4%	1715000 1742466	101.6%	2024000 2152110	106.3%	2210000 2305900	104.3%	7658000 7951526	103.8%

Just above the table are two `select` elements. These controls' labels indicate that the table's data can be sorted by a number of criteria, and that the results of each sort can be ordered in different ways. The example table offers the following sorting possibilities:

```
Representative's Name
Sales Region
Q1 Forecast
Q1 Actual
Q1 Performance
[the last three also for Q2, Q3, Q4]
Total Forecast
Total Actual
Total Performance
```

Ordering of the sorted results is a choice between "Low to High" or "High to Low." Although ordering of most sort categories is obviously based on numeric value, the sorting of the representatives' names is based on the alphabetical order of the last names. One other point about the user interface is that the design needs to signify, via table cell background color, the sales region of each representative. The colors aren't easily distinguishable in Figure 60-1, but if you open the actual example in a browser you will see the coloration. You'll have to make sure that the code you're opening in your browser is coming from an HTTP server.

Implementation Plan

Clearly, all the data needed for numerous sorted and ordered views arrives in one batch from the XML file. Despite the element- and node-referencing properties and methods of the W3C DOM, trying to use the XML elements as the sole place for scripts to sort the data each time would be impractical. For one thing, none of the elements have ID attributes — there's no need for it in the XML stored on the server database. And even if they did have IDs, how would scripts that you desire to write for generalizability make use of them unless the IDs were generated in a well-known sequence? Moreover, after a sales rep's record is rendered in the table, how easy would it be to dive back into that record and drill down for further information, such as the name of a representative's manager?

A solution that can empower the page author in this case is to use the node-walking properties and methods of the W3C DOM to assemble a JavaScript-structured database while the page loads. In other words, the conversion is performed just once during page loading, and the JavaScript version is preserved in an array (of XML "records," in this case) as a global variable. Any transformations on the data can be done from the JavaScript database with the help of additional powers of the language.

Given that route, the basic operation of the scripting of the page is schematically simple:

1. Use Ajax to load and convert the XML into an array of objects.
2. Predefine all necessary sorting functions based on properties of those objects.
3. Provide a function that rebuilds the HTML table each time data is sorted.

With this sequence in mind, look into the code that does the job.

The Code

Rather than work through the long document in source-code order, the following descriptions adhere to a more functional order. You can open the actual source code files (`salesrpt.html` and `salesrpt.js`) to see where the various functions are positioned. To best understand this application, seeing the "how" rather than the "where" is more important.

Style sheets

For the example provided on the CD-ROM, one set of style sheet rules is embedded in the HTML document. As you can see from the rule selectors, many are tied to very specific classes of table-related elements used to render the content. In a production version of this application, I would expect that there would be more and quite different views of the data available to the users, such as bar charts for each salesperson or region. Each view would likely require its own unique set of style sheet rules. In such a scenario, the proper implementation would be to use the LINK element to bring in a different external style sheet file for each view type. All style sheets could be linked in at the outset, but only the current `styleSheet` object would be enabled.

```
<style type="text/css">
   td
   {
      text-align:right
   }
   td.rep, td.grandTotalLabel
   {
      text-align:center
   }
   tr.East
   {
      background-color:#FFFFCC
   }
   tr.Central
   {
      background-color:#CCFFFF
   }
   tr.West
   {
      background-color:#FFCCCC
   }
   tr.QTotal
   {
      background-color:#FFFF00
   }
   td.repTotal
   {
      background-color:#FFFF00
   }
   td.grandTotal
   {
      background-color:#00FF00
   }
   h1
   {
      font-family:"Comic Sans MS",Helvetica,sans-serif
   }
</style>
```

One style sheet rule is essential: the one that suppresses the rendering of any XML element. That data is hidden from the user's view.

Initialization sequence

An `onload` event handler invokes the `init()` function, which triggers a series of events to get the document ready for user interaction. The URL of the XML data file is passed to the primary Ajax function (`loadXMLDoc()`), which not only loads the data, but upon successful loading assembles a JavaScript database from the XML elements.

```
// Create JavaScript object that simulates XML structure,
// plus some data transforms that will facilitate sorting
var db = new Array();

// Initialization called by onload
function init()
{
   loadXMLDoc("salesrpt.xml");
}
window.onload = init;
```

The `loadXMLDoc()` function gives priority to the native `XMLHttpRequest` object, but loads the ActiveX version for Internet Explorer prior to version 7. When the XML data has loaded successfully (the request object's `readyState` is `4` and the `status` is `200`), a copy of the XML data is assigned to a local variable, `xDoc`, primarily for the convenience of a shorter variable name. If it is further verified that the document has data, a `for` loop builds the JavaScript database (stored in the `db` global variable for use later). The assembled database is then sorted based on the current choice in the sorting `select` element. As you'll see in a moment, the `selectSort()` function then triggers the initial rendering of the table.

```
// initialize when the page has loaded
addEvent(window, "load", initialize);
```

Converting the data

The controlling factor for creating the JavaScript database is the structure of the XML data. With the complete XML document stored in a single variable, scripts can use DOM methods to look for elements bearing relevant tag names. Data for each sales rep is contained by a `salesrep` element. The number of `salesrep` elements determines how many records (JavaScript objects) are to be added to the `db` array. A call to the `getOneSalesRep()` function creates an object for each sales representative's data.

Despite the length of the `getOneSalesRep()` function, its operation is very straightforward. Most of the statements do nothing more than retrieve the data inside the various XML elements within a `salesrep` container and assign that data to a like-named property of the custom object. Following the structure of the XML example shown earlier in this chapter, you can see where some properties of a JavaScript object representing the data are, themselves, objects or arrays. For example, one of the properties is called `manager`, corresponding to the `manager` element.

That element has nested items inside; making those nested elements properties of a `manager` object is only natural. Similarly, the repetitive nature of the data within each of the four quarterly periods calls for even greater nesting: The object property named `sales` is an array, with each item of the array corresponding to one of the periods. Each period also has three properties (a period ID, forecast sales, and actual sales). Thus, the `sales` property is an array of objects.

```
function getOneSalesRep(xDoc, i)
{
   var oneRecord =
      new Object();
   var oneElem =
      xDoc.getElementsByTagName("salesrep")[i];
   oneRecord.id =
      oneElem.getElementsByTagName("employeeid")[0].firstChild.data;
   var contactInfoElem =
      oneElem.getElementsByTagName("contactinfo")[0];
   oneRecord.firstName =
      contactInfoElem.getElementsByTagName("firstname")[0].firstChild.data;
   oneRecord.lastName =
      contactInfoElem.getElementsByTagName("lastname")[0].firstChild.data;
   oneRecord.eMail =
      contactInfoElem.getElementsByTagName("email")[0].firstChild.data;
   oneRecord.phone =
      contactInfoElem.getElementsByTagName("phone")[0].firstChild.data;
   oneRecord.fax =
      contactInfoElem.getElementsByTagName("fax")[0].firstChild.data;
   oneRecord.manager =
      new Object();
   var oneMgrElem =
      oneElem.getElementsByTagName("manager")[0];
   oneRecord.manager.id =
      oneMgrElem.getElementsByTagName("employeeid")[0].firstChild.data;
   oneRecord.manager.firstName =
      oneMgrElem.getElementsByTagName("firstname")[0].firstChild.data;
   oneRecord.manager.lastName =
      oneMgrElem.getElementsByTagName("lastname")[0].firstChild.data;
   oneRecord.region =
      oneElem.getElementsByTagName("region")[0].firstChild.data;
   oneRecord.sales =
      new Array();
   var allPeriods =
      oneElem.getElementsByTagName("salesrecord")[0].childNodes;
   var temp;
   var accumForecast = 0, accumActual = 0;
   for (var i = 0; i < allPeriods.length; i++)
   {
      if (allPeriods[i].nodeType == 1)
      {
         temp =
            new Object();
         temp.period =
            allPeriods[i].getElementsByTagName("id")[0].firstChild.data;
```

```
            temp.forecast =
              parseInt(allPeriods[i].getElementsByTagName("forecast")
                      [0].firstChild.data);
            temp.actual =
               parseInt(allPeriods[i].getElementsByTagName("actual")
                      [0].firstChild.data);
            temp.quotaPct =
               getPercentage(temp.actual, temp.forecast);
            oneRecord.sales[temp.period] =
               temp;
            accumForecast += temp.forecast;
            accumActual += temp.actual;
         }
      }
      oneRecord.totalForecast = accumForecast;
      oneRecord.totalActual = accumActual;
      oneRecord.totalQuotaPct = getPercentage(accumActual, accumForecast);
      return oneRecord;
   }
   function getPercentage(actual, forecast)
   {
      var pct = (actual/forecast * 100) + "";
      pct = pct.match(/\d*\.\d/);
      return parseFloat(pct);
   }
   // End JavaScript object simulator
```

Assuming that the raw XML database stores only the sales forecast and actual dollar figures, it is up to analysis programs to perform their own calculations, such as how the actual sales compare against the forecasts. As you saw in the illustration of the rendered table, this application not only displays the percentage differences between the pairs of values, but it also provides sorting facilities on those percentages. To speed the sorting, the percentages are calculated as the JavaScript database is being accumulated, and stored as properties of each object. Percentage calculation is called upon in two different statements of the `getOneSalesRep()` function, so that the calculation is broken out to its own function, `getPercentage()`. In that function, the two passed values are massaged to calculate the percentage value, and then the string result is formatted to no more than one digit to the right of the decimal (by way of a regular expression). The value returned for the property assignment is converted to a number data type, because sorting on these values needs to be done according to numeric sorting, rather than string sorting.

You can already get a glimpse at the contribution JavaScript is making to the scripted representation of the data transmitted in XML form. By virtue of planning for subsequent calculations, the JavaScript object contains considerably more information than was originally delivered, yet all the properties are derived from “hard” data supplied by the server database.

Sorting the JavaScript database

With so many sorting keys for the user to choose from, it’s no surprise that sorting code occupies a good number of script lines in this application. All sorting code consists of two major blocks: *dispatching* and *sorting*.

The dispatching portion is nothing more than one gigantic `switch` construction that sends execution to one of the 17 (!) sorting functions that match whichever sort key is chosen in the `select` element on the page. This dispatcher function, `selectSort()`, is also invoked from the `init()` function at load time. Thus, if the user makes a choice in the page, navigates to another page, and then returns with the page still showing the previous selection, the `onload` event handler will reconstruct the table precisely as it was. When sorting is completed, the table is drawn, as you see shortly.

```
function selectSort(chooser)
{
   switch (chooser.value)
   {
   case "byRep" :
      db.sort(sortDBByRep);
      break;
   case "byRegion" :
      db.sort(sortDBByRegion);
      break;
   case "byQ1Fcst" :
      db.sort(sortDBByQ1Fcst);
      break;
   case "byQ1Actual" :
      db.sort(sortDBByQ1Actual);
      break;
   case "byQ1Quota" :
      db.sort(sortDBByQ1Quota);
      break;
   case "byQ2Fcst" :
      db.sort(sortDBByQ2Fcst);
      break;
   case "byQ2Actual" :
      db.sort(sortDBByQ2Actual);
      break;
   case "byQ2Quota" :
      db.sort(sortDBByQ2Quota);
      break;
   case "byQ3Fcst" :
      db.sort(sortDBByQ3Fcst);
      break;
   case "byQ3Actual" :
      db.sort(sortDBByQ3Actual);
      break;
   case "byQ3Quota" :
      db.sort(sortDBByQ3Quota);
      break;
   case "byQ4Fcst" :
      db.sort(sortDBByQ4Fcst);
      break;
   case "byQ4Actual" :
      db.sort(sortDBByQ4Actual);
```

```
      break;
   case "byQ4Quota" :
      db.sort(sortDBByQ4Quota);
      break;
   case "byTotalFcst" :
      db.sort(sortDBByTotalFcst);
      break;
   case "byTotalActual" :
      db.sort(sortDBByTotalActual);
      break;
   case "byTotalQuota" :
      db.sort(sortDBByTotalQuota);
      break;
   }
   drawTextTable();
}
```

Each specific sorting routine is a function that automatically works repeatedly on pairs of entries in an array (see Chapter 18, "The Array Object"). Array entries here (from the `db` array) are objects — and rather complex objects at that. The benefit of using JavaScript array sorting is that the sorting can be performed on any property of objects stored in the array. For example, sorting on the `lastName` property of each `db` array object is based on a comparison of the `lastName` property for each of the pairs of array entries passed to the `sortDBByRep()` function. But looking down a little further, you can see that the mechanism allows sorting on even more deeply nested properties, such as the `sales.Q1_2006.forecast` property of each array entry. If a property in an object can be referenced, it can be used as a sorting property inside one of these functions.

```
function sortDBByRep(a, b)
{
   if (document.getElementById("orderChooser").value == "inc")
   {
      return (a.lastName < b.lastName) ? -1 : 1;
   }
   else
   {
      return (a.lastName > b.lastName) ? -1 : 1;
   }
}
function sortDBByRegion(a, b)
{
   if (document.getElementById("orderChooser").value == "inc")
   {
      return (a.region < b.region) ? -1 : 1;
   }
   else
   {
      return (a.region > b.region) ? -1 : 1;
   }
}
```

```
function sortDBByQ1Fcst(a, b)
{
   if (document.getElementById("orderChooser").value == "inc")
   {
      return (a.sales.Q1_2006.forecast - b.sales.Q1_2006.forecast);
   }
   else
   {
      return (b.sales.Q1_2006.forecast - a.sales.Q1_2006.forecast);
   }
}
function sortDBByQ1Actual(a, b)
{
   if (document.getElementById("orderChooser").value == "inc")
   {
      return (a.sales.Q1_2006.actual - b.sales.Q1_2006.actual);
   }
   else
   {
      return (b.sales.Q1_2006.actual - a.sales.Q1_2006.actual);
   }
}
function sortDBByQ1Quota(a, b)
{
   if (document.getElementById("orderChooser").value == "inc")
   {
      return (a.sales.Q1_2006.quotaPct - b.sales.Q1_2006.quotaPct);
   }
   else
   {
      return (b.sales.Q1_2006.quotaPct - a.sales.Q1_2006.quotaPct);
   }
}
function sortDBByQ2Fcst(a, b)
{
   if (document.getElementById("orderChooser").value == "inc")
   {
      return (a.sales.Q2_2006.forecast - b.sales.Q2_2006.forecast);
   }
   else
   {
      return (b.sales.Q2_2006.forecast - a.sales.Q2_2006.forecast);
   }
}
function sortDBByQ2Actual(a, b)
{
   if (document.getElementById("orderChooser").value == "inc")
   {
      return (a.sales.Q2_2006.actual - b.sales.Q2_2006.actual);
   }
   else
```

```
      {
         return (b.sales.Q2_2006.actual - a.sales.Q2_2006.actual);
      }
   }
   function sortDBByQ2Quota(a, b)
   {
      if (document.getElementById("orderChooser").value == "inc")
      {
         return (a.sales.Q2_2006.quotaPct - b.sales.Q2_2006.quotaPct);
      }
      else
      {
         return (b.sales.Q2_2006.quotaPct - a.sales.Q2_2006.quotaPct);
      }
   }
   function sortDBByQ3Fcst(a, b)
   {
      if (document.getElementById("orderChooser").value == "inc")
      {
         return (a.sales.Q3_2006.forecast - b.sales.Q3_2006.forecast);
      }
      else
      {
         return (b.sales.Q3_2006.forecast - a.sales.Q3_2006.forecast);
      }
   }
   function sortDBByQ3Actual(a, b)
   {
      if (document.getElementById("orderChooser").value == "inc")
      {
         return (a.sales.Q3_2006.actual - b.sales.Q3_2006.actual);
      }
      else
      {
         return (b.sales.Q3_2006.actual - a.sales.Q3_2006.actual);
      }
   }
   function sortDBByQ3Quota(a, b)
   {
      if (document.getElementById("orderChooser").value == "inc")
      {
         return (a.sales.Q3_2006.quotaPct - b.sales.Q3_2006.quotaPct);
      }
      else
      {
         return (b.sales.Q3_2006.quotaPct - a.sales.Q3_2006.quotaPct);
      }
   }
   function sortDBByQ4Fcst(a, b)
   {
      if (document.getElementById("orderChooser").value == "inc")
```

```
      {
         return (a.sales.Q4_2006.forecast - b.sales.Q4_2006.forecast);
      }
      else
      {
         return (b.sales.Q4_2006.forecast - a.sales.Q4_2006.forecast);
      }
   }
   function sortDBByQ4Actual(a, b)
   {
      if (document.getElementById("orderChooser").value == "inc")
      {
         return (a.sales.Q4_2006.actual - b.sales.Q4_2006.actual);
      }
      else
      {
         return (b.sales.Q4_2006.actual - a.sales.Q4_2006.actual);
      }
   }
   function sortDBByQ4Quota(a, b)
   {
      if (document.getElementById("orderChooser").value == "inc")
      {
         return (a.sales.Q4_2006.quotaPct - b.sales.Q4_2006.quotaPct);
      }
      else
      {
         return (b.sales.Q4_2006.quotaPct - a.sales.Q4_2006.quotaPct);
      }
   }
   function sortDBByTotalFcst(a, b)
   {
      if (document.getElementById("orderChooser").value == "inc")
      {
         return (a.totalForecast - b.totalForecast);
      }
      else
      {
         return (b.totalForecast - a.totalForecast);
      }
   }
   function sortDBByTotalActual(a, b)
   {
      if (document.getElementById("orderChooser").value == "inc")
      {
         return (a.totalActual - b.totalActual);
      }
      else
      {
         return (b.totalActual - a.totalActual);
      }
```

```
}
function sortDBByTotalQuota(a, b)
{
   if (document.getElementById("orderChooser").value == "inc")
   {
      return (a.totalQuotaPct - b.totalQuotaPct);
   }
   else
   {
      return (b.totalQuotaPct - a.totalQuotaPct);
   }
}
```

For this application, all sorting functions branch in their execution based on the choice made in the "Ordered" `select` element on the page. The relative position of the two array elements under test in these simple subtraction comparison statements reverses when the sort order is reversed from low-to-high (increasing) to high-to-low (decreasing). This kind of array sorting is extremely powerful in JavaScript and probably escapes the attention of most scripters.

Constructing the table

As recommended in Chapter 41's discussion of `table` and related elements, it is often convenient to manipulate the structure of a `table` element by way of the specialized methods for tables, rather than mess with nodes and elements. The `drawTextTable()` function is devoted to employing those methods to create the rendered contents of the table below the headers (which are hard-wired in the document's HTML). Composing an 11-column table requires a bit of code, and the `drawTextTable()`'s length attests to that fact. You can tell by just glancing at the code, however, that for big chunks of it, there is a comfortable regularity that is aided by the JavaScript object that holds the data.

Additional calculations take place while the table's elements are being added to the `table` element. Column totals are accumulated during the table assembly (row totals are calculated as the object is generated, and preserved as properties of the object). A large `for` loop cycles through each (sorted) row of the `db` array; each row of the `db` array corresponds to a row of the table. Class names are assigned to various rows or cells so that they will pick up the style sheet rules defined earlier in the document. Another subtlety of this version is that the `region` property of a sales rep is assigned to the `title` property of a row. If the user pauses the mouse pointer anywhere in that row, the name of the region pops up briefly.

```
function drawTextTable()
{
   var newRow;
   var accumQ1F = 0, accumQ1A = 0, accumQ2F = 0, accumQ2A = 0;
   var accumQ3F = 0, accumQ3A = 0, accumQ4F = 0, accumQ4A = 0;
   deleteRows(document.getElementById("mainTableBody"));
   for (var i = 0; i < db.length; i++)
   {
      newRow = document.getElementById("mainTableBody").insertRow(i);
```

```
        newRow.className = db[i].region;
        newRow.title = db[i].region
                    + " Region";
        appendCell(newRow, "rep",
                   db[i].firstName +
                   " " +
                   db[i].lastName);
        appendCell(newRow, "Q1",
                   db[i].sales.Q1_2006.forecast +
                   "<br />" +
                   db[i].sales.Q1_2006.actual);
        appendCell(newRow, "Q1",
                   db[i].sales.Q1_2006.quotaPct +
                   "%");
        appendCell(newRow, "Q2",
                   db[i].sales.Q2_2006.forecast +
                   "<br />" +
                   db[i].sales.Q2_2006.actual);
        appendCell(newRow, "Q2",
                   db[i].sales.Q2_2006.quotaPct +
                   "%");
        appendCell(newRow, "Q3",
                   db[i].sales.Q3_2006.forecast +
                   "<br />" +
                   db[i].sales.Q3_2006.actual);
        appendCell(newRow, "Q3",
                   db[i].sales.Q3_2006.quotaPct +
                   "%");
        appendCell(newRow, "Q4",
                   db[i].sales.Q4_2006.forecast +
                   "<br />" +
                   db[i].sales.Q4_2006.actual);
        appendCell(newRow, "Q4",
                   db[i].sales.Q4_2006.quotaPct +
                   "%");
        accumQ1F += db[i].sales.Q1_2006.forecast;
        accumQ1A += db[i].sales.Q1_2006.actual;
        accumQ2F += db[i].sales.Q2_2006.forecast;
        accumQ2A += db[i].sales.Q2_2006.actual;
        accumQ3F += db[i].sales.Q3_2006.forecast;
        accumQ3A += db[i].sales.Q3_2006.actual;
        accumQ4F += db[i].sales.Q4_2006.forecast;
        accumQ4A += db[i].sales.Q4_2006.actual;
        appendCell(newRow, "repTotal",
                   db[i].totalForecast +
                   "<br />" +
                   db[i].totalActual);
        appendCell(newRow, "repTotal",
                   db[i].totalQuotaPct +
                   "%");
    }
```

```
   newRow = document.getElementById("mainTableBody").insertRow(i);
   newRow.className = "QTotal";
   newRow.title = "Totals";
   appendCell(newRow,
              "grandTotalLabel",
              "Grand Total");
   appendCell(newRow,
              "Q1",
              accumQ1F + "<br />" + accumQ1A);
   appendCell(newRow,
              "Q1",
              getPercentage(accumQ1A, accumQ1F) + "%");
   appendCell(newRow,
              "Q2",
              accumQ2F + "<br />" + accumQ2A);
   appendCell(newRow,
              "Q2",
              getPercentage(accumQ2A, accumQ2F) + "%");
   appendCell(newRow,
              "Q3",
              accumQ3F + "<br />" + accumQ3A);
   appendCell(newRow,
              "Q3",
              getPercentage(accumQ3A, accumQ3F) + "%");
   appendCell(newRow,
              "Q4",
              accumQ4F + "<br />" + accumQ4A);
   appendCell(newRow,
              "Q4",
              getPercentage(accumQ4A, accumQ4F) + "%");
   var grandTotalFcst = accumQ1F
                      + accumQ2F
                      + accumQ3F
                      + accumQ4F;
   var grandTotalActual = accumQ1A
                        + accumQ2A
                        + accumQ3A
                        + accumQ4A;
   appendCell(newRow,
              "grandTotal",
              grandTotalFcst + "<br />" + grandTotalActual);
   appendCell(newRow,
              "grandTotal",
              getPercentage(grandTotalActual, grandTotalFcst) + "%");
}

function appendCell(Trow, Cclass, txt)
{
   var newCell = Trow.insertCell(Trow.cells.length);
   newCell.className = Cclass;
   newCell.innerHTML = txt;
```

```
}
function deleteRows(tbl)
{
   while (tbl.rows.length > 0)
   {
      tbl.deleteRow(0);
   }
}
```

Note

As handy as it may be, in a strict W3C approach to JavaScript, you wouldn't use the `innerHTML` property since it isn't officially part of the W3C standard. However, it is often too powerful a convenience property to ignore, as much of the code throughout this book is a testament. The book does show the W3C node manipulation alternative to `innerHTML` in some examples. Refer to Chapter 29, "The Document and Body Objects," for a thorough explanation and examples of the W3C alternative to `innerHTML`. ■

Many standalone statements at the end of the `drawTextTable()` function are devoted exclusively to generating the Grand Total row, in which the accumulated column totals are entered. At the same time, the `getPercentage()` function, described earlier, is invoked several times again to derive the quota percentage for the accumulated grand total values in each quarter, as well as the complete year.

select controls

To round out the code listing for this application, the values assigned to the two `select` elements obviously have a lot to do with the execution of numerous functions in this application. Nothing magical takes place here, but you can see the extent of the detail required in assigning script-meaningful hidden values and human-meaningful text for both `select` elements. For example, dividing lines help organize the long sort key list into three logical blocks.

```
<p>Sort by:
 <select id="sortChooser" onchange="selectSort(this)">
   <option value="byRep">Representative</option>
   <option value="byRegion">Sales Region</option>
   <option value="">---------------------</option>
   <option value="byQ1Fcst">Q1 Forecast</option>
   <option value="byQ1Actual">Q1 Actual</option>
   <option value="byQ1Quota">Q1 Performance</option>
   <option value="byQ2Fcst">Q2 Forecast</option>
   <option value="byQ2Actual">Q2 Actual</option>
   <option value="byQ2Quota">Q2 Performance</option>
   <option value="byQ3Fcst">Q3 Forecast</option>
   <option value="byQ3Actual">Q3 Actual</option>
   <option value="byQ3Quota">Q3 Performance</option>
   <option value="byQ4Fcst">Q4 Forecast</option>
   <option value="byQ4Actual">Q4 Actual</option>
   <option value="byQ4Quota">Q4 Performance</option>
   <option value="">---------------------</option>
```

```
      <option value="byTotalFcst">Total Forecast</option>
      <option value="byTotalActual">Total Actual</option>
      <option value="byTotalQuota">Total Performance</option>
    </select>
       Ordered:
    <select id="orderChooser"
            onchange="selectOrder()">
      <option value="inc">Low to High</option>
      <option value="dec">High to Low</option>
    </select>
  </p>
```

Note

The property assignment event handling technique used in this example is a deliberate simplification to make the code more readable. It is generally better to use the more modern approach of binding events using the `addEventListener()` (NN6+/Moz/W3C) or `attachEvent()` (IE5+) methods. A modern cross-browser event handling technique is explained in detail in Chapter 32, "Event Objects." ■

Further Thoughts

Confining the example to just one type of view — a table of numbers — should help you grasp the important processes taking place. But with the XML data converted to JavaScript objects, you can build many other views of the same data into the same page. For example, a script could completely hide the numeric table and generate a different one that draws bar charts for each sales representative or each region (see Chapter 58, "Application: Decision Helper," for a scripted bar chart example). The horizontal axis would be the four quarters, and the vertical axis would be dollars or quota percentages. Clicking a bar opens a small window or layer to reveal more detail from the sales representative's record, such as the name of the person's manager. More `select` elements can let the user select any combination of subsets of the data in either bar chart or numeric table form to facilitate visual comparisons. You might be even more creative, and devise ways of showing the data by way of overlapping positioned elements.

CHAPTER

61

Application: Creating Custom Google Maps

IN THIS CHAPTER

The basics of Google mapping

Converting a physical address into geocoordinates

XML as a map language

Using Ajax to create Google maps

Seeing as how JavaScript is an incredibly practical technology, it's only fitting that this book should end with what may be the most practical of all JavaScript examples: a custom interactive map based upon Google's popular Google Maps tool. Google Maps is an online mapping tool that utilizes asynchronous JavaScript and XML (Ajax) to provide a traditional vector map view, along with a satellite photography view, and even a hybrid view that overlays vector street information onto the photographic satellite map. One of the features that makes Google Maps so interesting is the fact that it is customizable through a programming interface that Google has made available to web developers. Both JavaScript and XML factor heavily into Google Maps and how you go about customizing it. This chapter introduces you to the inner workings of Google Maps and guides you through a complete map customization example.

A Google Maps Primer

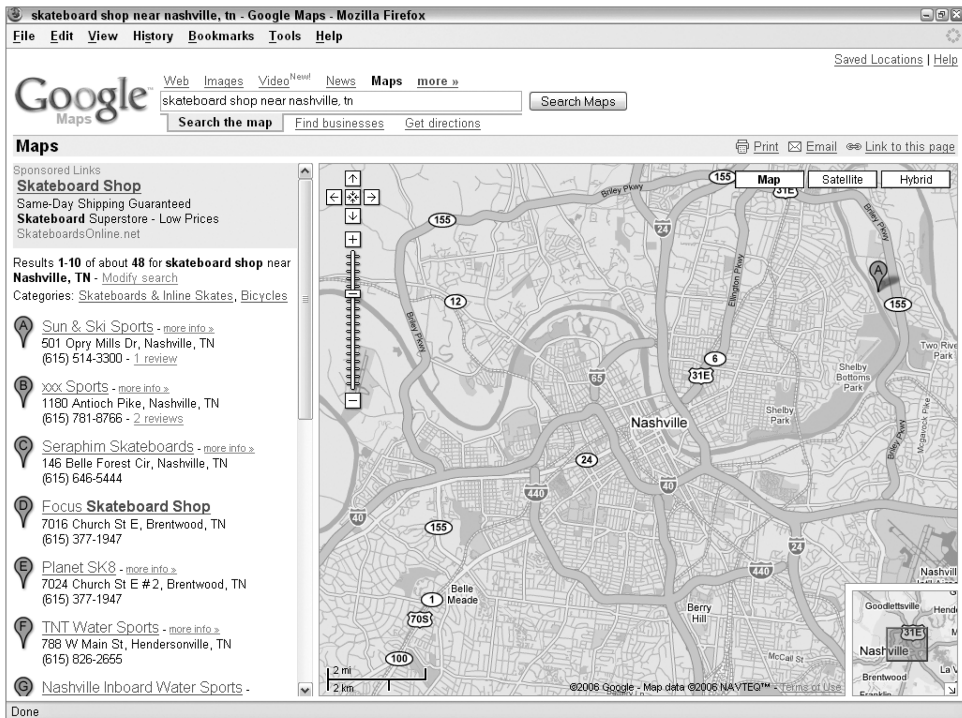
Although Google Maps is plenty of fun to tinker with purely from a user's perspective in terms of exploring the built-in map features, it's the development potential that truly makes it an exciting technology. In 2005 Google made available to the public an application programming interface (API) for Google Maps that allows web developers to build custom mapping applications. This API is the key to creating custom Google maps, such as the one examined in this chapter.

If you've never used Google Maps, take a moment to explore `http://maps.google.com`. It's important to understand the core tool before attempting to customize it to suit your own needs. When you get accustomed to how a standard Google map works, you'll have a greater appreciation of what goes into a custom map.

When Google Maps first starts, there is nothing particularly surprising about it, since all you see is a map of the United States. But keep in mind that this is Google we're talking about, the master of the search engine. Enter a search in Google Maps to watch it come to life. For example, enter "skateboard shop near nashville, tn" in the main search box, and click the Search button (feel free to insert your own hometown). Figure 61-1 shows the resulting map after searching for skateboard shops near Nashville, Tennessee.

FIGURE 61-1

The search feature in Google Maps is very effective at finding places of interest.

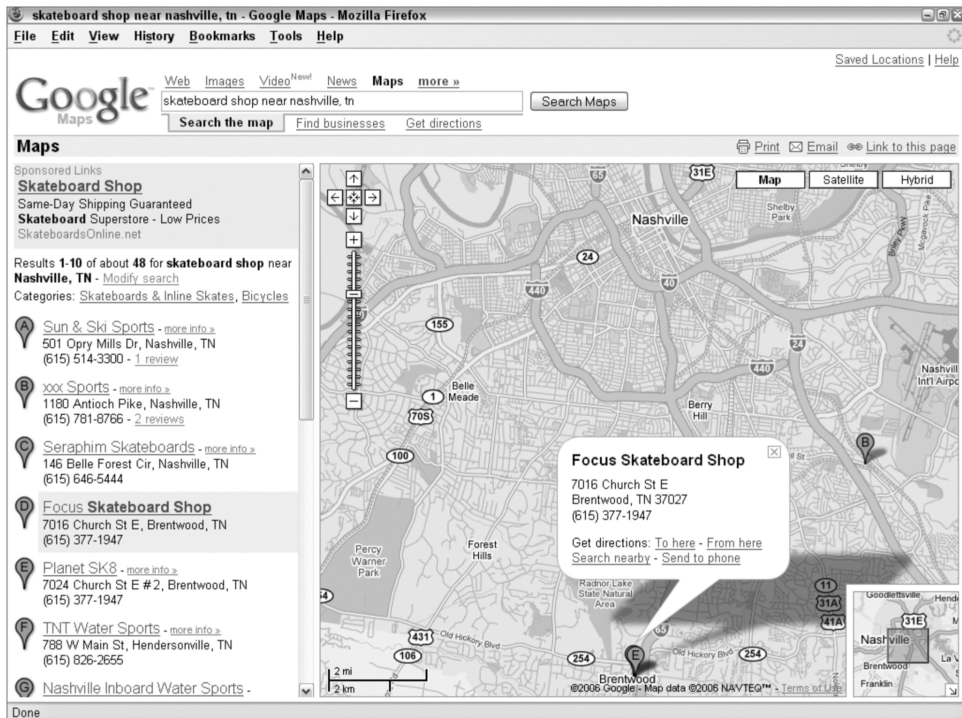


Now you're starting to see some of the power of Google Maps, and of the concept known as mashups. A *mashup* describes a web-based application that combines two existing applications to create an entirely new one. In this case, you can think of Google Maps itself as somewhat of a mashup because it combines an online map with a business directory. In reality, Google Maps has become a popular component of other mashups, some of which you find out about in a moment.

Getting back to the example, each search match in Google Maps results in a marker being placed on the map. To find out more information about one of the skateboard shops found, click it in the results list, or find its marker and click it on the map. Figure 61-2 shows how an information window appears that identifies the name of the location, along with its address. If a web site had been found for the business, it would also appear here.

FIGURE 61-2

Clicking a marker enables you to get more information about a location.



Keep in mind that at any point while using Google Maps you can click and drag the map or click the zoom control in the upper-left corner of the map. Or maybe you want to see an actual satellite photo image of the map instead of vector map graphics. Just click the Satellite button in the upper-right corner of the map. More than likely you'll find the Hybrid view to be more useful than the Satellite view. The Hybrid view displays a satellite image with streets and street names overlaid, which makes most maps much easier to read.

Note

You can use the plus (+) and minus (–) keys on your keyboard as shortcuts for zooming in and out of a map, respectively. ■

Local search is another very handy feature of Google Maps that you won't want to overlook. While viewing any map on the screen, you can click Local Search, and then perform a search on any piece of information. As an example, say you're planning on visiting Franklin, Tennessee, on business, and you're interested in doing a little cycling on the Natchez Trace Parkway while you're in town. You've already been exploring the area in Google Maps, but you don't know anything about area bicycle shops. Just enter "bicycle rental" as a local search and let Google Maps do the rest.

Google always has several interesting applications in the works. To learn more about the current experiments, visit `http://www.googlelabs.com/`.

There are a lot of other interesting features that Google Maps has to offer, but at some point I have to get to the point of this chapter, which is how to use XML to customize Google Maps. However, I'd like to leave you with a few Google Maps–related links to explore as you learn more about the service and what all it can do:

- **Google Moon:** The Moon as viewed through Google Maps; make sure you zoom all the way in (`http://moon.google.com/`)
- **Chicago Crime:** Locations of crimes committed in the Chicago metropolitan area (`http://www.chicagocrime.org/`)
- **Weather Bonk:** Real-time mapped weather information and web cams (`http://www.weatherbonk.com/`)
- **Google Maps Directory:** Directory of Google Maps applications (`http://www.gmdir.com/`)

This list provides plenty of interesting sites to keep you busy for a while. When you're finished traveling around these maps, prepare to take the next logical step: create your own mapping application.

Google Maps Customization Basics

Customizing Google Maps to create a custom mapping application is fairly straightforward, but it does require a few preliminary steps before you can even start thinking about JavaScript code or web pages.

- First off, although Google exposes the Google Maps API for anyone to use, the company requires you to obtain a special API key in order to use the API in your own web pages.
- Secondly, you need to understand some basics about the Google Maps API and how it is used to create and customize maps through JavaScript code.
- Finally, locations in Google Maps are specified through geocoordinates, which you probably don't have readily available for the locations you're interested in mapping. For this reason, you need to learn how to obtain the latitude and longitude of a location based upon its physical (mailing) address.

The next few sections explore each of these topics in more detail.

Getting your own API key

The easiest part of the map creation process is obtaining your own Google Maps API key. This virtual key is literally your key to being able to view, test, and share your map creations with others. A Google Maps API key is completely free of charge; presumably, it is required so that Google can keep close tabs on how their technology is being used.

You can sign up and obtain an API key by visiting `http://www.google.com/apis/maps/signup.html`. This page requires you to enter the URL of the web site to which you plan on publishing your maps. A single API key gives you the ability to publish maps to one folder on one web server. As an example, if I register an API key for `http://www.example.com/maps`, I can publish maps only to the `maps` folder on my web server, and nowhere else. (Well, technically I can publish them wherever I want on my web server, but they'll only work if I place them in the `maps` folder.) Make sure you actually publish your maps to the URL you specify when obtaining your API key. If you want to create different maps and store them in different folders, you'll need to obtain a different API key for each unique base URL.

The API key is provided to you as a long text code that you will cut and paste into your mapping code later. For now, copy and paste the code into a text file and save it for later.

Inside the Google Maps API

The Google Maps API consists of a set of JavaScript functions that you call to create and manipulate a map within an HTML web page. Every map must have a standard `<script>` tag in the head of the HTML document that references the Google Maps API and specifies your API key. Following is an example of how this tag is coded:

```
<script
src="http://maps.google.com/maps?file=api&amp;v=2&amp;key=ABQIAAAAY7yQRiC6EI41ks
qEpofW3BRdYuPG5WBWUHzdnWjZCVWXDwCyyRS26iZXfNWk97uGn615z44
   _i9klyg&amp;sensor=false" type="text/javascript"></script>
```

The API key is too long to fit on one line of printed text in this book, which is why you see it broken across multiple lines. In your HTML code, be sure not to add any spaces or line breaks in the API key. After placing the API key script code in the head of a web page, you can begin calling API functions to create the map itself. Unlike the API key script code, the actual map script code goes in the body of the document.

Note

As you will quickly see, the Google Maps API names its functions and objects with identifiers starting with a capital `G`. If you see a reference in the example code here that begins with `G`, it is not part of the JavaScript language or the browser's DOM, but rather something provided by Google's API. ■

As of this writing, the Google Maps API is at version 2. Version 1 is no longer supported, so this chapter's original application, written for an earlier edition of this book, no longer works. However, a copy of the version 1 code has been included in the CD-ROM, so that if you have to upgrade from version 1 to version 2, you'll have some clues as to the direction you should go. Be aware that the Google Maps API is updated often, sometimes weekly. Revisit your web site frequently and test to see if an API update has affected your map.

The `GMap2()` function is called to create a new map. This function expects, as its only argument, the element on the page that is to contain the map:

```
var map = new GMap2(document.getElementById("myMap"));
```

The map container element is typically a div element, as in the following example code:

```
<div id="myMap" style="width:800px; height:600px"></div>
```

Notice that the ID of the div element is myMap, which corresponds to the ID of the element passed into the GMap2() function. This is how the map gets connected to a container element on the web page.

The Google Maps API offers several different user interface controls for you to use. The standard control that consists of full-sized pan/zoom buttons is represented by the GLargeMapControl object. There is also a smaller control called GSmallMapControl, as well as a control with no pan features at all called GSmallZoomControl. To set the control for a map, you call the addControl() method on the newly created map, like this:

```
map.addControl(new GLargeMapControl());
```

There is also a control that determines whether or not you can switch between the different map views (Map, Satellite, and Hybrid). To enable this control, add the GMapTypeControl object to the map with the following piece of code:

```
map.addControl(new GMapTypeControl());
```

With the map and controls in place, you're ready to set the default area for the map, which is based upon a geocoordinate as well as a zoom level. You learn how to find a geocoordinate for a location in the next section. For now, just understand that it consists of two numbers that represent the latitude and longitude of a location. Furthermore, the zoom level of the map is set to an integer number that you will likely need to experiment with to find a zoom level that suits your specific map. Following is the code that centers and zooms a map at a specific geocoordinate and zoom level:

```
var point = new GLatLng(36.071689, -88.053171);
map.setCenter(point, 8);
```

The last step in creating a custom map is creating the markers on the map, which can also involve using custom icon images, if you so choose. Custom icons in Google Maps actually consist of two images: the icon image and a shadow for the icon. You learn more about these images a bit later in the chapter. For now, take a look at the following code, which shows how to create a marker with a custom icon, as well as how to set a listener function that opens an information window when the marker is clicked.

```
var baseIcon = new GIcon();
baseIcon.iconSize = new GSize(48, 48);
baseIcon.shadowSize = new GSize(70, 48);
baseIcon.iconAnchor = new GLatLng(38, 24);
baseIcon.infoWindowAnchor = new GLatLng(20, 24);
var icon = new GIcon(baseIcon);
icon.image = "ghosticon.png";
icon.shadow = "ghosticon_sh.png";
var marker = new GMarker(point, icon);
```

```
GEvent.addListener(marker, "click",
   function()
   {
      // code to build the HTML goes here
      marker.openInfoWindowHtml(placeHTML);
   }
);
```

The main thing to note in this code is how the various icon sizes are specified, including the relative offset of the icon anchor and the information window anchor. These offsets determine how the marker icon image is positioned relative to the location on the map, as well as the offset of the information window with respect to the marker. The last seven lines of code look messier than they truly are; all they do is open an information window and display within it an HTML element, which you might have to build. You'll see an example later.

Obtaining the geocoordinates of a location

Although Google Maps is typically queried based upon the mailing address of a location, when you deal directly with the Google Maps API, you are required to use more accurate location data. More specifically, you must use a location's latitude and longitude, also known as its geocoordinates, when specifying its position to the Google Maps API. Since you probably haven't committed to memory the latitude and longitude of your favorite hang outs, you'll likely need to use a tool to find out the coordinates of any address that you want to include on a map. Fortunately, exactly such a tool exists in the form of the geocoder.us web site, located at `http://geocoder.us`.

This web site enables you to enter an address much as you would enter it in Google Maps. Assuming the address is successfully found, geocoder displays the latitude and longitude of the address, which you can then use in Google Maps to specify the exact position of the location.

Another decent option for obtaining the latitude and longitude of a location is to use a GPS receiver. Of course, you'll have to physically travel to the location so that its latitude and longitude are registered on your GPS device.

Note

If you have trouble finding a match for an address on the geocoder.us site, you might consider just getting close by using a known nearby address. ■

Designing a Google Maps Mashup

There are all kinds of interesting prospects out there when it comes to dreaming up your own custom Google Maps application. The example application that you work through in the remainder of this chapter is based upon the notion of organizing a collection of relevant places on a map. More specifically, you find out how to create a haunted map that reveals several haunted places in the state of Tennessee.

In this example, the custom mapping application involves several facets:

- Developing an XML language for coding haunted places
- Interacting with the Google Maps API to open and display a map centered on a certain place
- Using the Google Maps API to create custom markers for the places
- Using CSS with generated HTML to present a unique information window for each place when it is clicked in Google Maps

Although this example map is certainly intended to be for fun, you could just as easily plug in more serious data and create a map that serves a vital purpose. That's what's so great about data-driven applications such as Google Maps.

Developing a Custom Map Document

Developing a custom Google Maps application first involves deciding on a format for the data that you plan on feeding into Google Maps. Since the example application you're working through in this chapter involves mapping haunted places, it's worth considering what pieces of information you might want to code into an XML document to map a place that is supposedly haunted:

- Place name
- Geocoordinates (latitude and longitude)
- Physical address (mailing address)
- Thumbnail image
- Summary of why the place is considered haunted
- Link to a web site containing more information

These pieces of information are sufficient to describe any haunted place for the purposes of displaying information about it in Google Maps. The trick is then determining the best way to effectively represent this information in the context of an XML document. Listing 61-1 contains a portion of a document that solves this problem.

LISTING 61-1

Modeling Haunted Place Data in XML

```
<?xml version="1.0"?>
<places>
   <place>
      <location lat="36.585414" long="-87.061648" />
      <description>
         <name>Bell Witch Cave</name>
```

continued

LISTING 61-1 *(continued)*

```
         <url>http://www.bellwitchcave.com/</url>
         <address>430 Keysburg Rd</address>
         <address2>Adams, TN 37010</address2>
         <img>bellwitch.jpg</img>
         <summary>Without a doubt the most famous Tennessee ghost story, the
         Bell Witch tormented the Bell family in the early 1800s. Legend has
         it that the witch was even responsible for the death of John Bell,
         then owner of the Bell farm. Bell Witch sightings exist to this day, and
         the witch is thought to live in a cave on the property that has become
         known as Bell Witch Cave.</summary>
      </description>
   </place>
   <place>
      <location lat="35.904865" long="-86.862472" />
      <description>
         <name>Carnton Mansion</name>
         <url>http://www.carnton.org/</url>
         <address>1345 Carnton Ln</address>
         <address2>Franklin, TN 37064</address2>
         <img>carnton.jpg</img>
         <summary>The Battle of Franklin represents one of the bloodiest
         Confederate losses in the Civil War, and Carnton Mansion played host
         to many of the dead and wounded soldiers. Five generals died on the
         front porch of the mansion, and one of them has since reportedly been
         seen riding a horse through the fields around the mansion. There is
         also legend of a restless soldier who has been seen and heard walking
         through the house.</summary>
      </description>
   </place>
...
</places>
```

The listing contains a portion of the code for the places.xml example document that houses XML data for the haunted places example mapping application. The document is laid out as a series of <place> elements, each representing an individual haunted place. These elements appear within the root <places> element. Inside of each <place> element is a location element that contains the latitude and longitude and a <description> element that describes more details about the place. The <name>, <url>, <address>, <address2>, <img>, and <summary> elements all combine to provide data that will appear in the information window in Google Maps when the user clicks on a marker.

Although the description information is important for adding context to the map, all Google Maps really cares about is the latitude and longitude stored within the <location> element. Everything else in the document is just supplementary data to provide additional information when the user clicks one of the markers on the map.

Note

It's important to point out that the haunted place images, CSS file, and XML file in this example document are specified without any path information, which means that they are expected to reside in the same directory as the HTML document. ■

Hacking Together a Custom Google Map

Developing a customized map for Google Maps is really a three-step process:

1. You put together a suitable XML document to house your map data, which you've already done.
2. Then you create an HTML web page with requisite JavaScript code that creates the map and handles the majority of the work in running the application.
3. Finally, you create a function that is responsible for generating the HTML content to be displayed in an information window when a marker is clicked on the map. You might also choose to develop an external CSS style sheet for formatting the content.

Displaying the custom map

Earlier in the chapter, I mentioned that Google Maps relies on Ajax as a critical part of its design. You now get to see how JavaScript code is used to manipulate XML into creating a custom interactive map, all with the power of asynchronous Ajax code.

Cross-Reference

Refer to Chapter 39, "Ajax, E4X, and XML," if you need to brush up on Ajax. ■

Listing 61-2 contains the complete code for the `hauntmap.html` web page.

LISTING 61-2

Taming Haunted Google Maps with JavaScript

```
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Strict//EN"
    "http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" xml:lang="en" lang="en">
   <head>
      <meta http-equiv="content-type" content="text/html;charset=utf-8" />
      <title>Haunted Places Map</title>
      <script

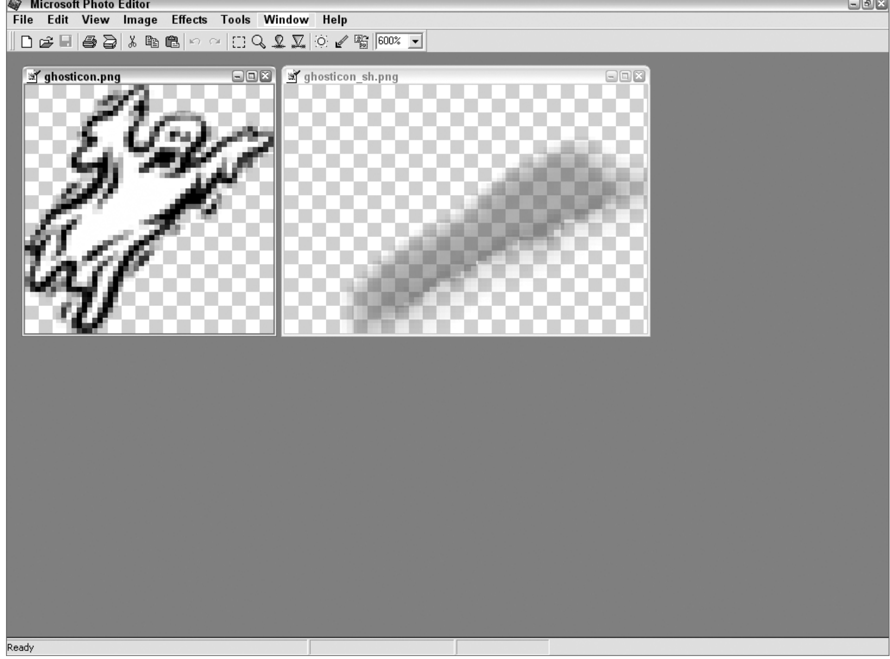
                    parseFloat(hauntedLocations[i].getAttribute("lat")),
                    parseFloat(hauntedLocations[i].getAttribute("long"))
                );
                var marker = createMarker(hauntedPlaces[i], hauntedPoint,
                                          descriptions[i]);
                map.addOverlay(marker);
            }
        }
        );
    //-->
    </script>
  </body>
</html>
```

The first part of this web page should be somewhat familiar to you, thanks to the earlier primer on the Google Maps API. Most of this code follows the general template you saw earlier, regarding how a map is created, controls are added, a default view is established, and so on. You'll notice that two marker images are required in the script: one for the ghost marker icon and one for its shadow. Figure 61-3 shows the two marker images used in this example application.

FIGURE 61-3

A marker actually consists of two images: the marker icon and its shadow.



The figure shows how a marker that appears on a Google Maps map actually consists of two icons: the marker image and a shadow image with transparency. When combined, these two icons provide a clever visual trick that makes the markers appear to rise off of the map in 3-D.

Once the map and its icon variables are initialized, you'll see the function `buildHTML` that generates the HTML string that is used later by the `createMarker()` function. You'll notice that an external CSS file is specified so that each information window will have the same look and feel.

Each custom icon is used to create a custom marker in the `createMarker()` function that also establishes the information window. Additionally, this function extracts node data from the XML description node that was grabbed in the `GDownloadUrl` function (described next) and calls the `buildHTML` function to generate the custom HTML string from the data in the XML document. This code is important because it binds a special listener function to the `onclick` event for the newly created marker. This results in the display of an information window in response to the user clicking a marker.

The last big chunk of code in the HTML document is the `GDownloadUrl` where the XML document is processed. The XML file is opened and its relevant nodes (`place`, `location`, and `description`) are grabbed. A loop is then entered that cycles through the haunted places, creating a marker on the map for each one via calls to the previously mentioned `createMarker()` function.

The HTML document has now created the custom map in Google Maps, complete with unique markers and information windows ready to spring into action when the markers are clicked.

Styling a custom information window

The CSS style sheet for the haunted places map application has only one responsibility: format the text data for the haunted place and display it next to the thumbnail image of the place. Listing 61-3 contains the code for the `hauntedPlaces.css` style sheet.

LISTING 61-3

Formatting the XML Data for the HTML String

```
body              {
   font-family:Georgia; serif;
}

img               {
   width:175px; height:175px;
}
```

continued

LISTING 61-3 *(continued)*

```
:link             {
   color:black;
}

.hauntedData      {
   width:450px; height:200px;
   text-align:left;
   font-size:6pt;
}

.hauntedImage     {
   text-align:right;
}

.hauntedLocation  {
   vertical-align:top;
}

.hauntedURL       {
   font-weight:bold; font-size:8pt;
}
```

Testing the finished map

Figure 61-4 shows the haunted places map example upon first being loaded and viewed in Firefox.

Not surprisingly, the application starts out with all the ghost place markers in view on the map. This is no accident, by the way — I carefully selected the initial viewing area and zoom level of the map so that you could see all of the places. Don't forget that what makes your custom Google Maps application so interesting is that you can still use all of the familiar navigational features built into Google Maps. You can drag the map around to view other areas, as well as

zoom in and out on the places and their surroundings. You can also switch back and forth between Map, Satellite, and Hybrid views. Perhaps most importantly, you can click any of the place markers to get information about each specific place. Figure 61-5 shows the haunted places map, zoomed in, with one of the place information windows open.

This figure reveals how compelling the merger of a geographical XML database and Google Maps can be. You've effectively taken an extremely powerful online tool and customized it with your own data. The net effect is an application that would be unbelievably difficult to create from scratch.

FIGURE 61-4

The haunted places map begins with all the places in view.

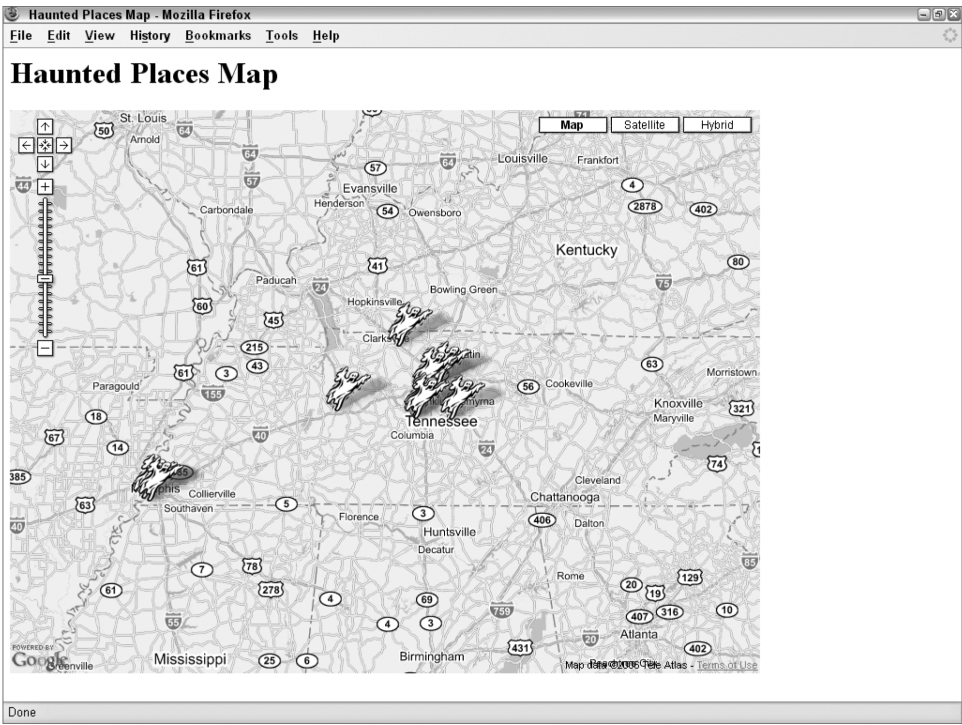


FIGURE 61-5

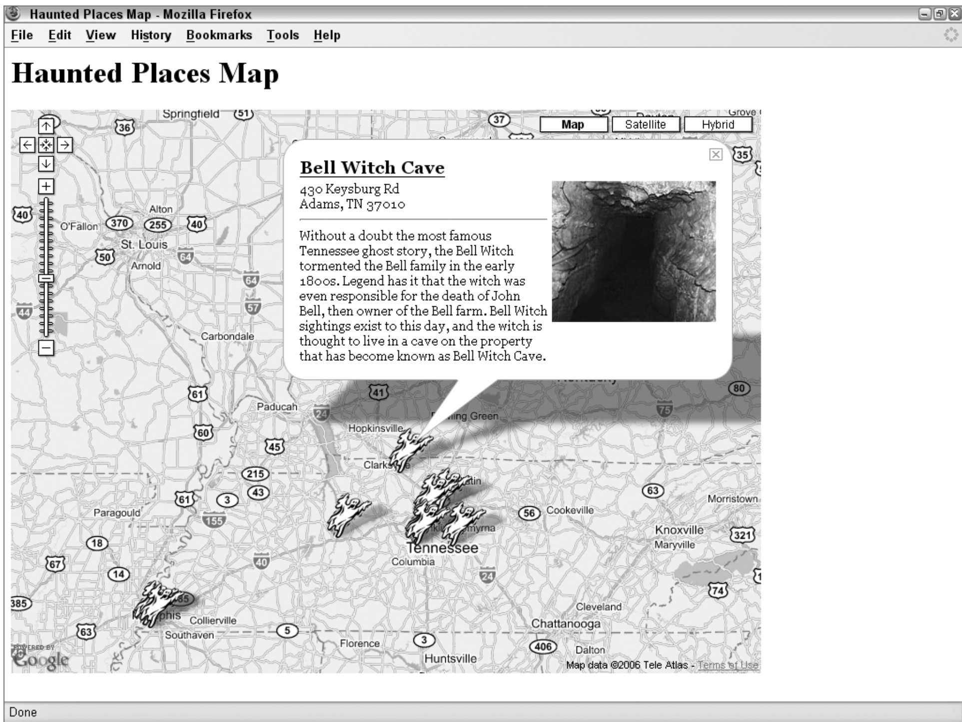
Clicking a ghost marker reveals additional information about a haunted place.



Further Thoughts

Who would've thought a few years ago that the Web would make it possible to view up-to-date crime statistics on a map of where they occurred? This is only the tip of the iceberg in terms of how an application such as Google Maps can improve our interactions with the world. And thanks to Google opening up their API to developers, you can be a part of it all. Perhaps you have some unique local knowledge that you could add to a map others would find useful. Hopefully the haunted places example in this chapter will spark you to try creating something unique using JavaScript and Google Maps.

Think about any data you may have access to that could somehow be presented geographically. Massage the data into an XML format, and you'll have your very own Google Maps mashup.

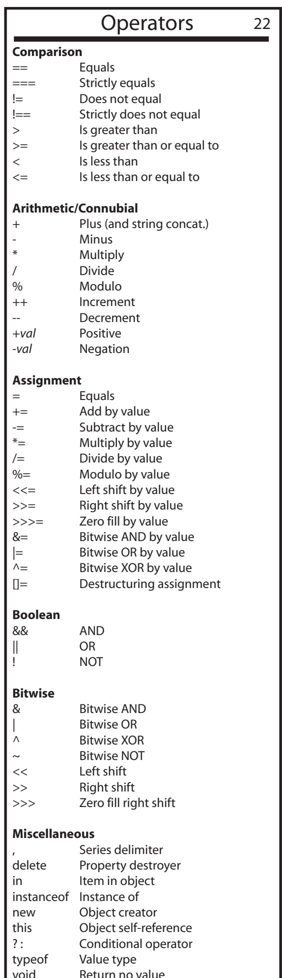
How to Use This Quick Reference

This guide contains quick reference info for the core JavaScript language and browser object models starting with IE 5.5, Mozilla, and Safari.

Numbers in the upper right corners of object squares are chapter numbers in which the object is covered in detail.

Each term is supported by all baseline browsers unless noted with a superscript symbol indicating browser brand and version:
E—Internet Explorer M—Mozilla S—Safari
O—Opera C—Google Chrome
For example, M1.4 means the term is supported only by Mozilla 1.4 or later; E means the terms is supported only by Internet Explorer.



Operators 22

Comparison

==	Equals
===	Strictly equals
!=	Does not equal
!==	Strictly does not equal
>	Is greater than
>=	Is greater than or equal to
<	Is less than
<=	Is less than or equal to

Arithmetic/Connubial

+	Plus (and string concat.)
-	Minus
*	Multiply
/	Divide
%	Modulo
++	Increment
--	Decrement
+*val*	Positive
-*val*	Negation

Assignment

=	Equals
+=	Add by value
-=	Subtract by value
*=	Multiply by value
/=	Divide by value
%=	Modulo by value
<<=	Left shift by value
>>=	Right shift by value
>>>=	Zero fill by value
&=	Bitwise AND by value
|=	Bitwise OR by value
^=	Bitwise XOR by value
[]=	Destructuring assignment

Boolean

&&	AND
||	OR
!	NOT

Bitwise

&	Bitwise AND
|	Bitwise OR
^	Bitwise XOR
~	Bitwise NOT
<<	Left shift
>>	Right shift
>>>	Zero fill right shift

Miscellaneous

,	Series delimiter
delete	Property destroyer
in	Item in object
instanceof	Instance of
new	Object creator
this	Object self-reference
? :	Conditional operator
typeof	Value type
void	Return no value

APPENDIX

B

What's on the CD-ROM

The accompanying Windows–Macintosh CD-ROM contains additional chapters that include many more JavaScript examples, an electronic version of the Quick Reference shown in Appendix A for printing, a complete, searchable version of the entire book, and the Adobe Reader.

System Requirements

To derive the most benefit from the example listings, you should have a Mozilla-based browser (for example, Firefox 3.6+, -, or Camino 2+), Internet Explorer 8+, a WebKit-based browser (for example, Safari 4+, or Google Chrome 5+) or a Presto-based browser (for example, Opera 10+) installed on your computer. Although many scripts run in these and other browsers, several scripts demonstrate features that are available on only a limited range of browsers. To write scripts, you can use a simple text editor, word processor, or dedicated HTML editor.

To use the Adobe Reader (version 7.0), you need the following:

- For Windows XP Pro/Home, or Windows XP Table PC Edition, you should be using a Pentium computer with 128 MB of RAM and 90 MB of hard disk space.
- Macintosh users require a PowerPC G3, G4, or G5 processor, OS X v10.2.8 or later, at least 128 MB of RAM, and 110 MB of disk space.

Disc Contents

When you view the contents of the CD-ROM, you will see files tailored for your operating system. The contents include the following items.

JavaScript listings for text editors

Starting with Part III of the book, almost all example listings are on the CD-ROM in the form of complete HTML files, which you can load into a browser to see the JavaScript item in operation. A directory called Listings contains the example files, with nested folders named for each chapter. The name of each HTML file is keyed to the listing number in the book. For example, the file for Listing 26-1 is named `jsb26-01.html`. Note that no listing files are provided for the tutorial chapters of Part II, because you are encouraged to enter HTML and scripting code manually.

For your convenience, the `_index.html` file in the `Listings` folder provides a front-end table of contents to the HTML files for the book's program listings. Open that file from your browser whenever you want to access the program listing files. If you intend to access that index page frequently, you can bookmark it in your browser(s). Using the index file to access the listing files can be very important in some cases, because several individual files must be opened within their associated framesets to work properly. Accessing the files through the `_index.html` file ensures that you open the frameset. The `_index.html` file also shows browser compatibility ratings for all the listings. This saves you time from opening listings that are not intended to run on your browser. To examine and modify the HTML source files, open them from your favorite text editor program (for Windows editors, be sure to specify the `.html` file extension in the Open File dialog box).

You can open all example files directly from the CD-ROM, but if you copy them to your hard drive, access is faster and you will be able to experiment with modifying the files more readily. Copy the folder named `Listings` from the CD-ROM to any location on your hard drive.

Printable version of the JavaScript and Browser Object Quick Reference from Appendix A

If you like the quick reference in Appendix A, you can print it out with the help of the Adobe Reader, included with the CD-ROM.

Adobe Reader

The Adobe Reader is a helpful program that enables you to view the Quick Reference from Appendix A and the searchable version of this book, both of which are in PDF format on the CD-ROM. To install and run Adobe Reader, follow these steps:

For Windows

1. Navigate to the Adobe_Reader folder on the CD-ROM.
2. In the Adobe_Reader folder, double-click the lone executable file and follow the instructions presented on-screen for installing Adobe Acrobat Reader.

For Macintosh

1. Open the Adobe_Reader folder on the CD-ROM.
2. In the Adobe_Reader folder, double-click the Adobe Reader disk image icon; this will mount the disk image on your computer. Then open the mounted image and copy the Adobe Reader folder to the Applications directory of your computer.

PDF version of book with topical references

In many places throughout the reference chapters of Parts III and IV, you see notations directing you to the CD-ROM for a particular topic being discussed. All these topics are located in the chapters as they appear in complete Adobe Acrobat form on the CD-ROM. A single PDF file is located on the CD-ROM, and it serves as an electronic version of the entire book, complete with full topics that are listed as CD-ROM references in the printed book. For the fastest access to these topics, copy the entire PDF file for the book to your hard disk.

Like any PDF document, the PDF version of the book is searchable. Recent versions of Adobe Reader should automatically load the index file (with the `.pdx` extension) to supply indexed search capabilities (which is much faster than Acrobat's Find command).

To begin an actual search, click the Search icon (binoculars in front of a sheet of paper). Enter the text for which you're searching. To access the index and search facilities in future sessions, the CD-ROM must be in your CD-ROM drive — unless, of course, you've copied both the `.pdx` and `.pdf` files to your hard drive.

Troubleshooting

If you have difficulty installing or using the CD-ROM programs, try the following solutions:

- **Turn off any anti-virus software that you may have running.** Installers sometimes mimic virus activity and can make your computer incorrectly believe that a virus is infecting it. (Be sure to turn the anti-virus software back on later.)
- **Close all running programs.** The more programs you're running, the less memory is available to other programs. Installers also typically update files and programs; if you keep other programs running, installation may not work properly.
- **Reference the ReadMe file.** Refer to the ReadMe file located at the root of the CD-ROM for the latest product information at the time of publication.

Customer Care

If you have trouble with the CD-ROM, please call the Customer Support phone number at (800) 762-2974. Outside the United States, call 1(317) 572-3994. You can also contact Wiley Product Technical Support at `http://support.wiley.com`. John Wiley & Sons will provide technical support only for installation and other general quality control items. For technical support on the applications themselves, consult the program's vendor or author.

To place additional orders or to request information about other Wiley products, please call (877) 762-2974.

Appendix D
Answers to Tutorial Exercises

Appendix E
JavaScript and DOM Internet Resources

APPENDIX

C

JavaScript Reserved Words

Every programming language has a built-in vocabulary of keywords that you cannot use for the names of variables and the like. Because a JavaScript function is an object that uses the function name as an identifier for the object, you cannot employ reserved words for function names either. It's worth nothing that many of the keywords in the list are not technically a part of the JavaScript language just yet, but they are reserved for potential future use. Remember that JavaScript keywords are case-sensitive. Although you may get away with using these words in other cases, it may lead to unnecessary confusion for someone reading your scripts.

abstract	boolean	break	byte
case	catch	char	class
const	continue	debugger	default
delete	do	double	else
enum	export	extends	false
final	finally	float	for
function	goto	if	implements
import	in	instanceof	int
interface	long	native	new
null	package	private	protected
public	return	short	static
super	switch	synchronized	this
throw	throws	transient	true
try	typeof	var	void
volatile	while	with	

APPENDIX

Answers to Tutorial Exercises

This appendix provides answers to the tutorial exercises that appear in Part II of this book (Chapters 5 through 14).

Chapter 5 Answers

1. The paragraph in Listing 5-1 was originally:

```
<p>It is currently <span id="output">now</span>.</p>
```

The JavaScript code modifies the contents of the `span` element because, and only because, it has the ID of `output`. Therefore, we can get the script to replace the contents of the entire paragraph simply by shifting the ID to the `p` tag:

```
<p id="output">It is currently <span>now</span>.</p>
```

The `span` element is no longer useful:

```
<p id="output">It is currently now.</p>
```

2. The JavaScript does not need to change in order to reflect this change to the HTML. The steps it performs are as follows:

   a. If there is a first child element,

   b. remove the first child element,

   c. then return to step a.

Notice how versatile and re-purposeable the deletion loop is. It could easily be made into a generic function to delete the contents of any DOM element.

3. The style sheet does not have to be changed to assign the paragraph the same font attributes that the `span` had before, because the styling refers to the element's ID and not its tag name:

```
#output
{
   font-style: italic;
   color: #C33;
}
```

Here again, the CSS rule is not overly specific (it did not point to `span#output` but merely `#output`) and therefore is easily re-purposeable even as the HTML undergoes modest change.

Chapter 6 Answers

1. The catalog page (a) and temperature calculator (d) are good client-side JavaScript applications. Even though the catalog relies on server storage of the image files, you can create a more engaging and responsive user interface of buttons and swappable images. The temperature calculator is a natural for JavaScript, because all processing is done instantaneously on the client, rather than having to access the server for each conversion.

   The Web site visit counter (b) that accumulates the number of different visitors to a Web site is a server-side application, because the count must be updated and maintained on the server. At best, a client-side counter could keep track of the number of visits the user has made to a site and report to the user how many times he or she has been to the site. The storage requires scripting the cookie. A chat room application (c) done properly requires server facilities to open up communication channels among all users connected simultaneously. Client-side scripting by itself cannot create a live chat environment.

2. **a.** Valid, because it is one contiguous word. InterCap spelling is fine.

   b. Valid, because an underscore character is acceptable between words.

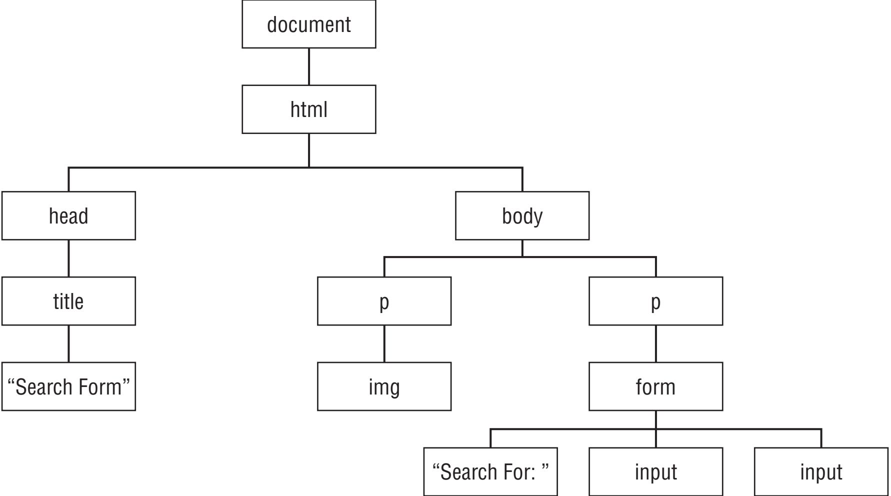
   c. Not valid, because an identifier cannot begin with a numeral.

   d. Not valid, because no spaces are allowed.

   e. Not valid, because apostrophes are not allowed.

   f. Valid, because the colon, hyphen, and period are acceptable characters in HTML IDs. Take caution, however, as JavaScript will choke on such IDs if used outside of quotation marks.

3. The diagram is as follows.



The paragraph element reference is:

```
document.getElementById("logoPar")
```

4. In common:
   - Both are types of nodes, derived from the basic DOM node.
   - Both may be children of parent nodes that act as containers.

   Different:
   - An element node is created by a tag, while a text node has no tag associated with it.
   - A text node cannot be a parent to any other node, but an element node can be either a parent (branch node) or end node (leaf node).

5. HTML:

```
<input type="button" name="Hi" id="Hi" value="Howdy" >
```

JavaScript:

```
var oButton = document.getElementById("Hi");
   if (oButton)
   {
      oButton.onclick=helloBack;
   }
```

```
function helloBack(evt)
{
   alert('Hello to you, too!')
}
```

Chapter 7 Answers

1.
```
<script type="text/javascript">

<!--
document.write("Hello, world.");
// -->
</script>
```

2.
```
<html>

<body>
<script type="text/javascript">
<!--
   document.write("Hello, world.");
// -->
</script>
</body>
</html>
```

3.
```
<html>

<body>
<script type="text/javascript">
<!--
   // write a welcome message to the world
   document.write("Hello, world.");
// -->
</script>
</body>
</html>
```

4. My answer is written so that both event handlers call separate functions. You can also have each event handler invoke the `alert()` method inline. If you prefer to follow the XHTML format, include a space and forward slash character before the right angle bracket of the `input` element's tag.

```
<html>
<head>
<title>An onload script</title>
<script type="text/javascript">
<!--
function done() {
   alert("The page has finished loading.");
```

```
}
function alertUser() {
   alert("Ouch!");
}
// -->
</script>
</head>
<body onload="done()">
Here is some body text.
<form>
    <input type="button" name="oneButton" value="Press Me!"
                     onclick="alertUser()">
</form>
</body>
</html>
```

5. **a.** The page displays two text fields.
   b. The user enters text into the first field and either clicks or tabs out of the field to trigger the `onchange` event handler.
   c. The function writes an all-uppercase version of one field in the other.

Chapter 8 Answers

1. **a.** Valid.
   b. Not valid. The variable needs to be a single word, such as `howMany` or `how_many`.
   c. Valid. The trailing semicolon is missing, but because it is optional for a one-line statement, browsers accept the statement as written.
   d. Not valid. The variable name cannot begin with a numeral. If the variable needs a number to help distinguish it from other similar variables, then put the numeral at the end: `address1`.
2. **a.** 4
   b. 40
   c. “4020”
   d. “Robert”
3. The functions are `parseInt()` and `parseFloat()`. Strings to be converted are passed as parameters to the functions: `parseInt(document.getElementById("entry").value)`.
4. Both text field values are strings that must be converted to numbers before they can be arithmetically added together. You can use the `parseFloat()` functions either on the variable assignment expressions. For example, `var value1 = parseFloat(document.getElementById("inputA").value)` or in the addition expression `(document.getElementById("output").value = parseFloat(value1) + parseFloat(value2))`.
5. Concatenate means to join two strings into one string.

Chapter 9 Answers

1. The following answer shows the HTML markup portion in XHTML, where elements not acting as containers (notably the `input` elements) include a space and forward slash to simulate XHTML's required close tag.

```
<html>
<head>
<script type="text/javascript">
var USStates = new Array(51);
USStates[0] = "Alabama";
USStates[1] = "Alaska";
USStates[2] = "Arizona";
USStates[3] = "Arkansas";
USStates[4] = "California";
USStates[5] = "Colorado";
USStates[6] = "Connecticut";
USStates[7] = "Delaware";
USStates[8] = "District of Columbia";
USStates[9] = "Florida";
USStates[10] = "Georgia";
USStates[11] = "Hawaii";
USStates[12] = "Idaho";
USStates[13] = "Illinois";
USStates[14] = "Indiana";
USStates[15] = "Iowa";
USStates[16] = "Kansas";
USStates[17] = "Kentucky";
USStates[18] = "Louisiana";
USStates[19] = "Maine";
USStates[20] = "Maryland";
USStates[21] = "Massachusetts";
USStates[22] = "Michigan";
USStates[23] = "Minnesota";
USStates[24] = "Mississippi";
USStates[25] = "Missouri";
USStates[26] = "Montana";
USStates[27] = "Nebraska";
USStates[28] = "Nevada";
USStates[29] = "New Hampshire";
USStates[30] = "New Jersey";
USStates[31] = "New Mexico";
USStates[32] = "New York";
USStates[33] = "North Carolina";
USStates[34] = "North Dakota";
USStates[35] = "Ohio";
USStates[36] = "Oklahoma";
USStates[37] = "Oregon";
USStates[38] = "Pennsylvania";
USStates[39] = "Rhode Island";
USStates[40] = "South Carolina";
USStates[41] = "South Dakota";
```

```
USStates[42] = "Tennessee";
USStates[43] = "Texas";
USStates[44] = "Utah";
USStates[45] = "Vermont";
USStates[46] = "Virginia";
USStates[47] = "Washington";
USStates[48] = "West Virginia";
USStates[49] = "Wisconsin";
USStates[50] = "Wyoming";

var stateEntered = new Array(51);
stateEntered[0] = 1819;
stateEntered[1] = 1959;
stateEntered[2] = 1912;
stateEntered[3] = 1836;
stateEntered[4] = 1850;
stateEntered[5] = 1876;
stateEntered[6] = 1788;
stateEntered[7] = 1787;
stateEntered[8] = 0000;
stateEntered[9] = 1845;
stateEntered[10] = 1788;
stateEntered[11] = 1959;
stateEntered[12] = 1890;
stateEntered[13] = 1818;
stateEntered[14] = 1816;
stateEntered[15] = 1846;
stateEntered[16] = 1861;
stateEntered[17] = 1792;
stateEntered[18] = 1812;
stateEntered[19] = 1820;
stateEntered[20] = 1788;
stateEntered[21] = 1788;
stateEntered[22] = 1837;
stateEntered[23] = 1858;
stateEntered[24] = 1817;
stateEntered[25] = 1821;
stateEntered[26] = 1889;
stateEntered[27] = 1867;
stateEntered[28] = 1864;
stateEntered[29] = 1788;
stateEntered[30] = 1787;
stateEntered[31] = 1912;
stateEntered[32] = 1788;
stateEntered[33] = 1789;
stateEntered[34] = 1889;
stateEntered[35] = 1803;
stateEntered[36] = 1907;
stateEntered[37] = 1859;
stateEntered[38] = 1787;
stateEntered[39] = 1790;
stateEntered[40] = 1788;
stateEntered[41] = 1889;
```

```
stateEntered[42] = 1796;
stateEntered[43] = 1845;
stateEntered[44] = 1896;
stateEntered[45] = 1791;
stateEntered[46] = 1788;
stateEntered[47] = 1889;
stateEntered[48] = 1863;
stateEntered[49] = 1848;
stateEntered[50] = 1890;

function getStateDate() {
   var selectedState = document.getElementById("entry").value;
   for ( var i = 0; i < USStates.length; i++) {
      if (USStates[i] == selectedState) {
         break;
      }
   }
   alert("That state entered the Union in " + stateEntered[i] + ".");
}
</script>
</head>
<body>
<form name="entryForm">
   Enter the name of a state:
   <input type="text" name="entry" />
   <input type="button" value="Look Up Entry Date" onclick="getStateDate()" />
</form>
</body>
</html>
```

2. Several problems plague this function definition. Parentheses are missing from the first `if` construction's condition statement. Curly braces are missing from the second nested `if...else` construction. A mismatch of curly braces also exists for the entire function. The following is the correct form (changes and additions in boldface):

```
function format(ohmage) {
   var result;
   if (ohmage >= 10e6) {
      ohmage = ohmage / 10e6;
      result = ohmage + " Mohms";
   } else {
      if (ohmage >= 10e3) {
         ohmage = ohmage / 10e3;
         result = ohmage + " Kohms";
      } else {
         result = ohmage + " ohms";
      }
   }
   alert(result);
}
```

3. Here is one possibility:

```
for (var i = 1; i < tomatoes.length; i++) {
   if (tomatoes[i].looks == "mighty tasty") {
      break;
   }
}
var myTomato = tomatoes[i]
```

4. The new version defines a different local variable name for the dog.

```
<html>
<head>
<script type="text/javascript">
var aBoy = "Charlie Brown";    // global
var hisDog = "Snoopy";        // global
function demo() {
  var WallacesDog = "Gromit"; // local version of hisDog
  var output = WallacesDog + " does not belong to " + aBoy
             + ".<br>";
  document.write(output);
}
</script>
<body>
<script type="text/javascript">
  demo();       // runs as document loads
  document.write(hisDog + " belongs to " + aBoy + ".");
</script>
</body>
</html>
```

5. The application uses three parallel arrays and is structured very much like the solution to question 1. Learn to reuse code whenever you can.

```
<html>
<head>
<script type="text/javascript">
var planets = new Array(4);
planets[0] = "Mercury";
planets[1] = "Venus";
planets[2] = "Earth";
planets[3] = "Mars";

var distance = new Array(4);
distance[0] = "36 million miles";
distance[1] = "67 million miles";
distance[2] = "93 million miles";
distance[3] = "141 million miles";

var diameter = new Array(4);
diameter[0] = "3100 miles";
```

```
diameter[1] = "7700 miles";
diameter[2] = "7920 miles";
diameter[3] = "4200 miles";

function getPlanetData() {
   var selectedPlanet = document.getElementById("entry").value;
   for ( var i = 0; i < planets.length; i++) {
      if (planets[i] == selectedPlanet) {
         break;
      }
   }
   var msg = planets[i] + " is " + distance[i];
   msg += " from the Sun and ";
   msg += diameter[i] + " in diameter.";
   document.getElementById("output").value = msg;
}
</script>
</head>
<body>
<form name="entryForm">
   Enter the name of a planet:
   <input type="text" name="entry" id="entry" />
   <input type="button" value="Look Up a Planet" onclick="getPlanetData()" />
   <br />
   <input type="text" size="70" name="output" id="output" />
</form>
</body>
</html>
```

Chapter 10 Answers

1. **a.** Close, but no cigar. Array references are always plural: `window.document.forms[0]`

   b. Not valid: `self` refers to a window and `entryForm` must refer to a form. Where's the `document`? It should be `self.document.entryForm.entryField.value`.

   c. Valid. This reference points to the `name` property of the third form in the document.

   d. Not valid. The uppercase "D" in the method name is incorrect.

   e. Valid, assuming that `newWindow` is a variable holding a reference to a subwindow.

2. `window.alert("Welcome to my Web page.");`

3. `document.write("<h1>Welcome to my Web page.</h1>");`

4. A script in the `body` portion invokes a function that returns the text entered in a `prompt()` dialog box.

```
<html>
<head>
<script type="text/javascript">
function askName() {
   var name = prompt("What is your name, please?","");
```

```
   return name;
}
</script>
</head>
<body>
<script type="text/javascript">
  document.write("Welcome to my web page, " + askName() + ".");
</script>
</body>
</html>
```

5. The URL can be derived from the `href` property of the `location` object.

```
<html>
<head>
<script type="text/javascript">
function showLocation() {
   alert("This page is at: " + location.href);
}
</script>
</head>
<body onload="showLocation()">
Blah, blah, blah.
</body>
</html>
```

Chapter 11 Answers

1. For Listing 11-2, pass the text input element object because that's the only object involved in the entire transaction.

```
<html>
<head>
<title>Text Object value Property</title>
<script type="text/javascript">
function upperMe(field) {
   field.value = field.value.toUpperCase();
}
</script>
</head>
<body>
<form onsubmit="return false">
   <input type="text" name="convertor" value="sample" onchange="upperMe(this)">
</form>
</body>
</html>
```

For Listing 11-3, the button invokes a function that communicates with a different element in the form. Pass the form object.

```
<html>
<head>
<title>Checkbox Inspector</title>
<script type="text/javascript">
function inspectBox(form) {
   if (form.checkThis.checked) {
      alert("The box is checked.");
   } else {
      alert("The box is not checked at the moment.");
   }
}
</script>
</head>
<body>
<form>
   <input type="checkbox" name="checkThis">Check here<br>
   <input type="button" value="Inspect Box" onclick="inspectBox(this.form)">
</form>
</body>
</html>
```

For Listing 11-4, again the button invokes a function that looks at other elements in the form. Pass the form object.

```
<html>
<head>
<title>Extracting Highlighted Radio Button</title>
<script type="text/javascript">
function fullName(form) {
   for (var i = 0; i < form.stooges.length; i++) {
      if (form.stooges[i].checked) {
         break;
      }
   }
   alert("You chose " + form.stooges[i].value + ".");
}
</script>
</head>

<body>
<form>
   <p>Select your favorite Stooge:
   <input type="radio" name="stooges" value="Moe Howard" checked>Moe
   <input type="radio" name="stooges" value="Larry Fine">Larry
   <input type="radio" name="stooges" value="Curly Howard">Curly<br>
   <input type="button" name="Viewer" value="View Full Name..."
             onclick="fullName(this.form)"></p>
</form>
</body>
</html>
```

For Listing 11-5, all action is triggered by and confined to the `select` object. Pass only that object to the function.

```
<html>
<head>
<title>Select Navigation</title>
<script type="text/javascript">
  function goThere(list) {
   location = list.options[list.selectedIndex].value;
}
</script>
</head>

<body>
<form>
Choose a place to go:
<select name="urlList" onchange="goThere(this)">
   <option selected value="index.html">Home Page
   <option value="store.html">Shop Our Store
   <option value="policies">Shipping Policies
   <option value="http://www.google.com">Search the Web
</select>
</form>
</body>
</html>
```

2. Here are the most likely ways to reference the text box object:

```
document.getElementById("email")
document.forms[0].elements[0]
document.forms["subscription"].elements[0]
document.subscription.elements[0]
document.forms[0].elements["email"]
document.forms["subscription"].elements["email"]
document.subscription.elements["email"]
document.forms[0].email
document.forms["subscription"].email
document.subscription.email
```

The reference `document.all.email` (or any reference starting with `document.all`) works only in Internet Explorer and other browsers that emulate IE, but not in Mozilla or Safari. Other valid references may include the W3C DOM `getElementsByTagName()` method. Since the question indicates that there is only one form on the page, the text box is the first `input` element in the page, indicating that `document.body.getElementsByTagName("input")[0]` would be valid for this page.

3. The `this` keyword refers to the text input object, so that `this.value` refers to the `value` property of that object.

```
<html>
<head>
   <script>
      function showText(txt) {
```

```
         alert(txt);
      }
   </script>
</head>
<body>
   <p>Hello World!</p>
   <input type="button" value="Click Me"
          onclick="showText(this.value)" />
</body>
</html>
```

4.
```
document.accessories.acc1.value = "Leather Carrying Case";

document.forms[1].acc1.value = "Leather Carrying Case";
```

5. The `select` object invokes a function that does the job.

```
<html>
<head>
<title>Color Changer</title>
<script type="text/javascript">
function setColor(list) {
   var newColor = list.options[list.selectedIndex].value;
   document.bgColor = newColor;
}
</script>
</head>

<body>
<form>
   Select a background color:
   <select onchange="setColor(this)">
   <option value="red">Stop
   <option value="yellow">Caution
   <option value="green">Go
   </select>
</form>
</body>
</html>
```

Chapter 12 Answers

1. Use `string.indexOf()` to see if the field contains the "@" symbol.

```
<html>
<head>
<title>E-mail @ Validator</title>
<script type="text/javascript">
function checkAddress(form) {
   if (form.email.value.indexOf("@") == -1) {
      alert("Check the e-mail address for accuracy.");
```

```
      return false;
   }
   return true;
}
</script>
</head>

<body>
<form onsubmit="return checkAddress(this)">
   Enter your e-mail address:
   <input type="text" name="email" size="30"><br>
   <input type="submit">
</form>
</body>
</html>
```

2. Remember that the substring goes up to, but does not include, the index of the second parameter. Spaces count as characters.

```
myString.substring(0,3)    // result = "Int"
myString.substring(11,17)  // result = "plorer"
myString.substring(5,12)   // result = "net Exp"
```

3. The `indexOf()` function returns a `-1` if the character is not found. The `substring()` function will extract a substring starting at the indexed position +1. If there are no spaces in `stringA`, `firstSpace` will be = `-1`. Adding a `1` to that yields `0`. Strings start at position `0`, so `excerpt` will return the entire `stringA`.

4. The missing `for` loop is in boldface. You could also use the increment operator on the `count` variable (`++count`) to add 1 to it for each letter "e."

```
function countE(form) {
   var count = 0;
   var inputString = form.mainstring.value.toLowerCase();
   for (var i = 0; i < inputString.length; i++) {
      if (inputString.charAt(i) == "e") {
         count += 1;
      }
   }
   var msg = "The string has " + count;
   msg += " instances of the letter e.";
   alert(msg);
}
```

5. The formula for the random throw of one die is in the chapter.

```
<html>
<head>
<title>Roll the Dice</title>
<script type="text/javascript">
function roll(form) {
   form.die1.value = Math.floor(Math.random() * 6) + 1
```

```
   form.die2.value = Math.floor(Math.random() * 6) + 1
}
</script>
</head>

<body>
<form>
<input type="text" name="die1" size="2">
<input type="text" name="die2" size="2"><br>
<input type="button" value="Roll the Dice"
       onclick="roll(this.form)">
</form>
</body>
</html>
```

6. If you used the `Math.round()` method in your calculations, that is fine given your current exposure to the `Math` object. Another method, `Math.ceil()`, may be more valuable because it rounds up any fractional value.

```
<html>
<head>
<title>Waiting for Santa</title>
<script type="text/javascript">
function daysToXMAS() {
   var oneDay = 1000 * 60 * 60 * 24;
   var today = new Date();
   var XMAS = new Date("December 25, 2001");
   var diff = XMAS.getTime() - today.getTime();
   return Math.ceil(diff/oneDay);
}
</script>
</head>

<body>
<script type="text/javascript">
   document.write(daysToXMAS() + " days until Christmas.");
</script>
</body>
</html>
```

Chapter 13 Answers

1. `onload="parent.currCourse = 'history101'"`

2.

<Framesets>
Top Parent
<Frame> mechanics
<Frame> description
<Frame> navigation

3. All three frames are siblings, so references include the parent.

```
parent.mechanics.location.href = "french201M.html";
parent.description.location.href = "french201D.html";
```

4. A script in one of the documents is attempting to reference the `selector` object in one of the frames but the document has not fully loaded, causing the object to not yet be in the browser's object model. Rearrange the script so that it fires in response to the `onload` event handler of the framesetting document.

5. From the subwindow, the `opener` property refers back to the frame containing the `window.open()` method. To extend the reference to the frame's parent, the reference includes both pieces: `opener.parent.location`.

Chapter 14 Answers

1. As the document loads, the `<img>` tag creates a document image object. A memory image object is created with the `new Image()` constructor. Both objects have the same properties, and assigning a URL to the `src` property of a memory object loads the image into the browser's image cache.

2. `var janeImg = new Image(100,120);`

   `janeImg.src = "jane.jpg";`

3. `document.images["people"].src = janeImg.src;`

4. Surround `<img>` tags with link (`<a>`) tags, and use the link's `onclick`, `onmouseover`, and `onmouseout` event handlers. Set the image's `border` attribute to zero if you don't want the link highlight to appear around the image.

5. The following works in all W3C DOM-compatible browsers. The order of the first two statements may be swapped without affecting the script.

```
var newElem = document.createElement("a");
var newText = document.createTextNode("Next Page");
newElem.href = "page4.html";
newElem.appendChild(newText);
document.getElementById("forwardLink").appendChild(newElem);
```

APPENDIX

JavaScript and DOM Internet Resources

As an online technology, JavaScript has plenty of support online for scripters. Items recommended here were taken as a snapshot of Internet offerings in early 2010. But beware! Sites tend to change. URLs can change too. Be prepared to hunt around for these items if the information provided here is updated or moved around by the time you read this.

Support and Updates for This Book

The most up-to-date list of errata and other notes of interest pertaining to this edition of *JavaScript Bible* can be found at the book's web site, located at:

```
http://www.wiley.com/WileyCDA/WileyTitle/productCd-
  0470526912.html
```

FAQs

One situation that arises with a popular and accessible technology, such as JavaScript and DHTML authoring, is that the same questions get asked over and over, as newcomers arrive on the scene daily. Rather than invoke the ire of newsgroup users, look through existing FAQ files to see if your concern has already been raised and answered. Here are some of the best JavaScript FAQ sites:

```
http://javascript.faqts.com
http://javascripter.net/faq/index.htm
```

For less-frequently asked questions — but previously asked and answered in a public form — use the Google Groups search, described later in this appendix under Newsgroups.

Online Documentation

Locations of web sites that dispense official documentation for one browser or another are extremely fluid. Therefore, the following information contains links only to top-level areas of appropriate web sites, along with tips on what to look for after you are at the site.

Microsoft has condensed its developer documentation into a massive site called MSDN (Microsoft Developer Network). The place to begin is:

```
http://msdn.microsoft.com/library/
```

This page is the portal to many technologies, but the one most applicable to JavaScript and client-side scripting is one labeled "Library." Within the MSDN Library, you can then click "Web Development" to access information related to JavaScript and other Web development technologies. Inside the Web Development area of the library you'll find a section named "Scripting." Here you'll find plenty of documentation and technical articles for Microsoft scripting technologies, including JScript (Microsoft's flavor of JavaScript).

For Mozilla-based browser technologies, start at:

```
http://www.mozilla.org/docs/web-developer/
```

Finally, you can read the industry standards for HTML, CSS, and ECMAScript technologies online. Be aware that these documents are primarily intended for developers of tools that we use — browsers, WYSIWYG editors, and so forth — to direct them on how their products should respond to tags, style sheets, scripts, and so on. Reading these documents has frequently been cited as a cure for insomnia. That said, however, you can still glean a lot of useful information about scripting, HTML code, and CSS code from them.

```
http://www.ecma-international.org/publications/standards/Ecma-262.htm
http://www.w3.org/TR/html401/
http://www.w3.org/TR/html5/
http://www.w3.org/TR/xhtml1/
http://www.w3.org/TR/xhtml2/
http://www.w3.org/standards/techs/css
http://www.w3.org/DOM/
http://www.w3.org/TR/xml/
http://www.w3.org/TR/
```

Please note that just because a particular item is described in an industry standard doesn't mean that it is implemented in any or all browsers. In the real world, we must develop for the way the technologies are actually implemented in browsers.

World Wide Web

The number of web sites devoted to JavaScript tips and tricks is mind-boggling. Many sites come and go in the middle of the night, leaving no trace of their former existence. If you are looking for more example code for applications not covered in this book, perhaps the best place to begin your journey is through the traditional search engines. Narrowing your search through careful keyword choice is vital. In addition to the Mozilla and (heavily Windows-oriented) Microsoft developer web sites (plus numerous online articles of mine listed at `http://www.dannyg.com/pubs/index.html`), a few other venerable sites are:

```
http://www.javascript.com/
http://www.w3schools.com/js/
http://www.webreference.com/js/
http://en.wikipedia.org/wiki/Javascript
https://wiki.mozilla.org/JavaScript
http://javascript.internet.com/
http://www.d.umn.edu/itss/support/Training/Online/webdesign/javascript.html
http://www2.webkit.org/perf/sunspider-0.9/sunspider.html
```

Feeds and Blogs

The current way to read news and articles about JavaScript (or any subject for that matter) is via RSS feeds, Atom feeds, and blogs. Typically, these feeds are read in a dedicated RSS feed reader program, email client, or browser. Google provides a free reader, called Google Reader. The following links can be added as subscriptions to any of the feed readers:

```
http://www.alistapart.com/site/rss
http://z.about.com/6/g/javascript/b/rss2.xml?r=9F
http://z.about.com/6/o/m/javascript_t2.xml?r=9F
http://accessify.com/rss/accessify_rss.xml
http://feeds.feedburner.com/deanedwards/weblog
http://groups.google.com/group/firefoxpow/feed/rss_v2_0_msgs.xml
http://feeds2.feedburner.com/blogspot/Egta
http://blogs.msdn.com/ie/rss.xml
http://www.javascript.com/jss.rdf
http://www.webreference.com/js/tips/channels/last1512.rdf
http://labs.opera.com/rss.dml
http://www.feedzilla.com/rss/programming/javascript
http://feeds.feedburner.com/scriptaculous
http://feeds.feedburner.com/vitaminmasterfeed
http://webkit.org/blog/feed/
http://meyerweb.com/eric/thoughts/category/tech/rss2/full
http://www.d.umn.edu/itss/support/Training/Online/webdesign/webdesign.xml
http://www.webreference.com/webreference.rdf
```

Some blog sites allow you to post questions and get answers, although usually you can only comment on an article or respond to other comments. Hosts for RSS feeds and blogs are still evolving and competing for mind-share. Bloggers will frequently change hosts, so if you can't find a blogger at a link above, just do a search for the title or author to find the new host. Sometimes a blogger will leave a terminal message.

Newsgroups and Forums

The time-honored places to get quick answers to your pressing questions are online newsgroups and forums. To use newsgroups, you will need a newsgroup reader. Most browsers have dropped support for newsfeeds. Some email clients (such as Thunderbird) know how to do this. Newsgroups don't charge fees, but some of the NNTP servers do. You can use your search engine to look for a free NNTP reader.

Here are the top JavaScript-related newsgroups:

On most news servers:

```
comp.lang.javascript
```

On `news://msnews.microsoft.com`:

```
microsoft.public.scripting.jscript
microsoft.public.inetsdk.programming.scripting.jscript
microsoft.public.inetsdk.programming.dhtml_editing
microsoft.public.inetexplorer.scripting
microsoft.public.dotnet.languages.jscript
```

On `news://news.mozilla.org`:

```
mozilla.dev.tech.javascript
mozilla.dev.tech.js-engine
mozilla.dev.tech.js-engine.rhino
mozilla.dev.apps.js-debugger
```

Forums today, on the other hand, are primarily browser-based. Here are some of the top JavaScript-related forums:

```
http://en.wikipedia.org/wiki/Internet_forum
http://www.ajaxtalk.com/
http://groups.google.com/group/firefoxpow/
http://tech.groups.yahoo.com/group/ydn-javascript/
http://old.nabble.com/forum/Search.jtp?query=javascript&page=0&fsearch=y
```

Before you post a question to a newsgroup or forum, read about FAQs discussed earlier in this chapter and also use the extremely valuable newsgroup archive search facility of Google Groups. Visit the Google Groups search page at:

```
http://groups.google.com/
```

Enter the keyword or phrase into the top text box, but then also try to narrow your search by limiting the newsgroup(s) to search. For example, if you have a question about weird behavior you are experiencing with the `borderCollapse` style property in IE, enter `borderCollapse` into the search field, and then try narrowing the search to a specific newsgroup (forum) such as `comp.lang.javascript`.

If you post a question to a newsgroup or forum, you will most likely get a quick and intelligent response if you also provide either some sample code that's giving you a problem, or a link to a temporary file on your server that others can check out. Visualizing a problem you've spent days on is very hard for others. Be as specific as possible, including the browser(s) versions(s) and operating system(s) on which the code must run and the nature of the problem.

Final Thoughts

These sites are by no means the only worthwhile JavaScript and DHTML destinations on the Web. Sometimes having too many sources is as terrifying as having not enough. The links and newsgroups described in this appendix should take you a long way.

Wiley Publishing, Inc.
End-User License Agreement

READ THIS. You should carefully read these terms and conditions before opening the software packet(s) included with this book "Book". This is a license agreement "Agreement" between you and Wiley Publishing, Inc. "WPI". By opening the accompanying software packet(s), you acknowledge that you have read and accept the following terms and conditions. If you do not agree and do not want to be bound by such terms and conditions, promptly return the Book and the unopened software packet(s) to the place you obtained them for a full refund.

1. **License Grant.** WPI grants to you (either an individual or entity) a nonexclusive license to use one copy of the enclosed software program(s) (collectively, the "Software," solely for your own personal or business purposes on a single computer (whether a standard computer or a workstation component of a multi-user network). The Software is in use on a computer when it is loaded into temporary memory (RAM) or installed into permanent memory (hard disk, CD-ROM, or other storage device). WPI reserves all rights not expressly granted herein.
2. **Ownership.** WPI is the owner of all right, title, and interest, including copyright, in and to the compilation of the Software recorded on the physical packet included with this Book "Software Media". Copyright to the individual programs recorded on the Software Media is owned by the author or other authorized copyright owner of each program. Ownership of the Software and all proprietary rights relating thereto remain with WPI and its licensers.
3. **Restrictions On Use and Transfer.**
   - **(a)** You may only (i) make one copy of the Software for backup or archival purposes, or (ii) transfer the Software to a single hard disk, provided that you keep the original for backup or archival purposes. You may not (i) rent or lease the Software, (ii) copy or reproduce the Software through a LAN or other network system or through any computer subscriber system or bulletin-board system, or (iii) modify, adapt, or create derivative works based on the Software.
   - **(b)** You may not reverse engineer, decompile, or disassemble the Software. You may transfer the Software and user documentation on a permanent basis, provided that the transferee agrees to accept the terms and conditions of this Agreement and you retain no copies. If the Software is an update or has been updated, any transfer must include the most recent update and all prior versions.
4. **Restrictions on Use of Individual Programs.** You must follow the individual requirements and restrictions detailed for each individual program in the About the CD-ROM appendix of this Book or on the Software Media. These limitations are also contained in the individual license agreements recorded on the Software Media. These limitations may include a requirement that after using the program for a specified period of time, the user must pay a registration fee or discontinue use. By opening the Software packet(s), you will be agreeing to abide by the licenses and restrictions for these individual programs that are detailed in the About the CD-ROM appendix and/or on the Software Media. None of the material on this Software Media or listed in this Book may ever be redistributed, in original or modified form, for commercial purposes.
5. **Limited Warranty.**
   - **(a)** WPI warrants that the Software and Software Media are free from defects in materials and workmanship under normal use for a period of sixty (60) days from the date of purchase

of this Book. If WPI receives notification within the warranty period of defects in materials or workmanship, WPI will replace the defective Software Media.

(b) WPI AND THE AUTHOR(S) OF THE BOOK DISCLAIM ALL OTHER WARRANTIES, EXPRESS OR IMPLIED, INCLUDING WITHOUT LIMITATION IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE, WITH RESPECT TO THE SOFTWARE, THE PROGRAMS, THE SOURCE CODE CONTAINED THEREIN, AND/OR THE TECHNIQUES DESCRIBED IN THIS BOOK. WPI DOES NOT WARRANT THAT THE FUNCTIONS CONTAINED IN THE SOFTWARE WILL MEET YOUR REQUIREMENTS OR THAT THE OPERATION OF THE SOFTWARE WILL BE ERROR FREE.

(c) This limited warranty gives you specific legal rights, and you may have other rights that vary from jurisdiction to jurisdiction.

6. **Remedies.**

(a) WPI's entire liability and your exclusive remedy for defects in materials and workmanship shall be limited to replacement of the Software Media, which may be returned to WPI with a copy of your receipt at the following address: Software Media Fulfillment Department, Attn.: *JavaScript Bible, 7e*, Wiley Publishing, Inc., 10475 Crosspoint Blvd., Indianapolis, IN 46256, or call 1-800-762-2974. Please allow four to six weeks for delivery. This Limited Warranty is void if failure of the Software Media has resulted from accident, abuse, or misapplication. Any replacement Software Media will be warranted for the remainder of the original warranty period or thirty (30) days, whichever is longer.

(b) In no event shall WPI or the author be liable for any damages whatsoever (including without limitation damages for loss of business profits, business interruption, loss of business information, or any other pecuniary loss) arising from the use of or inability to use the Book or the Software, even if WPI has been advised of the possibility of such damages.

(c) Because some jurisdictions do not allow the exclusion or limitation of liability for consequential or incidental damages, the above limitation or exclusion may not apply to you.

7. **U.S. Government Restricted Rights.** Use, duplication, or disclosure of the Software for or on behalf of the United States of America, its agencies and/or instrumentalities "U.S. Government" is subject to restrictions as stated in paragraph (c)(1)(ii) of the Rights in Technical Data and Computer Software clause of DFARS 252.227-7013, or subparagraphs (c) (1) and (2) of the Commercial Computer Software - Restricted Rights clause at FAR 52.227-19, and in similar clauses in the NASA FAR supplement, as applicable.

8. **General.** This Agreement constitutes the entire understanding of the parties and revokes and supersedes all prior agreements, oral or written, between them and may not be modified or amended except in a writing signed by both parties hereto that specifically refers to this Agreement. This Agreement shall take precedence over any other documents that may be in conflict herewith. If any one or more provisions contained in this Agreement are held by any court or tribunal to be invalid, illegal, or otherwise unenforceable, each and every other provision shall remain in full force and effect.
